EAC 2013, PRAGUE

European Aerosol Conference

1–6 September 2013

czech aerosol society

European Aerosol Conference 2013,

Prague, Czech Republic, September 1 to 6, 2013
Conference chair: Jiří Smolík, co-chair: Martin Braniš
Hosting Aerosol Association: Czech Aerosol Society (CAS)

Contents:

Welcome	p. 9
Technical information	pp. 13 - 16
Committees and Societies	pp. 17 - 18
Further Information	pp. 19 - 26
Conference Program Overview	pp. 29 – 31
Conference Program - orals	pp. 35 – 62
Conference Program – posters	pp. 73 - 113
Sponsors and exhibitors	pp. 115 – 131

Abstracts:

Monday, September 2, 2013

Plenary lecture: Aerosol particles in the marine environment by Merete Bilde	pp. 132 - 133
Session: Atmospheric Aerosols, *Remote sensing and optical properties of aerosols*	pp. 134 – 141
Session: Atmospheric Aerosols, *SOA and aerosol hygroscopicity*	pp. 142 - 149
Session: Aerosol Chemistry, *Chemistry of organic aerosols 1*	pp. 150 – 158
Session: Indoor and Working Place Aerosols, *Indoor environment*	pp. 159 - 166
Session: Instrumentation, *New techniques*	pp. 167 - 175
Special Session: PMx, *Source apportionment-AMS and carbon based*	pp. 176 - 184
Session: Instrumentation, *Combustion aerosol*	

and chemical measurements pp. 185 – 192
Session: Aerosol Modelling,
Models for aerosol emission and nucleation pp. 193 – 199
Session: Combustion Aerosols, *Characterization methods of combustion aerosols* pp. 200 – 208
Session: PMx, *Urban PMx* pp. 209 – 216
Session: Aerosol-based Nanotechnology
Applications of engineered nanoparticles pp. 217 – 224
Special Session: Aerosol Chemistry
Radical chemistry and aerosol formation pp. 225 – 232

Poster Session A: *Atmospheric Aerosols* pp. 233 - 451
Posters A001 to A229

Tuesday, September 3, 2013

Plenary lecture: Primary Biological Atmospheric Aerosols
By Ruprecht Jaenicke pp. 452 – 454

Session: Atmospheric Aerosols
Carbonaceous aerosols pp. 455 – 463
Session: Atmospheric Aerosols
New particle formation between ground and free troposphere pp. 464 – 472
Session: Aerosol Chemistry
Chemistry of organic aerosols 2 pp. 473 – 481
Session: Indoor and Working Place Aerosols
Workplace exposure pp. 482 - 490
Session: Instrumentation
Ambient aerosol instrumentation pp. 491 - 499
Special Session: *PMx, Source apportionment-intercomparisons and trends* pp. 500 – 508
Session: Atmospheric Aerosols
New particle formation pp. 509 – 516
Session: Aerosol Modelling
Modelling aerosols in different environments pp. 517 – 524
Session: Combustion Aerosols

Combustion and industrial aerosols pp. 525 – 532
Session: PMx, *Urban and regional PMx* pp. 533 – 540
Session: Aerosol-based Nanotechnology
Fabrication of nanostructured materials pp. 541 – 548

Poster session B,
Aerosol Chemistry, Posters B001 – B063 pp. 549 – 611
Aerosol Modelling, Posters B064 – B125 pp. 612 – 668
Aerosol-based Nanotechnology, B126 – B166 pp. 669 – 705
Combustion Aerosols, Posters B167 – B241 pp. 706 – 765
Reserve posters B223 – B237 pp. 766 – 780

Wednesday, September 4, 2013

Plenary lecture: The Dynamics of Indoor Aerosol:
What is important, where, when and why?
By Lidia Morawska pp. 781 - 782

Session: Atmospheric Aerosols,
Physico-chemical properties and transport pp. 783 – 791
Session: Atmospheric Aerosols, *Urban aerosols-*
from particle counts to chemical compostion pp. 792 – 799
Session: Aerosol Modelling,
Modelling atmospheric aerosols pp. 800 – 808
Session: Indoor and Working Place Aerosols,
Chemistry / Instrumentation pp. 809 – 817
Session: Aerosol-based Nanotechnology,
Nanoparticle synthesis in the gas phase pp. 817 – 827
Special Session: Particle-Lung Interactions
Bioaerosols and health pp. 828 – 835

Thursday, September 5, 2013

Plenary lecture: Nucleation of vapours-molecular content of critical clusters and activation of nanoparticles
By Paul E. Wagner and P.M. Winkler pp. 836 - 837

Session: Atmospheric Aerosols
Aerosol cloud interaction pp. 838 – 846
Session: Atmospheric Aerosols, *Turbulent exchange, transport and transformation* pp. 847 - 855
Session: Combustion Aerosols,
Engines related emissions pp. 856 – 864
Session: Electrical Effects, *Electrical effects* pp. 865 – 873
Session: Fundamentals,
Nucleation theory and experiments pp. 874 – 882
Session: Aerosol Chemistry
Heterogeneous chemistry of aerosol pp. 883 – 890
Session: PMx, *Source-specific emissions of carbonaceous aerosol from combustion processes* pp. 891 – 898
Session: Particle-Lung Interactions,
Exposure and dosimetry pp. 899 – 906
Special Session: Combustion Aerosols,
Composition and health effects pp. 907 – 914
Session: Atmospheric Aerosols
Biomass burning and bioaerosols pp. 915 – 921
Special Session: Aerosol Modelling, Atmospheric Aerosols
European Year of Air Quality 2013 pp. 922 – 928

Poster session C

Electrical effects, Posters C001 – C009 pp. 929 – 938
Fundamentals, Posters C010 – C043 pp. 939 – 970
Instrumentation, Posters C044 – C083 pp. 971 – 1010
Particle-Lung Interactions, C084 – C098 pp. 1011 – 1025
Indoor and Working Place Aerosols,
Posters C099 – C154 pp. 1026 – 1081
PMx, Posters C155 – C201 pp. 1082 – 1128
Reserve Posters, C202 – C216 pp. 1129 – 1144

Friday, September 6, 2013

Plenary lecture: Urban aerosol: tendencies and challenges
By Imre Salma pp. 1145 – 1146

Session: Atmospheric Aerosols, *Aerosol-cloud interaction and climate effects of aerosols* pp. 1147 – 1155
Session: Atmospheric Aerosols, *Mineral dust, marine aerosols and others* pp. 1156 – 1164
Session: Fundamentals, *Aerosol properties and dynamics* pp. 1165 – 1173
Session: Aerosol Chemistry, *Chemical characterisation techniques for aerosols* pp. 1174 – 1182
Session: Particle-Lung Interactions, *PM toxicity* pp. 1183 - 1190

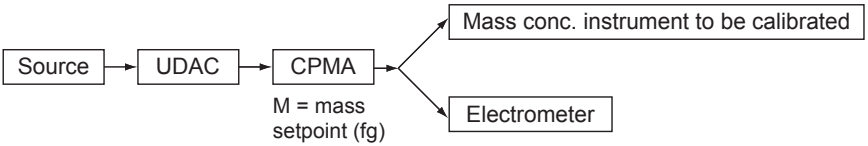
CAMBUSTION Aerosol Science

Centrifugal Particle Mass Analyzer

Classifies aerosol particles by their mass: charge ratio.

Forms an aerosol mass standard, (when combined with a unipolar charger andaerosol electrometer):



m_{total} = mass *setpoint* × indicated electrometer *concentration* + zero charge correction

(Symonds et al., Aerosol Science and Technology 47:8 i–iv)

Unipolar Diffusion Aerosol Charger

Places a high level of charge on aerosol particles.

Use in mass standard above.

Electrostatic Precipitator

Use in mass standard above, to quantify uncharged particles.

Includes high voltage supply

EAC booth #14

Welcome to Prague

The 2013 European Aerosol Conference (EAC 2013) will be held in the historical city of Prague, Czech Republic, during the period of 1st-6th September 2013 under the auspices of the European Aerosol Assembly (EAA), a body that now represents 12 national or regional aerosol societies.
In the past, the European Aerosol Conference was organized in Prague under the umbrella of the Gesellschaft für Aerosolforschung in 1999 when the Czech Aerosol Society was established. During the EAC 2013 the Czech Aerosol Society will celebrate its 14th anniversary and the 11th year of membership in the European Aerosol Assembly. It is a pleasure and honour for the Czech Aerosol Society to organize such important meeting of scientists from all over the world.

Patronage

The conference will be held under the auspices of:

Prof. Jiří Drahoš
President of The Academy of Sciences of the Czech Republic

Prof. Václav Hampl
Rector, Charles University in Prague, Czech Republic

THE ACADEMY OF SCIENCES OF THE CZECH REPUBLIC

The European Aerosol Assembly

The European Aerosol Assembly (EAA) is the organisation which has the responsibility to plan for the future hosting of European Aerosol Conferences, as well as to promote the development of the field of aerosol science through its working groups. It consists of 12 national or regional societies across Europe, though membership of these societies is not limited to European nationals, and operates under a formal constitution. The major activity of the EAA and its working groups takes place at the European Aerosol Conference, held in three out of every four years (the missing year being that in which the International Aerosol Conference, an event designed to foster links between research communities in all regions of the world, is held).

The Czech Aerosol Society

The Czech Aerosol Society (CAS) was formed in 1999 from the former Working Group on Aerosol Research of the Czech Society of Chemical Engineering at the ocassion of the Europen Aerosol Conference held in Prague in 1999. As given in its constitution the Society maintains a forum of researchers from various Czech Institutions and Universities in order to:

- **promote collaboration in all areas of aerosol research**
- **promote by means of meetings and publications the spread of information between the members and the public**
- **support education in aerosol related fields at all levels**
- **support international co-operation**

General Information

Conference Venue

The European Aerosol Conference 2013 is held at the Clarion Congress Hotel Prague represents a four-star comfort hotel with modern congress center and is easily accessible by all means of transport - the Old Town can be reached within 10 minutes.

Transport to the Conference Venue

By taxi

AAA Radiotaxi	+420 222 333 222, +420 729 331 133
CITY taxi	+ 420 257 257 257
Taxi PRAHA	+ 420 222 111 000

The maximum prices for taxi services in the district of the capital city of Prague:

Ride in the district of the capital city of Prague	**28,- CZK/km**
Boarding fee	**40,- CZK**
Waiting time	**6,- CZK/min**

A typical taxi fares:

From the Conference Venue to the city centre	**10-15 EUR**
From the Conference Venue to the Prague airport	**25-30 EUR**

By metro

Clarion Congress Hotel is located next door to Vysočanská metro station (yellow line B).

Basic ticket (ticket is valid for 90 minutes after validation)	**32,- CZK**
Short-term ticket (ticket is valid for 30 minutes after validation)	**24,- CZK**
1 day (24 hrs) ticket	**110,- CZK**
3 days (72 hrs) ticket	**310,- CZK**

Each fully registered participant will obtain FREE PASS FOR PRAGUE PUBLIC TRANSPORTATION valid for the period of September 1 – 6, 2013 together with registration materials at the registration desk.

Name Badges

Upon registration you will receive a name badge which should be worn at all conference sessions including social events.

Lunch, Coffee, Tea and Snacks

Coffee breaks will be served in the foyer of conference rooms (incl. in the registration fee). Lunches will be served in the hotel restaurant (tickets available at the registration desk). There are several other restaurants at the food court of the adjacent shopping mall Pheonix.

Internet

A Wi-Fi internet connection is available throughout the conference rooms.

Currency

The official currency of the Czech Republic is the Czech Crown = Česká koruna (CZK = Kč). Exchange of foreign currency is available at Prague international Airport and at most hotels, banks and exchange offices throughout the city. International credit cards are accepted for payments in hotels, restaurants and shops. Payment in cash in EUR is also available in some restaurants and shops, please ask for details on-site.

Drinking Water

Tap water is of good quality and can be consumed safely throughout the city. Bottled mineral and spring water is available in shops and restaurants.

Conference Information

Registration desk

Registration and information desk will be open at the conference floor of the Clarion Congress Hotel Prague as follows:

Sunday September 1	**10:00-21:00**
Monday September 2	**08:00-18:00**
Tuesday September 3	**08:30-18:00**
Wednesday September 4	**08:30-13:30**
Thursday September 5	**08:30-17:00**
Friday September 6	**08:30-14:00**

Contact details

Emergency number to the registration desk	**+420 606 918 277**
Email:	**eac2013@cbttravel.cz**

Exhibition

The exhibition is situated in the congress foyer of the Clarion Congress hotel, close to all meeting activities such as scientific sessions, poster exhibition, registration and coffee breaks and will be open to all participants throughout the duration of the conference.

Social Programme

Welcome Reception

Included in the registration fee.

Date:	**Sunday, September 1**
Venue:	**Foyer of the Clarion Congress hotel**
Time:	**19:00**

Concert

Included in the registration fee.

Date:	**Monday, September 2**
Venue:	**Bethlehem Chapel / Betlémská kaple**
Address:	**Betlémské náměstí 255/4, 110 00 Prague 1**
Time:	**19:00**

Bethlehem Chapel is located in the heart of Prague, the Old Town district. It was built as a holy place where sermons could be held in Czech. Jan Hus - university professor and Czech religious reformer - preached there between 1402 and 1413. As he was also the Rector of Charles University, it is believed that the Chapel was linked to this institution.

Conference Dinner

Date:	**Thursday, September 5, 2013**
Venue:	**Municipal House / Obecní dům**
Address:	**Náměstí Republiky 1090/5, 110 00 Prague 1**
Time:	**19:30**
Price:	**70€ per person (tickets available at the registration desk)**

The dinner will be served in a buffet style.

The Municipal House, a national cultural landmark, is among the most significant Art Nouveau buildings in Prague. It is located in the very centre of Prague, directly neighbouring the Powder Gate.

The most significant Czech painters and sculptors of the time participated in the decoration of the Municipal House. That list included: Jan Preisler, Mikoláš Aleš, Max Švabinský, František Ženíšek, Ladislav Šaloun, Josef Mařatka, Josef Václav Myslbek, Alfons Mucha.

Meetings

Monday, September 2nd

12:50-14:00	GAeF Board Meeting
18:00	Elsevier Board Meeting

Tuesday, September 3rd

12:50-14:00	IARA Meeting
18:00	GAeF General Assembly Meeting
18:00	Working Group Meetings

Wednesday, September 4th

12:50-14:00	EAA Board Meeting
afternoon	HEXACOMM
13:00-18:00	ACTRIS ACSM/AMS meeting

Thursday, September 5th

12:50-14:00	EAA Working Group Chairs Meeting

Friday, September 6th

13:00-18:00	ACTRIS ACSM/AMS meeting

EAA Working Group Meetings

The purpose of these meetings is to discuss general matters within the various topic areas to help plan future events, particularly the next EAC. All delegates are welcome.

Tuesday, September 3rd, 18:00, the following groups will meet at the Meridian Hall.

WG 1 **Aerosol-based Nanotechnology**
WG 2 **Aerosol Chemistry**
WG 3 **Aerosol Modelling**
WG 4 **Atmospheric Aerosols - Aerosol Processes and Properties**
WG 5 **Atmospheric Aerosols - Specific Aerosol Types**
WG 6 **Electrical Effects**
WG 7 **Fundamentals**
WG 8 **Combustion Aerosols**
WG 9 **Indoor and Working Place Aerosols**
WG 10 **Instrumentation**
WG 11 **Particle-Lung Interactions**
WG 12 **PMx**

Assembly

GAeF General Assembly will meet on Tuesday, September 3rd, 18:00, at the Aquarius & Taurus Hall.

Presentation Information

Abstracts

All abstracts will be published in electronic form and distributed to participants on USB memory key.

Instructions for Oral Presentations

Every speaker is entitled to speak for 20 minutes, including questions and answers. Due to the very tight schedule, we kindly ask that you respect these time limitations.

How to upload your oral presentation

All presentations should be brought to the Speaker´s Preview Room /QUADRANT/ any time during the official hours but at the least 2 hours before the section starts (or the day prior when your session is scheduled in the morning) or in the conference room one hour before your presentation.

A qualified technician will help you to upload your presentation to our system. Please use the USB key or CD / DVD-Rom. Speaker Preview Room opening times are the same as operating times of the registration desk.

Speaker's Preview Room opening times:

Sunday, September 1	**10:00-21:00**
Monday, September 2	**08:00-18:00**
Tuesday, September 3	**08:30-18:00**
Wednesday, September 4	**08:30-18:00**
Thursday, September 5	**08:30-17:00**
Friday, September 6	**08:30-14:00**

Instructions for oral reserve presentations

Oral reserve presentations are poster presentations that will also be offered a slot for oral presentation should a vacancy become available. Presenters should check with chairs at the start of the relevant oral session.

Poster Sessions Schedule

Posters will be located at the hall Zenit and Nadir. Participanst are kindly asked to display and also take down their poster according to this poster session schedule. For those who will not take down their poster on time please come to Quadrant room where they will be kept for you during the time of the conference. Presenting authors are kindly asked to be available to present their posters during the poster sessions time schedule.

Poster Session A:

Atmospheric Aerosols

Days:	**Sunday, September 1 - Monday, September 2**
Time to display:	**Sunday evening**
Time to uncover:	**Monday evening**
Presenatation time:	**Monday, 16:00-18:00**

Poster Session B:

Aerosol Chemistry, Aerosol Modelling, Aerosol-based Nanotechnology, Combustion Aerosols

Days:	**Tuesday, September 3 - Wednesday, September 4**
Time to display:	**Tuesday morning**
Time to uncover:	**Wednesday evening**
Presentation time:	**Tuesday, 16:00-18:00**

Poster Session C

Electrical Effects, Fundamentals, Indoor Working Place Aerosols, Instrumentation, Particle-Lung Interactions, PMx

Days:	**Thursday, September 5 - Friday, September 6**
Time to display:	**Thursday morning**
Time to uncover:	**Friday up to 12 o'clock**
Presentation time:	**Thursday, 16:00 - 18:00**

Late Posters

Late posters will be displayed according to their topics and will be located at the poster area (room Zenit and Nadir) as per poster sessions schedule.

Programme Overview

Sunday, September 1st

10:00-21:00	Registration
19:00	Welcome Reception, Exhibition Opening

Monday, September 2nd

8:00-18:00	Registration					
8:45-9:00	Opening Ceremony, A (Meridian)					
9:00-10:00	Plenary lecture: Merete Bilde - Aerosol particles in the marine environment, A (Meridian)					
10:00-10:30	Coffee break					
	A (Meridian)	B (Leo + Virgo)	C (Aquarius + Taurus)	D (Kepler)	E (Tycho)	F (Stella)
10:30-12:50	Atmospheric Aerosols	Atmospheric Aerosols	PMx (Special session)	Aerosol Chemistry	Indoor and Working Place Aerosols	Instrumentation
12:50-14:00	Lunch, GAeF Board Meeting					
14:00-16:00	Aerosol Modelling	Instrumentation	Combustion Aerosols	PMx	Aerosol Chemistry (Special Session)	Aerosol-based Nanotechnology
16:00-16:30	Coffee break					
16:00-18:00	Poster Session A - Authors' Presentations					
18:00	Elsevier Board Meeting					
19:00	Concert					

Tuesday, September 3rd

8:30-18:00	Registration					
9:00-10:00	Plenary lecture: Ruprecht Jaenicke - Primary Biological Atmospheric Aerosols, A (Meridian)					
10:00-10:30	Coffee break					
	A (Meridian)	B (Leo+Virgo)	C (Aquarius+Taurus)	D (Kepler)	E (Tycho)	F (Stella)
10:30-12:50	Atmospheric aerosols	Atmospheric aerosols	Aerosols chemistry	Indoor and Working Place Aerosols	Instrumentation	PMx (Special session)
12:50-14:00	Lunch, IARA Meeting					
14:00-16:00	Atmospheric aerosols	Aerosol modelling	Combustion Aerosols	PMx	Aerosol-based Nanotechnology	–
16:00-16:30	Coffee break					
16:00-18:00	Poster Session B - Authors' Presentations					
18:00	Working Group Meetings, GAeF General Assembly Meeting					

Wednesday, September 4th

8:30-13:30	Registration					
8:45-9:45	Plenary lecture: Lidia Morawska - The Dynamics of Indoor Aerosol: what is important, where, when and why?, A (Meridian)					
9:45-10:00	Smoluchowski Award, A (Meridian)					
10:00-10:30	Coffee break					
	A (Meridian)	B (Leo+Virgo)	C (Aquarius+Taurus)	D (Kepler)	E (Tycho)	F (Stella)
10:30-12:50	Atmospheric aerosols	Atmospheric aerosols	Aerosol modelling	Indoor and Working Place Aerosols	Aerosol-based Nanotechnology	Particle-Lung Interactions (Special session)
12:50-14:00	Lunch, EAA Board Meeting					
14:00	Free Afernoon					

Thursday, September 5th

8:30-17:00	Registration					
9:00-10:00	Plenary lecture: Paul E. Wagner - Nucleation of vapours - molecular content of critical clusters and activation of nanoparticles, A (Meridian)					
10:00-10:30	Coffee break					
	A (Meridian)	B (Leo+Virgo)	C (Aquarius+Taurus)	D (Kepler)	E (Tycho)	F (Stella)
10:30-12:50	Atmospheric aerosols	Atmospheric aerosols	Combustion Aerosols	Electrical Effects	Fundamentals	–
12:50-14:00	Lunch, EAA Working Group Chairs Meeting					
14:00-16:00	Atmospheric aerosols	Aerosol chemistry	PMx	Combustion Aerosols	Aerosols modeling, Atmospheric aerosols (Special session)	Particle-Lung Interactions
16:00-16:30	Coffee break					
16:00-18:00	Poster Session C - Authors' Presentations					
19:30	Conference Dinner					

Friday, September 6th

8:30-14:00	Registration					
9:00-10:00	Plenary lecture: Imre Salma - Urban aerosol: tendencies and challenges, A (Meridian)					
10:00-10:30	Coffee break					
	A (Meridian)	B (Leo+Virgo)	C (Aquarius+Taurus)	D (Kepler)	E (Tycho)	F (Stella)
10:30-12:50	Atmospheric aerosols	Atmospheric aerosols	Aerosols chemistry	Fundamentals	Particle-Lung Interactions	–

Programme

Sunday, September 1st

10:00-21:00 Registration
Room: Conference foyer

19.00 Welcome Reception, Exhibition Opening
Room: Conference foyer

Monday, September 2nd

8:45-9:00 **Opening Ceremony**
Room: A (Meridian)

9:00-10:00 **Plenary lecture: Aerosol particles in the marine environment**
Plenary speaker: Merete Bilde
Plenary chairs: Regina Hitzenberger, Ilona Riipinen
Room: A (Meridian)

10:00-10:30 Coffee break
Room: Conference foyer

10:30-12:50 **Session: Atmospheric Aerosols**
Remote sensing and optical properties of aerosols
Chairs: Lucas Alados Arboledas, Arnaud Apituley
Room: A (Meridian)

10:30-10:50 **Relationship between oxidation level and optical properties of secondary organic aerosol**
A. T. Lambe, C. D. Cappa, P. Massoli, T. B. Onasch, S. D. Forestieri, A. T. Martin, M. J. Cummings, D. R. Croasdale, W. H. Brune, D. R. Worsnop, P. Davidovits

10:50-11:10 **Satellite and ground-based retrievals of aerosol optical properties in Arctic (2003-2011)**
P. Glantz, M. Tesche, K. Stebel, A. Herber, H. Struthers, J. Karlsson, A. Bourassa, L. Thomason, M. Maturilli

11:10-11:30 **iSPEX: First Results of Aerosols Measured by Smartphones in The Netherlands**
A. Apituley, iSPEX team

11:30-11:50 **Operational boundary layer height determination with in-situ and ground-based remote sensing instruments: validation and first climatology on the Swiss plateau**
C. Praz, M. Collaud Coen, A. Haefele, D. Ruffieux

11:50-12:10 **Assessment of parameterizations of optical properties and hygroscopic growth of aerosols**
A. R. Esteve, E. J. Highwood, W. T. Morgan, H. Coe, R. G. Grainger, P. Brown, C. L. Ryder, K. Szpek, J. A. Martínez-Lozano

12:10-12:30 **The optical properties of aerosols in Amazonia: from natural biogenic to biomass burning particles**
Paulo Artaxo, Xuguang Chi, Henrique M. J. Barbosa, Luciana V. Rizzo, Andrea Arana, Joel F. Brito, Elisa T. Sena, Joel Schaefer, Meinrat O. Andreae

12:30-12:50 **In-situ absorption measurement of HULIS and mineral dust components as well as winter time ambient aerosol using multi-wavelength photoacoustic instrument. A laboratory and a field study**
T. Ajtai, N. Utry, Á. Filep, Z. Bozóki, G. Szabó

Reserve paper **Black carbon aerosol concentrations and mixing state in Pallas, Finland**
T. Raatikainen, D. Brus, A.-P. Hyvärinen, J. Svensson, H. Lihavainen

10:30-12:50 Session: Atmospheric Aerosols

SOA and aerosol hygroscopicity

Chairs: U. Baltensperger, M.R. Alfarra
Room: B (Leo+Virgo)

10:30-10:50 **Vapour pressures of substituted polycarboxylic acids are much lower than previously reported**
A. J. Huisman, U. K. Krieger, A. Zuend, C. Marcolli, Th. Peter

10:50-11:10 **Investigation of the effects of chemical and physical factors on the phase state of SOA particles**
A. Pajunoja, M. R. Alfarra, A. Buchholz, W. T. Hesson, G. B. McFiggans, A. Virtanen

11:10-11:30 **Impact of semi-volatiles on hygroscopic growth and CCN activity of secondary organic aerosol**
A. Buchholz, M. R. Alfarra, W. T. Hesson, G. McFiggans

11:30-11:50 **A new inlet for simultaneous gas and particle phase measurements coupled to a chemical ionisation high-resolution time-of-flight mass spectrometer**
C. Mohr, F. Lopez-Hilfiker, B. H. Lee, D. S. Covert, D. R. Worsnop, J. A. Thornton

11:50-12:10 **Gas and Particle Phase Acids in a Ponderosa Pine Forest**
H. Stark, R. L. N. Yatavelli, S. L. Thompson, J. R. Kimmel, B. B. Palm, D. A. Day, P. Campuzano-Jost, M. J. Cubison, J. T. Jayne, D. R. Worsnop, J. A. Thornton, J. L. Jimenez

12:10-12:30 **Hygroscopic Properties and Mixing state of Ultrafine Aerosol Particles over two Urban Background Sites**
S. Bezantakos, E. Konstenidou, K. Florou, A. Bougiatioti, K. Eleftheriadis, N. Mihalopoulos, A. Nenes, S. Pandis, G. Biskos

12:30- 12:50 **Profiling of hygroscopic properties during the Po-Valley PEGASOS campaign 2012**
B. Rosati, E. Weingartner, P. Zieger, M. Gysel, G. Wehrle, U. Baltensperger

Reserve paper **Observations on atmospheric electricity and aerosol-cloud interactions**
Hanna E. Manninen, Hannes Tammet, Antti Mäkelä, Jussi Haapalainen, Sander Mirme, Tuomo Nieminen, Alessandro Franchin, Tuukka Petäjä, Markku Kulmala, Urmas Hõrrak

10:30-12:50 Session: Aerosol Chemistry

Chemistry of organic aerosols 1

Chairs: Ivan Kourtchev, Yoshi Iinuma
Room: D (Kepler)

10:30-10:50 **Revisiting the formation of secondary organic aerosol from the photooxidation of anthropogenic precursors**
M. R Alfarra, A. Buchholz, W. T. Hesson, R. Lidster, I. White , A. Pajunoja, J. F. Hamilton, P. Monks, A. Virtanen, G. B. McFiggans

10:50-11:10 **Gas-Phase Measurements of Oxidized Organic Compounds Generated by a Potential Aerosol Mass (PAM) Reactor using Acetate Chemical Ionization High-Resolution Time-of-Flight Mass Spectrometry**
P. Chhabra, A. Lambe, M. Canagaratna, H. Stark, P. Massoli, J. Kimmel, J. Jayne, D. Worsnop

11:10-11:30 **Time-resolved chemical composition of chamber generated SOA originated from monoterpene oxidation**
A. Mutzel, O. Böge, A. Kahnt, Y. Iinuma, H. Herrmann

11:30-11:50 **Dependence of α-pinene secondary organic aerosol formation on relative humidity and aerosol surface distribution**
L. Pfaffenberger, P. Barmet, R. Wolf, S. M. Platt, I. El-Haddad, J. G. Slowik, J. Dommen, A. S. H. Prévôt, U. Baltensperger

11:50-12:10 **Characterization of secondary organic aerosol from ozonolysis of β-pinene**
Ågot K. Watne, Eva U. Emanuelsson, Anna Lutz, Evert Ljungström, Mattias Hallquist

12:10-12:30 **Formation of anthropogenic secondary organic aerosol (SOA) and its influence on biogenic SOA properties**
E. U. Emanuelsson, M. Hallquist, D.-F. Zhao, B. Bohn, H. Fuchs, B. Kammer, A. Kiendler-Scharr, S. Nehr, F. Rubach, R. Tillmann, A. Wahner, H.-C. Wu, K. Kristensen, M. Glasius, Y. Rudich, Th. F. Mentel

12:30-12:50 **Effect of Nucleation Precursors on the Atmospheric Oxidation of Organic Compounds**
J. Elm, M. Bilde, K. V. Mikkelsen

Reserve paper **Secondary organic aerosol formation in the ozonolysis of biogenic volatile organic compounds performed in a laminar flow reactor**
T. Braure, V. Riffault, A. Tomas, M. Duncianu, Y. Bedjanian, P. Coddeville

10:30-12:50 Session: Indoor and Working Place Aerosols

Indoor environment
Chairs: Ian Colbeck, Martin Braniš
Room: E (Tycho)

10:30-10:50 **Number concentration and modal Structure of indoor/outdoor fine particles in four European Cities**
M. Lazaridis, K. Eleftheriadis, V. Ždímal, J. Schwarz, Z. Wagner, J. Ondracek, Y. Drossinos, T. Glytsos, S. Vratolis, K. Torseth, J. Smolík

10:50-11:10 **Spatial variation of air pollutants in a multilevel office building**
C. He, L. Morawska

11:10-11:30 **Effect of Anti-idling Campaign on the Outdoor and Indoor Aerosol Exposure at Schools**
S. A. Grinshpun, M. Yermakov, J. Y. Kim, T. Reponen, C. Shaffer, P. Ryan

11:30-11:50 **Exposure assessment to air pollutants in Elderly Care Centers**
Almeida-Silva, S. M. Almeida, H. T. Wolterbeek

11:50-12:10 **Exposure to ultrafine particles in indoor and outdoor school environments across Barcelona (Spain)**
M. Viana, I. Rivas, J. Sunyer, L. Bouso, M. Álvarez, C. Sioutas, X. Querol, A. Alastuey

12:10-12:30 **Sources, sinks, chemical composition and transport of aerosol particles in a university lecture hall**
I. Salma, K. Dosztály, T. Borsós, T. Weidinger, G. Kristóf, N. Péter, Zs. Kertész

12:30-12:50 **The effect of size, location, occupancy and microclimatic factors on air quality of university lecture rooms**
M. Branis, K. Stupkova

Reserve paper **Particulate Matter in Indoor Aor in two Schools in Vienna, Austria**
A. Kasper-Giebl, N. Jankowski, K. Kassin, E. Can Cetintas, H. Bauer, H. Grothe

10:30 -12:50 Session: Instrumentation

New techniques
Chairs: Martin Fierz, Christof Asbach
Room: F (Stella)

10:30-10:50 **A fast-scanning DMA train for the precision quantification of nanoparticle dynamics**
P. M. Winkler, J. Ortega, P. H. McMurry, J. N. Smith

10:50-11:10 **Fast scanning mobility particle sizing system and classifier**
J. Farnsworth, F. Quant, H-G. Horn, B. Osmondson, R. Caldow

11:10-11:30 **A Drift Tube Ion Mobility Spectrometer (DT-IMS) combined with a Condensation Particle Counter for Analysis of Sub 10 nm Aerosol Particles**
Derek R. Oberreit, Peter H. McMurry, Christopher J. Hogan Jr.

11:30-11:50 **A new version of the Particle Size Magnifier for detection of airborne molecular clusters and nano-particles as small as 1 nm**
K. Lehtipalo, A. Franchin, J. Mikkilä, J. Vanhanen, J. Kangasluoma, T. Petäjä, M. Kulmala

11:50-12:10 **First results of a new Gas Aerosol Nucleation Spectrometer: GANS**
P. Dohányosová, E. Montoya, E. Ramiro, S. López-Vidal

12:10-12:30 **The versatile Size Analyzing Nuclei Counter (vSANC)**
T. Pinterich , P. M. Winkler , P. E. Wagner , M. Kulmala , A. Vrtala

12:30-12:50 **Charging efficiency of the single-wire corona unipolar charger with radial sheath flow**
V. Wattanamekhinkul, C.L. Chein, C.J. Tsai

Reserve paper **Application of broadband optical cavity methods to studying the optical properties of aerosols at short wavelengths**
E. M. Wilson, J. C.Wenger, D. S. Venables

10:30-12:50 Special Session: PMx

Source apportionment-AMS and carbon based
Chairs: André S. H. Prévôt, Regina Hitzenberger
Room: C (Aquarius+Taurus)

10:30-10:50 **ME-2 analysis of long-term on-line mass spectrometric data of non-refractory submicron aerosol in the city of Zurich**
F. Canonaco, J. G. Slowik, U. Baltensperger, A. S. H. Prévôt

10:50-11:10 **A Year-long C-TOF-AMS Dataset in London: Investigating Chemical Composition, Seasonal Trends and Sources of Aerosols**
D. E. Young, J. D. Allan, D. C. Green, P. I. Williams, H. Coe,

11:10-11:30 **Primary and secondary organic aerosol origin by combined gas-particle phase source apportionment**
M. Crippa, F. Canonaco, J. G. Slowik, I. El Haddad, P. F. DeCarlo, C. Mohr, M. F. Heringa, R. Chirico, N. Marchand, B. Temime-Roussel, E. Abidi, L. Poulain, A. Wiedensohler, U. Baltensperger, A. S. H. Prévôt

11:30-11:50 **Long-term monitoring, chemical composition and source apportionment study of PM2.5 in Augsburg, Germany**
R. M. Qadir, G. Abbaszade, J. Schnelle-Kreis, R. Zimmermann

11:50-12:10 **Composition and Source Identification of Ambient Single Particles during the NANO-INDUS 2012 Campaign in Dunkirk, France**
J. Arndt, R. Healy, A. Setyan, K. Deboudt, V. Riffault, A. Blondel, A. Anderson, L. Y. Alleman, S. Mbengue, P. Flament, J. Wenger

12:10-12:30 **Radiocarbon-based source apportionment of elemental carbon and organic carbon at a regional background site on Hainan Island, South China**
Y. L. Zhang, J. Li, G. Zhang, A. S. H. Prévôt, S. Szidat,

12:30-12:50 **Wood-burning emissions within a continuous-flow photooxidation reactor: Soot-Particle Aerosol Mass Spectrometer characterization**
J. C. Corbin, A. Keller, H. Burtscher, B. Sierau, U. Lohmann, A. A. Mensah

Reserve paper **Micromarkers of source-specific combustion aerosols**
O. B. Popovicheva, E. D. Kireeva, N. M.Persiantseva

12:50-14:00 Lunch break

14:00-16:00 Session: Instrumentation

Combustion aerosol and chemical measurements

Chairs: Markus Pesch, Michal Vojtíšek-Lom
Room: B (Leo+Virgo)

14:00-14:20 **Measurement of chemisorption on metallic nanoparticles using aerosol photoemission spectroscopy**
S. Onel, M. Seipenbusch

14:20-14:40 **Validation of an online, real-time, soft photon ionisation (SPI) time of flight mass spectrometer for mainstream tobacco smoke analysis**
J. Hawke, M. Bente Von Frowein

14:40-15:00 **An accurate, real-time and low-cost method to measure biomass smoke**
Yungang Wang, Daniel L. Wilson, Philip K. Hopke, Ashok J. Gadgil

15:00-15:20 **Multi-wavelength characterization of carbonaceous aerosol**
P. Prati, V. Ariola, V. Bernardoni, M.C. Bove, G. Calzolai, M. Chiari, F. Lucarelli, D. Massabò, S. Nava, A. Piazzalunga, G. Valli, R. Vecchi

15:20-15:40 **Characterization of Black Carbon concentration, sources and age using an Aethalometer AE33**
L. Drinovec, G. Močnik, J. E. Petit, J. Sciare, O. Favez, P. Zotter, R. Wolf, A. S. H. Prévôt, A. D. A. Hansen

15:40-16:00 **Hyphenation of a Thermal/Optical Carbon Analyzer to photo-ionization mass spectrometry for determination of the organic content of aerosol particles**
T. Streibel, J. Grabowsky, J. C. Chow, J. G. Watson, R. Zimmermann

Reserve paper **Organic aerosol speciation with in-situ thermal desorption gas chromatography: a brief history of the TAG instrument**
N. M. Kreisberg, S. V. Hering, A. P. Teng, G. Isaacman, Y. Zhao, D. R. Worton, A. W. H. Chan, B. J. Williams, J. T. Jayne, A. T. Lambe, T. Hohaus, J. R. Kimmel, D. T. Sueper, W. Brooks, L. R. Williams, A. M. Trimborn, D. R. Worsnop, A. H. Goldstein

14:00-16:00 Session: Aerosol Modelling

Models for aerosol emission and nucleation

Chairs: Sabine Wurzler, Michael Boy
Room: A (Meridian)

14:00- 14:20 **Contribution of ion-assisted nucleation to new particle formation in a tropical boundary layer**
V. P. Kanawade, S. N. Tripathi, D. K. Siingh, A. S. Gautam A. K. Srivastava, A. K. Kamra

14:20-14:40 **The role of sulphuric acid in the formation of atmospheric particles based on a long-term explicit modelling approach**
M. Boy, L. Zhou, D. Mogensen, A. Sogachev, S. Smolander

14:40-15:00 **Hydration of Sulfuric Acid Clusters and the Impact of Bases**
H. Henschel, I. K. Ortega, O. Kupiainen, T. Olenius, T. Kurtén, H. Vehkamäki

15:00-15:20 **Simulations of SOA formation from alpha-pinene ozonolysis and photo-oxidation in chamber experiments**
G. Capes, D. Lowe, G. McFiggans

15:20-15:40 **Effects of electric vehicles on air quality in street canyons**
T. Schöllnhammer, F. Lommes, T. Schulz, H. Hebbinghaus, S. Wurzler

15:40-16:00 **Remapping of aerosol emissions in a modal models as a source of error**
T. Korhola, H. Kokkola, H. Korhonen, A.-I. Partanen, A. Laaksonen, S. Romakkaniemi

Reserve paper **Impact of biogenic emissions on PM2.5 concentration over Europe**
E. Tagaris, R. E. P. Sotiropoulou, N. Gounaris, S. Andronopoulos, D. Vlachogiannis

14:00-16:00 Session: Combustion Aerosols

Characterization methods of combustion aerosols
Chairs: F.X. Ouf, N. Ivleva
Room: C (Aquarius+Taurus)

14:00-14:20 **Automatized determination of the primary particles size of soot aggregates by TEM image analysis**
A. Bescond, J. Yon, C. Rozé, F. X. Ouf

14:20-14:40 **Electrical Conductivity Measurements in Combination with Raman Microspectroscopy and Temperature Programmed Oxidation for Analysis of Microstructure and Reactivity of Soot**
B. Grob, F. Knoller, N. P. Ivleva, R. Niessner

14:40-15:00 **Aerosol mass spectrometry of refractory black carbon containing particles**
T. B. Onasch, E. C. Fortner, P. Massoli, L. R. Williams, A. T. Lambe, A. M. Trimborn, J. T. Jayne, P. Davidovits, D. R. Worsnop

15:00-15:20 **REMPI-Laser-mass spectrometry: On-line and off-line analysis of the molecular signature of polycyclic aromatic hydrocarbons (PAH) in gas- and particle-phase of combustion aerosols**
R. Zimmermann, C. Radischat, O. Sippula, M. Kelbg, M. Sklorz, J. Passig, C. Busch, M. Oster, H. Harndorf, A. Walte, B. Stengel, T. Streibel

15:20-15:40 **Carbonaceous aerosols and variations in their light absorbing properties**
C. Linke, I. Ibrahim , R. Hitzenberger, M. Schnaiter

15:40-16:00 **Effective density of particles from different combustion conditions and engineered TiO2 nanoparticles**
J. Leskinen, M. Ihalainen, T. Torvela, J. Ruusunen, M. Miettinen, I. Nuutinen, J. Lyyränen, A. Auvinen, J. Joutsensaari, O. Sippula, J. Tissari, J. Jokiniemi

Reserve paper **Dilution affects particle properties originating from residential biomass combustion**
H. Lamberg, T. Kaivosoja, J. Leskinen, M. Kortelainen, A. Viren, H. Koponen, V. Tiihonen, M. Miettinen, J. Pyykönen, J. Jokiniemi, J. Tissari1

14:00-16:00 Session: PMx

Urban PMx
Chairs: Regina Hitzenberger, M. Van Poppel
Room: D (Kepler)

14:00-14:20 **Road surface dust load is dependent on road surface macro texture**
G. Blomqvist, M. Gustafsson, T. Lundberg

14:20-14:40 **Evaluating the use of dust suppressant to control local PM10 concentrations**
G. W. Fuller, B. Barratt, D. Carslaw, D. Green, A. H. Tremper

14:40-15:00 **CHEMKAR PM10: A year-long chemical characterization of PM10 in Flanders (Belgium) in 4 major cities and 3 types of locations**
J. Vercauteren , D. Roet, C. Matheeussen, E. Roekens, R. Vermeylen, W. Maenhaut, M. Claeys

15:00-15:20 **Non-exhaust PMx emissions from road traffic**
M. Maasikmets, , E. Teinemaa, T. Arumäe, V. Kimmel

15:20-15:40 **Atmospheric particulate mercury in the megacity Beijing – spatio-temporal variations, sources, and efficiency of mitigation measures**
N. J. Schleicher, J. Schäfer, G. Blanc, Y. Chen, F. Chai, S. Wang, S. Norra

15:40-16:00 **Air Quality Study within Steel Works Town in the UK**
R. Vecchi, S. Nava, G. Calzolai, F. Lucarelli, G. Valli, D. C. S. Beddows, A. M. Taiwo, R. M. Harrison

Reserve paper **Blue sky over the Ruhr – a review of the effectiveness of more than 50 years of air quality measures in Germany**
S. Wurzler, H. Hebbinghaus, P. Bruckmann, J. Friesel, U. Pfeffer

14:00-16:00 Session: Aerosol-based Nanotechnology

Applications of engineered nanoparticles
Chairs: J. Davis, G. Biskos
Room: F (Stella)

14:00-14:20 **Nanostructural engineering of Pt/C catalyst via spray drying for elec trocatalyst applications**
R. Balgis, G. M. Anilkumar, S. Sago, T. Ogi, K. Okuyama

14:20-14:40 **Gas sensors by flame aerosol deposition: Correlations between blood glucose and breath components from portable gas sensors and mass spectroscopy**
M. Righettoni, A. Schmid, A. Amann, S. E. Pratsinis

14:40-15:00 **Aerosol synthesis of porous Particles for structured layers as catalyst support for Fischer–Tropsch reaction**
L. Zeng, A. P. Weber

15:00-15:20 **Optical heating of nanorods in a laser tweezers**
P. B. Roder, B. E. Smith, P. J. Pauzauskie, E. J. Davis

15:20-15:40 **Correlation between Catalytic Activity and Production of Reactive Oxygen Species for Airborne Engineered Palladium Nanoparticles**
N. Neubauer, J. Palomaeki, H. Alenius, G. Kasper

15:40-16:00 **Substance release kinetics of spherical and non-spherical hybrid nanoparticles generated by aerosol-photopolymerization**
E. Akgün, M. Vranceanu, B. Sachweh, J. Hubbuch, M. Wörner

Reserve paper **Industrial by-products as precursors for gas-phase nanoparticle synthesis**
T. Karhunen, A. Lähde, T. Torvela, J. Jokiniemi

14:00-16:00 Special Session: Aerosol Chemistry

Radical chemistry and aerosol formation
Chairs: Thorsten Hoffman, Thomas Zeuch
Room: E (Tycho)

14:00-14:20 **Partially oxidized radicals – crucial intermediates during atmospheric aerosol formation**
J. Ahrens, P. T. M. Carlsson, C. Keunecke, M.-C. Maas, J. L. Wolf, T. Zeuch

14:20-14:40 **Formation of organosulfates from the sulfate radical induced oxidation of methacrolein and methyl vinyl ketone**
J. Schindelka, Y. Iinuma, D. Hoffmann, H. Herrmann

14:40-15:00 **The oxidation of alpha-pinene and limonene in a flow tube, investigated using the CI-APi-TOF**
M. P. Rissanen, M. Sipilä, M. Ehn, N. Sarnela, T. Jokinen, J. Kangasluoma, T. Petäjä, H. Junninen, D. Worsnop, M. Kulmala

15:00-15:20 **Ozonolysis of shikimic acid particles caught in the act**
S. Steimer, A. J. Huisman, U. K. Krieger, T. Peter, M. Lampimäki, G. Gržinić, E. Coz, B. Watts, J. Raabe, M. Ammann

15:20-15:40 **Aerosol particles in molecular beams: pickup of molecules, chemistry and photochemistry**
M. Fárník, V. Poterya, A. Pysanenko, J. Lengyel, J. Kočišek, J. Fedor

15:40-16:00 **Photoionization and infrared excitation of clusters with radical sites: Probing size and structure of neutral, sodium doped water clusters**
C. C. Pradzynski, U. Buck, R. M. Forck, F. Zurheide, T. Zeuch

Reserve paper **Pressure dependency of ozonolysis product formation of α-pinene focusing on low volatile compounds such as organic acids and dimeric compounds**
M. Beck, C. Keunecke, T. Zeuch, T. Hoffmann

16:00-16:30 Coffee break
Room: Conference foyer

16:00-18:00 Poster Session A - authors' presentations

19:00 Concert
Venue: Bethlemen Chapel

Tuesday, September 3rd

9:00-10:00 **Plenary lecture: Primary Biological Atmospheric Aerosols**

Plenary speaker: Ruprecht Jaenicke
Plenary chairs: Ian Colbeck, Andrei Bologa
Room: A (Meridian)

10:00-10:30 Coffee break
Room: Conference foyer

10:30-12:50 **Session: Atmospheric Aerosols**

Carbonaceous aerosols
Chairs: A. Petzold, U. Dusek
Room: A (Meridian)

10:30-10:50 **Recommendations for the interpretation of "black carbon" measurements**
A. Petzold, John A. Ogren

10:50-11:10 **Comparability of methods to measure black and elemental carbon in two European urban areas - site and seasonal similarities and differences**
R. Hitzenberger, J. Schwarz, I. Aschauer, R. Haindl, W. Ludwig, R Wagner, A. Wonaschuetz, G. Zecha, I. Ševčíková, P. Vodička , N. Zíková, V. Ždímal

11:10-11:30 **Seasonal variations of black carbon physical properties influenced by different sources in London urban environment**
Dantong Liu, James Allan, Michael Flynn, Dominique Young, Hugh Coe, Martin Gallagher

11:30-11:50 **Influence of vertical transport on the mixing state of black carbon at the high-alpine Jungfraujoch site**
M. Gysel, M. Laborde, N. Bukowiecki, E. Hammer, P. Zieger, U. Baltensperger, E. Weingartner

11:50-12:10 **Fossil and non-fossil sources of OC and EC in Switzerland for winter-smog episodes**
S. Szidat, P. Zotter, Y. L. Zhang,, V. G. Ciobanu, L. Wacker, Baltensperger, A. S. H. Prévôt

12:10-12:30 **Long-term variability of elemental and organic carbon in aerosols over Athens, Greece**
D. Paraskevopoulou, E. Liakakou, E. Gerasopoulos, N. Mihalopoulos

12:30-12:50 **Influence of the traffic on the black carbon particle mass concentration and particle number size distribution in La Paz, Bolivia**
A. Wiedensohler, K. Weinhold, M. Andrade, F. Velarde, I. Moreno, F. Avila

Reserve paper **Long-term observations of carbonaceous aerosols and related gaseous emissions near a crude-oil plant in South Italy**
M. Calvello, M. Lovallo F. Esposito, L. Mangiamele, G. Pavese

10:30-12:50 Session: Atmospheric Aerosols

New particle formation between ground and free troposphere

Chairs: Birgit Wehner, Michael Boy
Room: B (Leo+Virgo)

10:30-10:50 **Secondary particle formation in Arctic Russia**
E. Asmi, V. Kondratyev, D. Brus, H. Lihavainen, T. Laurila, M. Aurela, T. Uttal, V. Ivakhov, A. Makshtas

10:50-11:10 **New Aerosol Particle formation in Amazonia**
M. Matisans, P. Tunved, T. Hamburger, H. E. Manninen, J. Backman, L. Rizzo, P. Artaxo, I. Riipinen, E. Swietlicki, R. Krejci, M. Kulmala

11:10-11:30 **Formation and chemical properties of nano-sized particles in the lower free troposphere**
J. Tröstl, J. Duplissy, F. Bianchi, L. Rondo, H. Junninen, A. Adamov, A. P. Praplan, C. Fuchs, J. Dommen, E. Weingartner, U. Baltensperger

11:30-11:50 **Enhancement in CCN concentrations during new particle formation events**
Z. J. Wu, W. Birmili, L. Poulain, Z. B. Wang, A. Hamed, S. Henning, F. Stratmann, H. Herrmann

11:50-12:10 **NanoShip: Are there any new particle formation events over the North Sea?**
N. Kelbus, A. Massling, R. Lange, M. Fiebig, B. Henzing, M. Glasius, M. Bilde, Q. T. Nguyen, M. Moerman, G. de Leeuw, M. Dal Maso, Niku Kivekäs, A. Kristensson

12:10-12:30 **Onset of new particle formation in boundary layer**
H. E. Manninen, S. Mirme, M. Ehn, K. Leino, S. Schobesberger, H. Junninen, E. Järvinen, J. Kangasluoma, T. Nieminen, R. Tillmann, F. Angelini, G. P. Gobbi, A. Mirme, S. Decesari, A. Wahner, T. Petäjä, D. R. Worsnop, F. Rohrer, T. F. Mentel, M. Kulmala

12:30-12:50 **Events of increased particle number concentrations around trade wind cumuli near Barbados**
B. Wehner, F. Ditas, A. Wiedensohler, H. Siebert

Reserve paper **Characteristics of new particle formation events in Hungarian background air at K-puszta, 2008-2012**
Zs. Bécsi, Á. Molnár, K. Imre, P. P. Aalto

10:30-12:50 Session: Aerosol Chemistry

Chemistry of organic aerosols 2

Chairs: Magda Claeys, Josef Dommen
Room: C (Aquarius+Taurus)

10:30-10:50 **Novel smog chamber studies of wood burning emissions at low temperatures**
E. A. Bruns, I. El Haddad, S. M. Platt, B. Temime-Roussel, D. Kilic, J. G. Slowik, , A. Detournay, G. Močnik, N. Marchand, U. Baltensperger, A. S. H. Prévôt

10:50-11:10 **Atmospheric reactivity of biomass burning emitted compounds: methoxyphenols OH rate constants and Secondary Organic Aerosol formation**
A. Lauraguais, , C. Coeur-Tourneur, A. Cassez, J. C. Wenger, A. Seydi, K. Deboudt, , M. Fourmentin, M. Choël

11:10-11:30 **Particle-bound Methoxyphenols and their atmospheric nitration products as wood combustion tracers**
J. Orasche, J. Schnelle-Kreis, G. Abbaszade, M. Elsasser, R. Zimmermann

11:30-11:50 **Aqueous-phase photochemical oxidation and direct photolysis of vanillin as a model compound of methoxy-phenols from biomass burning**
Y. J. Li, H. Y. Cheung, D. D. Huang, W. H. Fan, L. E. Yu, C. K. Chan

11:50-12:10 **Secondary organic aerosol formation through aqueous phase photooxidation of aromatic compounds**
Z. Kitanovski, I. Grgić, A. Čusak, M. Claeys

12:10-12:30 **Photosensitized reactions at the air-sea interface: a potential source of aerosol**
R. Ciuraru, F. Bernard, S. Rossignol, L. Fine, C. George

12:30-12:50 **Black Carbon Containing Particles at a Rural Site Southeast of London during ClearfLo Winter IOP Detling Site**
L. R. Williams, S. Herndon, J. Jayne, A. Freedman, B. Brooks, J. Franklin, P. Massoli, E. Fortner, P. Chhabra, M. Zahniser, H. Stark, T. Onasch, M. R. Canagaratna, D. R. Worsnop, F. Lopez-Hilfiker, C. Mohr, J. Thornton, N. L. Ng, L. Xu, W. B. Knighton, M. Dubey, A. Aiken, K. Gorkowski, S. Liu, T. Martin, R. Coulter, S. Visser, M. Furger, P. Zotter, A. S. H. Prévôt

Reserve paper **Contribution of Inorganic aerosols and trace gases due to biomass burning during cooking hours at a rural site in India**
Sudha Singh, Gyan Prakash Gupta, Bablu Kumar, U. C. Kulshrestha

10:30-12:50 Session: Indoor and Working Place Aerosols

Workplace exposure

Chairs: Congrong He, Kaarle Hameri
Room: D (Kepler)

10:30-10:50 **Nanoparticle Release from Dental Composites during Restoration Grinding and Polishing**
C. Asbach, B. Hellack, B. Van Meerbeek, M. Peumans, P. Hoet, M. Wiemann, T. A. J. Kuhlbusch, K. L. Van Landuyt

10:50-11:10 **Micro and nanoparticles released from the thermal cutting of polystyrene foams and the associated isomerization of hexabromocyclododecane (HBCD) diastereomers**
Y.-Y. Kuo, H. Zhang, A. C. Gerecke, J. Wang

11:10-11:30 **Mixed dust exposure and health risk assessment in the ceramics industry**
B. Moroni, D. Cappelletti, F. Scardazza, S. Becagli, R. Traversi, R. Udisti

11:30-11:50 **A prototype of a new engineered nanoparticle monitoring device for workplaces: Device testing**
J. Ruusunen, J. Leskinen, T. Torvela, M. Ihalainen, T. Karhunen, I. K. Koponen, V. Niemelä, A. Lähde, J. Jokiniemi

11:50-12:10 **Occupational exposure to ultrafine particles – work place measurements**
A.-K. Viitanen, A. J. Koivisto, T. Kanerva, K. Hämeri

12:10-12:30 **The Use of Nuclepore Filter for Ambient and Workplace Nanoparticle Exposure Assessment**
Sheng-Chieh Chen, Jing Wang, Heinz Fissan, David Y.H. Pui

12:30-12:50 **Characterization and emission measurements of multi-walled carbon nanotube release during production**
L. Ludvigsson, C. Isaxon, P. T. Nilsson, M. Hedmer, H. Tinnerberg, M. E. Messing, J. Rissler, V. Skaug, A. Gudmundsson M. Bohgard, J. Pagels

Reserve paper **Particle characterization during abrasive treatment of composite material containing fibres by Cryo HRTEM**
K. I. Lieke, M. Levin, K. A. Jensen, I. K. Koponen

10:30-12:50 Session: Instrumentation

Ambient aerosol instrumentation

Chairs: Oliver Bischof, Wladyslaw Szymanski
Room: E (Tycho)

10:30-10:50 **Urban particulate matter monitoring on a mobile platform: a real time experiment on a long term scale**
B. Moroni, E. Scocchera, A. Piazzalunga, M. G. Ranalli , S. Castellini, D. Cappelletti

10:50-11:10 **A new aerosol conditioning system - Characterisation and first application**
M. Laborde, B. Rosati , P. Zieger, T. Petäjä, G. Kassell, D. Logan, E. Weingartner

11:10-11:30 **Particle number concentration monitor for atmospheric aerosols**
L. Hillemann, A. Zschoppe

11:30-11:50 **A new visual expansion-type Condensation Particle Counter**
B. Bühner, A. Wagner, A. Kürten, J. Curtius

11:50-12:10 **Development of a high volume air-into-liquid aerosol collector for PM2.5 and ultrafine particulate matter**
Dongbin Wang, Payam Pakbin, Arian Saffari, James J Schauer, Constantinos Sioutas

12:10-12:30 **Online Method for Size-Resolved Chemical Speciation of Nano-Particles**
A. Wagner, A. Kürten, C. Fuchs, J. Hoker, J. Curtius

12:30-12:50 **Development of an automated total carbon analyzer for atmospheric aerosols**
Y. Komazaki, Y. Kanaya

Reserve paper **Remotely operated PLUS-octocopter used as an aerosol measurement platform**
P. Madl, C. Oberauer, F. Steinhäusler

10:30-12:50 Special Session: PMx

Source apportionment-intercomparisons and trends

Chairs: Thomas Kuhlbusch, Willy Maenhaut
Room: F (Stella)

10:30-10:50 **European Intercomparison for Receptor Models Using a Synthetic Database**
C. A. Belis, F. Karagulian, F. Amato, M. Almeida, G. Argyropoulos, P. Artaxo, M. C. Bove , D. Cesari, D. Contini, E. Diapouli, K. Eleftheriadis, I. El Haddad, R. M. Harrison, S. Hellebust, E. Jang, H. Jorquera, D. Mooibroek, S.Nava, J. K. Nøjgaard, M. Pandolfi, M. G. Perrone, A. Pietrodangelo, G. Pirovano, P. Pokorná, P. Prati, C. Samara, D. Saraga, A. Sfetsos, G. Valli, R. Vecchi, M. Vestenius, E. Yubero, P. K. Hopke

10:50-11:10 **Ten-year study of fine aerosol at Sde Boker, Israel: time trends, seasonal variation, correlations, and source areas for anthropogenic elements**
W. Maenhaut, A. Karnieli, M. O. Andreae

11:10-11:30 **Impact of international shipping on European air quality**
M. Viana, A. Colette, J. van Aardenne, X. Querol, B. Degraeuwe, P. Hammingh, I. de Vlieger

11:30-11:50 **Hourly elemental composition and source identification of fine and coarse particulate matter in the high polluted industrial area of Taranto (Italy)**
F. Lucarelli, G. Calzolai, M. Chiari, S. Nava

11:50-12:10 **Source apportionment of size resolved particulate matter in European air pollution hot spot**
P. Pokorná, J. Hovorka, P. K. Hopke

12:10-12:30 **A mass closure and source apportionment study on PM1 in Milan (Italy)**
R. Vecchi, V. Bernardoni, M. Boretti, M. Elser, P. Fermo, A. Piazzalunga, R. Gonzalez Turrion, G. Valli

12:30-12:50 **Performance of the Chemical Mass Balance Model with Various Traffic Profiles**
Pallavi Pant, Jianxin Yin, Roy M. Harrison

Reserve paper **PMF source apportionment for fine and coarse PM in Athens, Greece: Evolution of source contributions over the last decade**
K. Eleftheriadis, E. Diapouli, A. Karanasiou, S. Vratolis, V. Vasilatou, M. Gini, D. Saraga, S. Pateraki, Th. Maggos

12:50-14:00 Lunch break

14:00-16:00 Atmospheric Aerosols

New particle formation
Chairs: Amar Hamed, Vladimír Ždímal
Room: A (Meridian)

14:00-14:20 **Role of organics in particle nucleation as viewed from a positive ion spectrometer**
F. Bianchi, J. Dommen, J. Tröstl, S. Schobesberger, H. Junninen, D. R. Worsnop, E. Weingartner, U. Baltensperger, the CLOUD collaboration

14:20-14:40 **Particle formation above natural and simulated salt lakes**
K. A. Kamilli, J. Ofner, T. Sattler, T. Krause, C. Zetzsch, A. Held

14:40-15:00 **Secondary aerosol formation from stress-induced biogenic emissions and possible climate feedbacks**
Th. F. Mentel, E. Kleist, S. Andres, M. Dal Maso, Th. Hohaus, A. Kiendler-Scharr, Y. Rudich, M. Springer, R. Tillmann, R. Uerlings, A. Wahner, J. Wildt

15:00-15:20 **Nanoparticle Growth Mechanisms During New Particle Formation**
M. V. Johnston, B. R. Bzdek, A. J. Horan, J. W. DePalma

15:20-15:40 **Comparative study of atmospheric particle formation using laboratory tools - COMPASS**
T.S. Sun, B. Bonn

15:40-16:00 **Estimating pre-existing aerosol effects on tropospheric aerosol production**
M. Dal Maso, L. Liao, H. Vehkamäki, H.Korhonen, K. E. J. Lehtinen

Reserve paper **Intercomparison of sulphuric acid measurements and neutral cluster composition in the lower free troposphere**
L. Rondo, M. Simon, H. Junninen, J. Duplisy, A. Praplan, A. Adamov, A. Kürten, M. Sipilä, F. Bianchi, J. Tröstl,E. Weingartner, U. Baltensperger, M. Kulmala, J. Curtius

14:00-16:00 Session: Aerosol Modelling

Modelling aerosols in different environments
Chairs: David Topping, Svetlana Tsyro
Room: B (Leo+Virgo)

14:00-14:20 **CFD prediction of the spatial distribution of particulate matter deposition indoors**
J. Grau-Bové , L. Mazzei , M. Strlič

14:20-14:40 **Correction of approximation errors with random forests applied to modelling of aerosol first indirect effect**
A. Lipponen, V. Kolehmainen, S. Romakkaniemi, H. Kokkola

14:40-15:00 **A simplified model to predict partitioning between the vapour and multiple condensed phases in mixed inorganic- organic aerosol particles**
D. Topping, G. McFiggans, M. Barley

15:00-15:20 **Wall losses of vapours distort yield calculations in SOA chamber experiments**
H. Kokkola, P. Yli-Pirilä, H. Korhonen, M. Vesterinen, H. Keskinen, S. Romakkaniemi, L. Hao, J. Joutsensaari, D. Worsnop, A. Virtanen, K. E. J. Lehtinen

15:20-15:40 **Development of the Secondary Organic Aerosol Processor (SOAP) model: multi-phase partitioning, non-ideality, phase separation and multi-layer representation of the semi-solid state of organic aerosols**
F. Couvidat, K. Sartelet

15:40-16:00 **Numerical studies of aerosol activation behaviour in warm clouds compared to in-situ measurements at the high-alpine site Jungfraujoch**
E. Hammer, C. R. Hoyle, B. P. Luo, M. Gysel, N. Bukowiecki, U. Lohmann, R. Vogt, C. Marcolli, T. Peter, U. Baltensperger, E. Weingartner

Reserve paper **Dependence of Aircraft Smoke Number on Black Carbon Size Distribution**
M. E. J. Stettler, J. J. Swanson, A. M. Boies

14:00-16:00 Session: Combustion Aerosols

Combustion and industrial aerosols
Chairs: A. Bologa, S. Grinshpun
Room: C (Aquarius+Taurus)

14:00-14:20 **Sulphuric Acid Aerosol Formation in Industrial Processes – Simulation and CPC measurement at a Pilot Plant**
L. Brachert, S. Sinanis, K. Schaber

14:20-14:40 **Inactivation of Aerosolized Spores in Combustion Environments Using Filled Nano-composite Materials: Study with Two Surrogates of Bacillus Anthracis**
S. A. Grinshpun, M. Yermakov, R. Indugula, X. He, T. Reponen, E. Dreizin, M. Schoenitz, S. Zhang, Y. Aly

14:40-15:00 **Size distribution and light scattering properties of standard test fire aerosols**
Zs. Jurányi, S. Lauber , A. Duric, M. Allemann, B. Schmid, M. Loepfe, H. Burtscher

15:00-15:20 **On-site estimation of secondary organic aerosol production potential from wood burning appliances**
A. Keller, J. C. Corbin, A. A. Mensah, B. Sierau, H. Burtscher

15:20-15:40 **Reference particles for toxicology studies of biomass combustion generated ash particles**
T. Torvela, O. Uski, A. Lähde, J. Grigonyte, T. Karhunen, T. Koponen, M.-R. Hirvonen, J. Jokiniemi

15:40-16:00 **Study of fine particle emissions from small scale wood chips combustion boiler**
A. Bologa, M. Ecker, H.-P. Rheinheimer, K. Woletz, H.-R. Paur

Reserve paper **Effects of severe congestion on PAH emissions from a heavy vehicle diesel engine**
M. Vojtisek-Lom, M. Pechout, M. Mazač, J. Topinka

14:00-16:00 Session: PMx

Urban and regional PMx

Chairs: Willy Maenhaut, Roberta Vecchi
Room: D (Kepler)

14:00-14:20 **EC/OC comparison exercise with same thermal protocols after temperature offsets correction**
P. Panteliadis, T. Hafkenscheid, B. Cary, W. Maenhaut

14:20-14:40 **The fossil fraction of carbon in PM2.5: Variations on seasonal and diurnal time scales**
U. Dusek, M. Monaco, A. Kappetijn, H. A. J. Meijer, S. Szidat, T. Röckmann

14:40-15:00 **Ultrafine particles at eight urban sites in Antwerp: instrument comparison and spatiotemporal variation in particle number concentration and size distribution**
J. Staelens, E. Frijns, P. Berghmans, G. P. A. Kos, C. Matheeussen, P. Panteliadis, B. Bergmans, E. P. Weijers, K. Wyche, E. Roekens

15:00-15:20 **Long term trend and weekly cycles of PM10 in the Po valley**
A. Bigi, G. Ghermandi

15:20-15:40 **Fugitive particle emissions from steel making: source characteristics and local air quality impact investigated with a mobile laboratory**
F. Drewnick, F. Freutel, S.-L. von der Weiden-Reinmüller, J. Fachinger, S. Borrmann

15:40-16:00 **Elemental composition and potential toxicity of airborne particles at some urban schools**
L. R. Crilley, G. A. Ayoko, E. Stelcer, D. D. Cohen, L. Morawaska

Reserve paper **Characterisation of the aerosol sources in Brindisi (Italy) harbour area within the CESAPO project: an overview of the experimental results**
D. Contini, D. Cesari, A. Donateo, A. Gambaro, A. Genga, G. Giovanelli, R. Giua, F.M. Grasso, E. Gregoris, P. Ielpo, S. Masieri, E. Merico, E. Morabito, A. Nocioni, T. Pastore, M. Siciliano

14:00-16:00 Session: Aerosol-based Nanotechnology

Fabrication of nanostructured materials with aerosol nanoparticles

Chairs: E. Kruis, J. Rosell-Llompart
Room: E (Tycho)

14:00-14:20 **Rapid synthesis of multi-layered & multi-functional polymer nanocomposite films**
C. O. Blattmann, G. A. Sotiriou, S. E. Pratsinis

14:20-14:40 **Electrostatic charging during electrospray deposition of polymer granular coatings**
E. Bodnár , N. Sochorakis , J. Grifoll , J. Rosell-Llompart

14:40-15:00 **Towards deposition of single layer graphene by an electrospray ion-assisted method**
L. B. Modesto-Lopez, O. V. Bilousov, J. M. Serres, J. Rosell-Llompart, J. J. Carvajal, F. Díaz

15:00-15:20 **Large-Area Patterning of Three-dimensional Nanoparticle Structure Arrays via Ion Assisted Aerosol Lithography (IAAL) and Multi-tip Spark Discharge**
K.-Y. Ha, H.-S. Choi, K.-N. Jung, K.-H. Han, J.-K. Lee, M. Choi

15:20-15:40 **Silver-decorated silica nanoparticles in a multilayered plasmonic structure**
J. Harra, M. Zdanowicz, M. Virkki, A. Rantamäki, M. Honkanen, G. Genty, M. Kauranen, J. M. Mäkelä

15:40-16:00 **Aerosol synthesis of semiconductor nanowires**
M. Heurlin, M. H. Magnusson, D. Lindgren, M. Ek, L. R. Wallenberg, L. Samuelson, K. Deppert

Reserve paper **Dry deposition of electrosprayed liquid suspensions**
S. Martin. B. Martinez-Vazquez, P. L. Garcia-Ybarra, J. L. Castillo

16:00-16:30 Coffee break
Room: Conference foyer

16:00-18:00 Poster Session B - authors' presentations

Wednesday, September 4th

8:45-9:45 **Plenary lecture: The Dynamics of Indoor Aerosol: what is important, where, when and why?**
Plenary speaker: Lidia Morawska
Plenary chairs: Mihalis Lazaridis, Erik Swietlicki
Room: A (Meridian)

9:45-10:00 **Smoluchowski Award**
Room: A (Meridian)

10:00-10:30 **Coffee break**
Room: Conference foyer

10:30-12:50 **Session: Atmospheric Aerosols**
Physico-chemical properties and transport
Chairs: J. Ström, E. Weingartner
Room: A (Meridian)

10:30-10:50 **Unmanned Aircraft Aerosol Sampling: Improvements in Capabilities and Sample Analyses**
C. F. Cahill, G. W. Walker, T. A. Cahill. C. R. Iceman, D. E. Barnes

10:50-11:10 **Aerosol mass spectrometry on a Zeppelin NT in the planetary boundary layer**
F. Rubach, A. Trimborn T. F. Mentel, A. Wahner, PEGASOS 0 Zeppelin Team

11:10-11:30 **Classification of aerosol size distributions observed at a tropical high altitude station**
T. Hamburger, M. Matisans, J. Ström, P. Tunved, G. Hoschild, J. Gross, S. Calderon, P. Hoffmann, T. Schmeissner, R. Krejci,

11:30-11:50 **Chemical composition (ions and selected metals) of size-segregated aerosol samples collected at Ny Alesund (Svalbard Island - Norway) during the 2010 and 2011 summer campaigns**
S. Becagli, M. Busetto, G. Calzolai, D. Cappelletti, D. Frosini, F. Lucarelli, A. Lupi, M. Mazzola, B. Moroni, S. Nava, M. Severi, R. Traversi, A. Viola, V. Vitale, R. Udisti

11:50-12:10 **Sub-micrometer non-refractory aerosol composition and their sources at Welgegund in the southern African grassland region**
P. Tiitta, V. Vakkari, M. Josipovic, P. Croteau, P. Beukes, P. Van Zyl, A. Venter, K. Jaars, J. Pienaar, S. Ng, M. Canagaratna, J. Jayne, V. Kerminen, M. Kulmala, A. Laaksonen, J. Jokiniemi, D. Worsnop, L. Laakso

12:10-12:30 **Chemical composition of the 300°C refractory fraction of the atmospheric aerosol at the Central European station Melpitz, Germany/Leibniz Institute for Tropospheric Research**
L. Poulain, W. Birmili, F. Canonaco, M. Crippa, Z. J. Wu, S. Nordmann, G. Spindler, A. S. H. Prévôt, A. Wiedensohler, H. Herrmann

12:30-12:50 **Seasonal and spatial variation of PM1 organic tracers in densely populated Mediterranean urban areas: Barcelona vs. Madrid**
B. L. van Drooge, M. Fontal, N. Bravo, P. Fernandez, M. A. Fernández, J. Muñoz-Arnanz, B. Jiménez, J. O. Grimalt

Reserve paper **Winter particulate matter (PM10) sources for an Austrian-Slovenian border region**
M. Kistler, E. C. Cetintas, H. Bauer, A. Kasper-Giebl

10:30-12:50 Session: Atmospheric Aerosols

Urban aerosols-from particle counts to chemical compostion
Chairs: Gary Fuller, Thomas Kuhlbusch
Room: B (Leo+Virgo)

10:30-10:50 **Nanoparticle emissions from road vehicles in Asian and European cities and allied health implications**
Prashant Kumar, Roy M. Harrison,

10:50-11:10 **Long-term Variations of Particle Sources in Beijing, China**
J. Gu, S. Breitner, A. Schneider, M. Hu, Z. J. Wu, Z. B. Wang, A. Wiedensohler, B. Wehner, U. Franck, J. Soentgen, A. Peters, J. Cyrys

11:10-11:30 **Road tunnels - particle properties, wet and dry conditions**
S. Janhall, M. Gustafsson, S. Abbasi, G. Blomqvist, A. Gudmundsson, C. Johansson, M. Norman, U. Olofsson, B. Sjovall

11:30-11:50 **Particle Number Size Distribution Statistics at Urban and Suburban Background and Remote Sites in Greece during Summer**
S. Vratolis, M. Gini, D. Siakavaras, S. Bezantakos, I. Stavroulas, N. Kalivitis, E. Kostenidou, E. Louvaris, G. Biskos, N. Mihalopoulos, S. Pandis, C. Pilinis, K. Eleftheriadis

11:50-12:10 **Highly time- and size-resolved measurements of trace elements in London during ClearfLo**
S. Visser, M. Furger, U. Flechsig, K. Appel, R. Dressler, P. Zotter, J. G. Slowik, A. S. H. Prevot, U. Baltensperger

12:10-12:30 **Exposure of schoolchildren to traffic-related air pollution: the HEAPS study**
Martine Van Poppel, Evi Dons, Luc Int Panis, S. De Prins, G. Koppen, Christina Matheeussen, Patrick Berghmans

12:30-12:50 **Aerosol particles from smoking, cooking, and various pyrotechnical devices: laboratory characterization and detection in a football stadium**
P. Faber, F. Drewnick, S. Borrmann

Reserve paper **Exposure of air pollutants inside vehicles while driving in road tunnels**
S. Silvergren, M. Norman, C. Johansson, B. Sjövall

10:30-12:50 Session: Aerosol Modelling

Modelling atmospheric aerosols
Chairs: Risto Makkonen, Ari Asmi
Room: C (Aquarius+Taurus)

10:30-10:50 **Linking climate change and air quality over Europe: Effects on aerosol concentrations**
A. G. Megaritis, C. Fountoukis, S. N. Pandis

10:50-11:10 **Particle Number Concentrations over Europe in 2030: The Role of Emissions and New Particle Formation**
L. Ahlm, J. Julin, C. Fountoukis, S. N. Pandis, I. Riipinen

11:10-11:30 **Predictions of aerosol extinction coefficients over Greece by means of a new modular software system**
P. E. Charalampidis Haralabidis, C. Pilinis , C. Fountoukis, A. Panagiotopoulou, S. N. Pandis

11:30-11:50 **Mitigation of Arctic warming by controlling European black carbon emissions (MACEB): modelling results**
J.-P. Pietikäinen, K. Kupiainen, Z. Klimont, A.-P. Hyvärinen, A. Laaksonen, H. Lihavainen

11:50-12:10 **Modeling biogenic secondary organic aerosol formation in the subarctic**
E. Hermansson, P. Roldin, A. Rusanen, D. Mogensen, S. Madronich, A. Hodzic, E. Swietlicki, M. Boy

12:10-12:30 **Taking the step from bulk to size-segregated aerosol description: Modelling of size distributions with the EMEP/MSC-W model**
M. Karl, S. Tsyro

12:30-12:50 **Contribution of primary emissions, secondary organic aerosol and nucleation on global aerosol number concentrations in NorESM**
R. Makkonen, Ø. Seland, A. Kirkevåg, T. Iversen, J. E. Kristjánsson

Reserve paper **Climate and biofuels in Brazil**
H. Vuollekoski, R. Makkonen, A. Asmi, R. Hillamo, T. Petäjä, M. Kulmala

10:30-12:50 Session: Indoor and Working Place Aerosols

Chemistry / Instrumentation
Chairs: Mihalis Lazaridis, Philip Hopke
Room: D (Kepler)

10:30-10:50 **The Effects of Mainstream and Sidestream Environmental Tobacco Smoke Composition for Enhanced Condensational Droplet Growth by Water Vapor**
X. Tang, Z. Zheng, H. S. Jung, A. Asa-Awuku

10:50-11:10 **A study on SVOC aerosol evaporation and its possible implications on workplace sampling**
G. C. Dragan, E. Karg, D. Breuer, M. Blaskowitz, H. Nordsieck, J. Schnelle-Kreis, R. Zimmermann

11:10-11:30 **Household products and indoor air quality: emission, reactivity and by-products in both gaseous and particulate phases**
A. Même, M. Nicolas, L. Chiappini, C. Rio, J. Nicolle, S. Rossignol, B. D'Anna

11:30-11:50 **Personal monitor for engineered nanoparticles using a MEMS cantilever balance**
S. Merzsch, H. S. Wasisto, I. Kirsch, A. Waag, E. Peiner, E. Uhde

11:50-12:10 **Test of indoor air cleaners**
B. Mølgaard, A. J. Koivisto, T. Hussein, K. Hämeri

12:10-12:30 **Use of portable particle counters for the assessment of residential exposure to indoor-generated particles**
A. Wierzbicka, G. Bekö, J. Toftum, G. Clausen

12:30-12:50 **Chemical composition of hookah smoke derived aerosol measured with an Aerosol Chemical Speciation Monitor**
P. L. Croteau, J. T. Jayne, D. R. Worsnop, T. Oh, C. DeForest Hauser

Reserve paper **An experimental approach to measure particle deposition in large circular ventilation ducts**
G. Da, E. Géhin, M. Ben-Othmane, M. Havet, C. Solliec, C. Motzkus

10:30-12:50 Session: Aerosol-based Nanotechnology

Nanoparticle synthesis in the gas phase

Chairs: A. Schmidt-Ott, S. Pratsinis
Room: E (Tycho)

10:30-10:50 **"Anti-agglomeration of spark discharge generated aerosols via unipolar air ions"**
Kyu-Tae Park, Massoud Massoudi Farid, Jungho Hwang

10:50-11:10 **A Controlled Spark Generator for Increased Nanoparticle Production**
T. V. Pfeiffer, P. Keijzer, A. Schmidt-Ott

11:10-11:30 **Experimental study on the transition from spark to arc discharge with respect to nanoparticle production**
E. Hontanon, J. M. Palomares, M. Stein, X. Guo, R. Engeln, H. Nirschl, F. E. Kruis

11:30-11:50 **Enclosed Flame Spray Pyrolysis: Control of Product Particle Characteristics by the Air Entrainment**
O. Waser, S. E. Pratsinis

11:50-12:10 **Flame spray synthesis of amorphous Indium-Zinc Oxide (IZO) nanoparticles and their electrical and optical properties - towards an application in field effect transistors**
D. Kilian, S. Polster, M.P.M. Jank, L. Frey, W. Peukert

12:10-12:30 **Parametric study of iron and iron-oxide nanoparticle synthesis via Aerosol Spray Pyrolysis**
G. Kastrinaki, S. Lorentzou, G. Karagiannakis, A. G. Konstandopoulos

12:30-12:50 **Aerosol synthesis of silicon germanium hybrid and alloy nanoparticles**
C. Mehringer, B. Butz, E. Spiecker, W. Peukert

Reserve paper **Synthesis of tailored organic-inorganic nanostructures by charge controlled coagulation**
S. Sigmund, E. Akgün, J. Meyer, M. Wörner, G. Kasper

10:30-12:50 Special Session: Particle-Lung Interactions

Bioaerosols and health

Chairs: Jeroen Buters, Otto Hanninen
Room: F (Stella)

10:30-10:50 **Daily values of bio-aerosols relevant in allergy: the biological exposome**
J. T. M. Buters, I. Weichenmeier, G. Pusch, E. Bartusel, D. Kupresanin, H. Behrendt, C. Schmidt-Weber

10:50-11:10 **Association of fungal tracers with biomass burning activity in northern Vietnam**
S. H. Chen, G. Engling

11:10-11:30 **Airborne influenza virus survival in the air environment**
O. Pyankov, O. Pyankova, E. V. Usachev, I. E. Agranovski

11:30-11:50 **Toxicological effects of the particulate emissions from diesel engines and wood combustion are affected by used technology**
P. I. Jalava, M. S. Happo, T. Brunner, I. Obernberger, T. Murtonen, P. Aakko-Saksa, J. Maki-Paakkanen, J. Jokiniemi, M.-R. Hirvonen

11:50-12:10 **Long-term effects of repeated exposure to fine and ultrafine particles on lung epithelial cells and fibroblasts**
L. Boublil, M. C. Borot, L. Martinon, J. Sciare, A. Baeza-Squiban

12:10-12:30 **Exposure and harm to combustion-derived particles: searching for biomarkers**
K. A. BeruBe, I. A. Guschina, A. J. Wlodarcyzk, Z. Prytherch, T. Jones, E. Karg, O. Sippula

12:30-12:50 **Studying the causes of health effects of combustion-derived aerosol in the framework of the HICE-Virtual Helmholtz Institute: First results on ship diesel and wood combustion aerosols**
R. Zimmermann, T. G. Dittmar, T. Kanashova, J. Buters, S. Öder, H. Paur, C. Schlager, S. Mülhopt, M. Dilger, C. Weiß, S. Diabate, H. Harndorf, B. Stengel, R. Rabe, K. Hiller, S. C. Sapccariu, K. A. BeruBe, A. J. Wlodarcyzk, O. Sippula, B. Michalke, T. Krebs, M. Kelbg, J. Tiggesbäumker, T. Streibel, E. Karg, S. Scholtes, J. Schnelle-Kreis, J. Lintelmann, M. Sklorz, M. Arteaga Salas, S. Klingbeil, J. Orasche, P. Richthammer, L. Müller, M. Elsasser, A. Rheda, B. Werner, J. Passig, T. Gröger, G. Abbaszade, C. Radischat

Reserve paper **Aerosol Deposition Measurement in the Model of Human Lungs**
F. Lizal, J. Jedelsky, J. Adam, M. Belka, M. Jicha

12:50-14:00 Lunch break

14:00 Free afternoon

Thursday, September 5th

9:00-10:00 **Plenary lecture: Nucleation of vapours-molecular content of critical clusters and activation of nanoparticles**

Plenary speaker: Paul E. Wagner

Plenary chairs: Ian Ford, Vladimír Ždímal

Room: A (Meridian)

10:00-10:30 Coffee break

Room: Conference foyer

10:30-10:50 **Session: Atmospheric Aerosols**

Aerosol cloud interaction

Chairs: Martin Gysel, Martina Krämer

Room: A (Meridian)

10:30-10:50 **Evaporation and condensation of semivolatile aerosol compounds in the DMT-CCN counter**
S. Romakkaniemi, A. Jaatinen, A. Laaksonen, A. Nenes, T. Raatikainen

10:50-11:10 **Long-term hygroscopic properties of ambient aerosol in a boreal environment, as measured by the size-resolved Cloud Condensation Nuclei counter (CCNc)**
M. Paramonov, M. Äijälä, P. P. Aalto, A. Asmi, N. Prisle, V.-M. Kerminen, M. Kulmala, T. Petäjä

11:10-11:30 **Mass spectrometric analysis of cloud droplet residuals in different orographic clouds**
J. Schneider, S. Mertes

11:30-11:50 **What controls cloud droplet number concentration of trade wind cumuli?**
F. Ditas, B. Wehner, H. Siebert, T. Schmeißner, M. Simmel, H. Wex, A. Wiedensohler

11:50-12:10 **Size-dependent aerosol activation properties measured in radiation and stratus lowering fog during the ParisFog 2012/13 field campaign**
E. Hammer, J. Hofer, M. Gysel, G. Roberts, N. Bukowiecki, J. C. Dupont, F. Burnet, M. Haeffelin, U. Baltensperger, E. Weingartner

12:10-12:30 **Assessment of cloud maximum supersaturation by size-resolved CCN measurements**
M. Krüger, D. Rose, Y. Cheng, H. Su, C. Pöhlker, J. Schneider, S. Schmidt, T. Klimach, S. Mertes, M. O. Andreae, U. Pöschl

12:30-12:50 **Comprehensive Investigations on the Ice Nucleation Efficiency of Natural Soil Dust Samples**
K. Höhler, I. Steinke, D. Cziczo, A. Danielczok, F. Frank, S. Garimella, O. Möhler, M. Raddatz, M. Schnaiter, O. Stetzer, E. Toprak

Reserve paper **Effect of local pollutant sources on aerosol-cloud interactions at Puijo measurement station**
H. Portin, A. Leskinen, A. Kortelainen, L. Hao, P. Miettinen, A. Jaatinen, S. Romakkaniemi, A. Laaksonen, K. E. J. Lehtinen, M. Komppula

10:30-10:50 Session: Atmospheric Aerosols

Turbulent exchange, transport and transformation

Chairs: Andreas Held, Birgit Wehner
Room: B (Leo+Virgo)

10:30-10:50 **Natural surfactants promote the uptake of soot-particles in aerosols**
T. Hede, C. Leck , L. Sun, Y. Tu, H. Ågren

10:50-11:10 **Annual cycle of Background Aerosol at Troll Station, Antarctica**
M. Fiebig, D. Hirdman, C. R. Lunder, J. A. Ogren, A. Stohl

11:10-11:30 **Monitoring ship emissions with continuous onshore SMPS measurements**
N. Kivekäs, R. Lange, A. Massling, Q. T. Nguyen M. Glasius, A. Kristensson

11:30-11:50 **Analysis of particle size distribution changes between three measurement sites in Northern Scandinavia**
R. Väänänen, E.-M. Kyrö, T. Nieminen, N. Kivekäs, H. Junninen, A. Virkkula, M. Dal Maso, H. Lihavainen, Y. Viisanen, B. Svenningsson, T. Holst, A. Arneth, P. P. Aalto, M. Kulmala, V.-M. Kerminen

11:50-12:10 **Airborne measurements of aerosol particle physical, optical and chemical properties in Finland**
E. Asmi, D. Brus, S. Carbone, R. Hillamo, J. Hatakka, T. Laurila, H. Lihavainen, E. Rouhe, S. Saarikoski, Y. Viisanen

12:10-12:30 **Annual measurement of size resolved particle fluxes in an urban environment**
M. J. Deventer, O. Klemm, F. Grießbaum

12:30-12:50 **New methods to quantify the contributions of rainout, washout and dry deposition to the total deposition flux of atmospheric aerosol on horizontal urban surfaces**
P. Laguionie, D. Maro, P. Roupsard, S. Percot, L. Solier, V. Ruban, M. Rozet, D. Hébert, O. Connan

Reserve paper **Air mass back trajectories and dry atmospheric aerosol mass size distributions in Prague**
J. Schwarz, L. Štefancová, W. Maenhaut, J. Smolík, V. Ždímal

10:30-10:50 Session: Combustion Aerosols

Engines related emissions

Chairs: J. Pagels, T. Rönkkö
Room: C (Aquarius+Taurus)

10:30-10:50 **Oxidation reactivity of (bio)diesel generated soot**
H. Bladt, N. P. Ivleva, R. Niessner

10:50-11:10 **Can scooter emissions dominate urban organic aerosol?**
I. El Haddad, S. M. Platt, A. A. Zardini, J. G. Slowik, M. Clairotte, C. Astorga, P. Barmet, R. Chirico, J. Dommen, U. Baltensperger, A. S. H. Prévôt

11:10-11:30 **Transformation of Black Carbon Aerosol in the Atmosphere – Observations from Smog Chamber Studies and Ambient Air**
J. H. Pagels, A. C. Eriksson, J. Rissler, E. Z. Nordin, C. Wittbom, P. T. Nilsson, A. Kristensson, P. Roldin, B. Svenningsson, E. Swietlicki

11:30-11:50 **Effect of atmospheric ageing on volatility and ROS of biodiesel exhaust nano-particles**
Alimohammad Pourkhesalian

11:50-12:10 **Real-world nanoparticle emissions of passenger cars and heavy duty diesel vehicles**
T. Rönkkö, L. Pirjola, P. Karjalainen, S. Saari, J. Keskinen

12:10-12:30 **Chemical composition of particulate and gas emissions from a 4-stroke marine diesel engine operated with heavy and distillate fuel oils**
O. Sippula, B. Stengel, M. Sklorz, T. Streibel, R. Rabe, H. Harndorf, J. Orasche, J. Lintelmann, B. Michalke, G. Abbaszade, C. Radischat, J. Schnelle-Kreis, R. Zimmermann

12:30-12:50 **Effects of secondary organic aerosols from gasoline exhaust on healthy and diseased respiratory epithelia**
M. Krapf, L. Künzi, N. Daher, J. Dommen, S. Schneider, N. Jeannet, S. Platt, J. G. Slowik, A. S. H. Prévôt, M. Kalberer, C. Sioutas, U. Baltensperger, M. Geiser

Reserve paper **Characterisation of solid and semi-volatile gas-turbine particulate matter using a catalytic stripper**
J. J. Swanson, T. J. Johnson, J. S. Olfert, M. P. Johnson, P. I. Williams, G. J. Smallwood, A. M. Boies

10:30-10:50 Session: Electrical Effects

Electrical effects
Chairs: Andrei Bologa, Caner Yurteri
Room: D (Kepler)

10:30-10:50 **Effects of induced gas flow on electrospray dynamics**
A. K. Arumugham, Jordi Grifoll, Joan Rosell-Llompart

10:50-11:10 **Reduction of fine particle emissions from small scale wood chips combustion boiler by use of compact electrostatic precipitator**
A. Bologa, M. Ecker, H.-P. Rheinheimer, K. Woletz, H.-R. Paur

11:10-11:30 **The formation of solid charged aerosol particles at the destruction of metal bodies and bodies of other materials**
A. B. Vatazhin, D. A. Golentsov, V. A. Likhter

11:30-11:50 **Generation of negative ion mobility standards using tetra-alkyl ammonium halide salts**
G. Steiner, J. Kangasluoma, M. Breitenlechner, E. Canaval, M. Sipilä, A. Hansel, M. Kulmala

11:50-12:10 **A New Effective Unipolar Charger for Calibration and Validation of Commercial Particle Number Measurement Systems**
B. Grob, R. Niessner

12:10-12:30 **The Unipolar Charging Rate and Bipolar Charge Distribution for Nonspherical Particles**
Ranganathan Gopalakrishnan, Christopher J. Hogan Jr.

12:30-12:50 **Bipolar diffusion charging of aerosol nanoparticles by means of AC-corona discharge and soft X-ray devices**
P. Kallinger, W. W. Szymanski

Reserve paper **Diurnal variation of small and large ion concentrations in an urban location**
E. R. Jayaratne, X. Ling, L. Morawska

10:30-10:50 Session: Fundamentals

Nucleation theory and experiments
Chairs: Paul M. Wikler, Yannis Drossinos
Room: E (Tycho)

10:30-10:50 **Nucleation in the Presence of Background Aerosol**
Charles Clement

10:50-11:10 **Numerical Investigation of the Effect of Hydrodynamic Mixing on Droplet Nucleation and Growth**
A. O. Alshaarawi, G. Scribano, K. Zhou, A. Attili, F. Bisetti

11:10-11:30 **Effect of Surface Energy Evolution on Particle Nucleation under GASP Conditions**
D. E. Rosner, M. Arias-Zugasti

11:30-11:50 **A heterogeneous nucleation theory with explicit account of vapor adsorption**
A. Laaksonen

11:50-12:10 **Heterogeneous Nucleation on Nanometer and Sub-Nanometer Sized Charged Atomic Clusters**
K. Barmpounis, A. Maisser, M. B. Attoui, G. Biskos, A. Schmidt-Ott

12:10-12:30 **Heterogeneous nucleation of sulfur vapor on tungsten oxide and NaCl nanoparticles: Determination of the radius and the contact angle of critical nucleus**
S. V. Valiulin, V. V. Karasev, S. V. Vosel, A. A. Onischuk, A. M. Baklanov

12:30-12:50 **A 19m deep well – a downward thermal diffusion cloud chamber?**
R. F. Holub, P. K. Hopke, J. Hovorka, P. Otahal, V. Ždímal

Reserve paper **Free energy barrier in the growth of sulfuric acid clusters**
T. Olenius, O. Kupiainen, I. K. Ortega, H. Vehkamäki

12:50-14:00 Lunch break

14:00-16:00 # Session: Aerosol Chemistry

Heterogeneous chemistry of aerosol
Chairs: Manabu Shiraiwa, Barbara D'Anna
Room: B (Leo+Virgo)

14:00-14:20 **Heterogeneous reaction of sulphur dioxide on Eyjafjallajökull's volcanic ash from the 2010 eruption**
Yoan Dupart, Laurence Burel, Pierre Delichere, Christian Geoage, Barbara D'Anna

14:20-14:40 **Estimating amorphous deliquescence time scales of SOA from biogenic and anthropogenic precursors: Implications for heterogeneous ice nucleation on glassy aerosols.**
T. Berkemeier, M. Shiraiwa, U. Pöschl, T. Koop

14:40-15:00 **Surfactants in cloud activation: do they matter?**
B. Mølgaard, J. Hong, M. Paramonov, T. Yli-Juuti, N. L. Prisle

15:00-15:20 **Gas-particle partitioning of atmospheric aerosols: Interplay of physical state, non-ideal mixing and morphology**
Manabu Shiraiwa, Andreas Zuend, Allan K. Bertram, John H. Seinfeld

15:20-15:40 **Role of organic and inorganic salts in atmospheric nanoparticle growth: a modelling study**
T. Yli-Juuti, K. Barsanti, L. Hildebrandt Ruiz, A.-J. Kieloaho, U. Makkonen, T. Petäjä, T. Ruuskanen, M. Kulmala, I. Riipinen

15:40-16:00 **Secondary organic aerosol production potential from diesel and gasoline vehicle exhaust under different ambient conditions**
S. M. Pieber, S. M. Platt, I. El Haddad, A. A. Zardini, R. Suarez-Bertoa, J. G. Slowik, R. Huang, S. Hellebust, B. Temime-roussel, N. Marchand, L. Drinovec, G. Mocnik, U. Baltensperger, C. Astorga, A. S. H. Prévôt

Reserve paper **Uptake of N2O5 to citric acid aerosol particles**
G. Gržinić, T. Bartels-Rausch, A. Türler, M. Ammann

14:00-16:00 Session: PMx

Source-specific emissions of carbonaceous aerosol from combustion processes

Chairs: Willy Maenhaut, Heinz Burtscher
Room: C (Aquarius+Taurus)

14:00-14:20 **Thermal/Optical Analysis of Major Elements (C, H, N, S, and O) for Particles from Different Emission Sources**
X. L. Wang, J. A. Robles, X. F. Yang, L.-W. A. Chen, J. C. Chow, J. G. Watson

14:20-14:40 **Assessing the Wintertime Contribution of Biomass Smoke to Organic Aerosol at 15 Sites in Switzerland by Analysing Filter Samples Using Aerosol Mass Spectrometry**
K. R. Dällenbach, I. El-Haddad, P. Zotter, J. Slowik, F. Canonaco, V. G. Ciobanu, A. Piazzalunga, P. Fermo, U. Baltensperger, S. Szidat, A. S. H. Prévôt

14:40-15:00 **Carbonaceous Aerosols Emitted from Light-Duty Vehicles Operating on Ethanol Fuel Blends**
M. D. Hays, R. Baldauf, B. J. George, J. Schmid, R. Snow, T. Long, W. Preston

15:00-15:20 **Emissions of a GDI vehicle operating with different composition engine oils**
L. Pirjola, T. Lähde, A. Malinen, J. Heikkilä, P. Karjalainen, T. Rönkkö, K. Kulmala, J. Keskinen

15:20-15:40 **Biodiesel with controlled physicochemical properties, a means to further reduce diesel engine particle emissions**
M. M. Rahman, A. M. Pourkhesalian, S. Stevanovic, M. J. Islam, H. Wang, B. Miljevic, P. Phamxuan, R. J. Brown, A. Masri, Z. D. Ristovski

15:40-16:00 **Preliminary measurement results on aerosol emission from materials combustion**
M. Targosz, C. Chivas-Joly, L. Saragoza, C. Motzkus, F. Gaie-Levrel

Reserve paper **Atmospheric tar balls: primary droplets from biomass burning?**
Á. Tóth, A. Hoffer, I. Nyírő-Kósa, M. Pósfai, A. Gelencsér

14:00-16:00 Session: Particle-Lung Interactions

Exposure and dosimetry

Chairs: Werner Hofmann, George Ferron
Room: F (Stella)

14:00-14:20 **Hygroscopic Particle Deposition Model for Rat Lungs**
G. A. Ferron, S. Upadhyay, R. Zimmermann, E. Karg

14:20-14:40 **Uptake of PM2.5 mass by respiratory tract region and particle size: Hypothetical estimates for the FINRISK Cohort, Helsinki, Finland**
O. Hänninen, R. Sorjamaa, P. Lipponen, L. Kangas, A. Karppinen, T. Yli-Tuomi

14:40-15:00 **Exposure to Particulate Matter and Pulmonary Function Status of Traffic wardens in Two Selected Local Government Areas in South-Western Nigeria**
Godson R.E.E Ana, Oluseye J. Olamijulo

15:00-15:20 **Dynamics of highly concentrated, fresh aerosols during inhalation**
L. Pichelstorfer, W. Hofmann

15:20-15:40 **Mechanistic exposure assessment of ultrafine PM**
D. A. Sarigiannis, Z. Samaras, E. Vouitsis, S. Karakitsios, V. Kalaitzis

15:40-16:00 **Using cloud motion for fast, efficient and realistic in vitro delivery of inhaled drugs to pulmonary cells**
A. G. Lenz, D. Cei, M. Schmidmeir, N. Pfister, G. Burgstaller, B. Lentner, O. Eickelberg, T. Stoeger, S. Meiners, O. Schmid

Reserve paper **Release of fine particles from birch pollen grains following impaction**
N. Visez, M. Choël, G. Loubert, G. Chassard, D. Petitprez

14:00-16:00 Special Session: Combustion Aerosols

Composition and health effects
Chairs: Ralf Zimmermann, Olli Sippula
Room: D (Kepler)

14:00-14:20 **Chemical Properties of Combustion Aerosols: An Overview**
M. D. Hays

14:20-14:40 **Chemical, physical and toxicological properties of biomass combustion aerosols**
M-R. Hirvonen, J. Jokiniemi

14:40-15:00 **Biological effects of ship diesel exposure on human bronchial epithelial cells – effects of gas phase vs. particle phase of different fuels at the air liquid interface**
S. Oeder, O. Sippula, B. Stengel, R. Rabe, H. Harndorf, H. Paur, C. Schlager, E. Karg, T. Streibel, C. Schmidt-Weber, R. Zimmermann, J. T. M. Buters

15:00-15:20 **Health relevant compounds in wood combustion and ship diesel aerosols: Evaluation of the toxicity due to polycyclic aromatic hydrocarbons**
J. Orasche, T. G. Dittmar, T. Kanashova, J. Buters, S. Öder, H. Paur, C. Schlager, S. Mülhopt, M. Dilger, C. Weiß, S. Diabate, H. Harndorf, B. Stengel, R. Rabe, K. Hiller, S. C. Sapccariu, K. A. BeruBe, A. J. Wlodarcyzk, O. Sippula, J. Jokiniemi, M.-R. Hirvonen, B. Michalke, T. Krebs, M. Kelbg, J. Tiggesbäumker, T. Streibel, E. Karg, G. Abbaszade, S. Scholtes, J. Schnelle-Kreis, J. Lintelmann, M. Sklorz, M. Arteaga Salas, S. Klingbeil, P. Richthammer, L. Müller, M. Elsasser, A. Rheda, B. Werner, J. Passig, T. Gröger, C. Radischat, R. Zimmermann

15:20-15:40 **Air-liquid interface exposure systems for the assessment of toxicity of combustion aerosols**
H.-R. Paur, S. Mülhopt, M. Dilger, C. Schlager, T. Krebs, R. Zimmermann, S. Diabaté, C. Weiss

15:40-16:00 **Oxidative potential of particulate matter in a major urban environment**
Frank J. Kelly, Ben Barratt, Cathryn Tonne, Ian Mudway

Reserve paper **A novel set-up for source characterization and human exposures of biomass combustion aerosols**
R. Nyström, E. Z. Nordin, J. H. Pagels, A. Blomberg, T. Sandström, C. Boman

14:00-16:00 Session: Atmospheric Aerosols

Biomass burning and bioaerosols
Chairs: J. Schneider, M.R. Alfarra
Room: A (Meridian)

14:00-14:20 **Particle characterisation during biomass burning events in Tasmania, Australia**
F. Reisen, C. P. Meyer, M. D. Keywood, S. Crumeyrolle

14:20-14:40 **Biomass burning layers measured during the Deep Convective Clouds and Chemistry experiment (DC3) with an airborne Single Particle Soot Photometer (SP2)**
K. Heimerl, B. Weinzierl, A. Minikin, D. Sauer, D. Fütterer, M. Lichtenstern, H. Schlager, J. P. Schwarz, M. Z. Markovic, A. E. Perring, D. W. Fahey, H. Huntrieser

14:40-15:00 **Airborne lidar observations of mineral dust and biomass burning aerosols**
F. Marenco, K. Turnbull, B. Johnson, J. Haywood, P. Rosenberg, L. Garcia-Carreras, J. B. McQuaid, V. Amiridis, E. Marinou, A. Tsekeri

15:00-15:20 **Primary particles and marker compounds from wood combustion in household stoves**
M. Maasikmets, , E. Teinemaa, K. Vainumäe, L. Parts, L. Lehes, T. Arumäe, V. Kimmel

15:20-15:40 **The comparison of long-term changes in the bioerosol components in Southwestern Siberia in the near-ground atmospheric layer and at the altitudes of 500 - 7000 m**
A. S. Safatov, G. A. Buryak, V. A. Vechkanov, I. S. Andreeva, S. T. Olkin, I. K. Reznikova, V. M. Generalov, M. Yu. Arshinov, B. D. Belan, D. V. Simonenkov, G. N. Tolmachev

15:40-16:00 **Filtration and inactivation of aerosolized bacteriophage MS2 with air ions and electric field**
J. Hyun, Y.-H. Joe, J. Hwang

Reserve paper **Measurements During The South American Biomass Burning Analysis (SAMBBA) Field Experiment**
J. D. Allan, W. T. Morgan, P. I. Williams, M. Flynn, E. Darbyshire, A. Hodgson, B. T. Johnson, J. M. Haywood, S. Freitas, K. Longo, P. Artaxo, H. Coe

14:00-16:00 Special Session: Aerosol Modelling, Atmospheric Aerosols

European Year of Air Quality 2013
Chairs: Alexander Schladitz, Markus Pesch, Sabine Wurzler
Room: E (Tycho)

14:00-14:20 **Experimental and modeling analyses of emission measurements for a heavy-duty diesel bus: the comparison between on-road and in-lab methods**
Y. J. Wang, Z. Tong, T. Rönkkö, J. Keskinen, L. Pirjola, K. M. Zhang

14:20-14:40 **Source apportionment of sub-micron particles in the urban background by Positive Matrix Factorization**
H. Yu, U. Quass, H. Kaminski, T. A. J. Kuhlbusch

14:40-15:00 **Air quality in a Mediterranean city-port: Particulate matter source apportionment using the WRF-CAMx modeling system**
A. Poupkou, N. Liora, A. Karagiannidis, T. Giannaros, D. Melas, A. Argiriou

15:00-15:20 **Size specific distribution of the atmospheric particulate persistent organic pollutants (POPs) on a seasonal scale**
Céline Degrendele, Krzysztof Okonski, Lisa Melymuk, Linda Landlová, Petr Kukučka, Jana Klánová

15:20-15:40 **Modelling multiphase night-time processes with WRF-Chem**
D. Lowe , S. Archer-Nicholls , W. Morgan , S. Utembe , G. McFiggans

15:40-16:00 **Air quality modeling of mega cities in Yangtze River Delta region**
L. L. Tang, B. Zhu, Y. J. Zhang, L. Tang

Reserve paper **Characterising the influence of anthropogenic emissions on regional background aerosols at the puy de Dome station in France**
E. J. Freney, E. Asmi, M. Hervo, C. Rose, A. Colomb, K. Sellegri

16:00-16:30 Coffee break
Room: Conference foyer

16:00-18:00 Poster Session C - authors' presentations

19:30 Conference Dinner
Venue: Municipal House

Friday, September 6th

9:00-10:00 **Plenary lecture: Urban aerosol: tendencies and challenges**

Plenary speaker: Imre Salma

Plenary chairs: Willy Maenhaut, Kostas Eleftheriadis

Room: A (Meridian)

10:00-10:30 Coffee break

Room: Conference foyer

10:30-12:50 **Session: Atmospheric Aerosols**

Aerosol-cloud interaction and climate effects of aerosols

Chairs: Helmut Horvath, Martin Gysel

Room: A (Meridian)

10:30-10:50 **Simplifying the water-affinity and CCN activation of complex organic aerosols: A model study**
I. Riipinen, N. Rastak, S. N. Pandis

10:50-11:10 **Marine Cloud Brightening - do implementation assumptions change its effectiveness?**
A. K. L. Jenkins, P. M. Forster

11:10-11:30 **The importance of organic compounds for the first aerosol indirect effect: sensitivity to cloud formation parameterizations and meteorological fields**
R. E. P. Sotiropoulou, E. Tagaris

11:30-11:50 **Local geological topsoil dust in the area of Rome: linking mineral composition, aerodynamic size and optical properties**
A. Pietrodangelo, R. Salzano, C. Bassani, S. Pareti, C. Perrino

11:50-12:10 **Modeling aerosol water uptake in the Arctic and its direct effect on climate**
N. Rastak, A. Ekman, S. Silvergren, P. Zieger, U. Wideqvist, J. Ström, B. Svenningsson, P. Tunved, I. Riipinen

12:10-12:30 **Pre-Industrial Atmospheric Black Carbon Concentrations in North America**
Liaquat Husain, Tanveer Ahmed

12:30-12:50 **Global model simulations of the impact of transport sectors emissions on atmospheric aerosol and climate**
M. Righi, J. Hendricks, R. Sausen

Reserve paper **Variations of levels of atmospheric electrical and meteorological parameters and natural radioactivity in response to heavy smog due to forest fires**
M. S. Cherepnev, A. V. Vukolov, I. I. Ippolitov, M. V. Kabanov, P. M. Nagorsky, Yu. A. Phalagov, S. V. Smirnov, V. S. Yakovleva

10:30-12:50 Session: Atmospheric Aerosols

Mineral dust, marine aerosols and others

Chairs: Alfred Wiedensohler, Francisco Jose Olmo
Room: B (Leo+Virgo)

10:30-10:50 **Below-cloud scavenging by snow and mixed precipitation events calculated from high temporal resolution in situ measurements**
G. Depuydt, O. Masson, J. L. Brenguier, C. Piot, J. L. Jaffrezo

10:50-11:10 **Diurnal and seasonal variations of (nano)aerosols in the Škocjan Caves, Slovenia, a natural treasure of planet Earth**
I. Grgić, I. Iskra, B. Podkrajšek, V. Debevec Gerjevič

11:10-11:30 **Aerosol Processes in PAH Infiltration and Population Exposure in Rome**
P. Lipponen, O. Hänninen, R. Sorjamaa, M. Gherardi, M. P. Gatto, A. Gordiani, A. Cecinato, P. Romagnoli, C. Gariazzo

11:30-11:50 **Two years of measured vertical profiles in the Arctic (Svalbard Islands): results from 2011-2012 spring-summer campaigns**
L. Ferrero, D. Cappelletti, B. Moroni, V. Vitale, R. Udisti, G. Sangiorgi, M. G. Perrone, M. Busetto, C. Lanconelli, M. Mazzola, A. Lupi, S. Becagli, R. Traversi, D. Frosini, M. Maturilli, R. Neuber, C. Ritter, J. Graeser, M. Fierz, G. Mocnik, E. Bolzacchini

11:50-12:10 **EMEP intensive measurements on mineral dust in PM10, summer 2012 and winter 2013**
W. Aas, X. Querol, F. Lucarelli, A. Alastuey, N. Pérez, H. Areskoug, V. Balan, J. N. Cape, M. Catrambone, D. Ceburnis, S. Conil, L. Gevorgyan, J. L. Jaffrezo, C. Hueglin, N. Mihalopoulos, M. Mitosinkova, T. Moreno, J.-P. Putaud, V. Riffault, K. Sellegri, G. Spindler

12:10-12:30 **The effect of hexanoic acid on the hygroscopic properties of sodium halide aerosols**
Lorena Miñambres, Estíbaliz Méndez, María N. Sánchez, Fernando Castaño, Francisco J. Basterretxea

12:30-12:50 **Marine Aerosol Hygroscopicity and Volatility, Measured on the Chatham Rise (New Zealand)**
L. Cravigan, M. Mallet, Z. D. Ristovski, P. Vaattovaara, N. Talbot, G. Olivares, M. Harvey, C. Law

Reserve paper **Assessment of emission sources in an industrial area using instrumental and biomonitoring techniques**
J. Lage, S. M. Almeida, M. A. Reis, P. C. Chaves, M. C. Freitas, T. Ribeiro, S. Garcia, J. P. Faria, B. G. Fernández, H. Th. Wolterbeek

10:30-12:50 Session: Fundamentals

Aerosol properties and dynamics

Chairs: Christopher J. Hogan Jr., Charles Clement
Room: D (Kepler)

10:30-10:50 **Evolution of the charge state z and the cross section W of mobility-selected protein ions held for tens of ms at temperatures from 25 to 100° C**
J. Fernandez de la Mora, M. Attoui

10:50-11:10 **Evaluation of the role played by multiple scattering on the radiative properties of soot fractal aggregates**
J. Yon, F. Liu, A. Bescond, C. Caumont-Prim, C. Rozé, F.-X. Ouf, A. Coppalle

11:10-11:30 **The role of the scaling-law prefactor in the morphology of fractal aggregates**
A. D. Melas, A. G. Konstandopoulos, L. Isella, Y. Drossinos

11:30-11:50 **The Collision Frequency of Fractal-like Aerosols in the Free Molecular Regime**
M. L. Eggersdorfer, S. E. Pratsinis

11:50-12:10 **Collision Cross Section Calculation and Differential Mobility Analysis-Mass Spectrometry (DMA-MS) of Po-210 and Electrospray Generated Ions**
Carlos Larriba-Andaluz, Hui Ouyang, Mark J. Meredith, Derek R. Oberreit, Christopher J. Hogan Jr.

12:10-12:30 **A new approach to the theory of Brownian coagulation**
M. S. Veshchunov, I. B. Azarov

12:30-12:50 **Oblique Impact Fragmentation of Nanoparticle Agglomerates**
M. Gensch, A. P. Weber

Reserve paper **Evaporation and growth dynamics of layered droplets: Theory and experiments**
H. H. Tu, A. K. Ray

10:30-12:50 Session: Aerosol Chemistry

Chemical characterisation techniques for aerosols
Chairs: Markus Kalberer, Rami Alfarra
Room: C (Aquarius+Taurus)

10:30-10:50 **Novel Viscosity Measurement Technique for Atmospheric Aerosols using Fluorescence Lifetime Imaging Microscopy (FLIM)**
C. Fitzgerald, N. Hosny, M. Kalberer, M. Kuimova, F. Pope

10:50-11:10 **Extractive electrospray ionisation: A novel mass spectrometry technique for the online characterisation of organic aerosol composition and reactivity**
P.J. Gallimore, M. Kalberer

11:10-11:30 **A Unique On-line Method to Infer Water-Insoluble Particulate Mass-Fractions**
Daniel Short, Michael Giordano, Yifang Zhu, Phillip Fine, Andrea Polidori, Akua Asa-Awuku

11:30-11:50 **Surface site density versus nucleation rate approaches of formulating ice formation in clouds – a comprehensive analysis based on AIDA cloud simulation experiments**
O. Möhler, N. Hiranuma, K. Höhler, C. Hoose, M. Hummel, M. Niemand, C. Oehm, T. Schmitt, I. Steinke, R. Wagner

11:50-12:10 **X-ray study of freshly emitted carbonaceous nano-aerosols by synchrotron radiation**
F.-X. Ouf, F.-A. Barreda, A. Coppalle, D. Ferry, X.-J. Liu, B. Marcillaud, C. Miron, J.-B. A. Mitchell, T. Mostefaoui, C. Nicolas, M. Patanen, P. Parent, E. Robert, O. Sublemontier, J. Yon

12:10-12:30 **Micro-Raman monitoring of photoevolution and hygroscopicity of single particles by using an environmental acoustic levitation cell**
Y. A. Tobon, M. Moreau, S. Sobanska, J. Barbillat

12:30-12:50 **Measurements of Oxidized Organic Compounds using Nitrate Chemical Ionization Time-of-Flight Mass Spectrometry coupled to an Atmospheric Pressure interface (NO3-CI-APi-ToF)**
P. Massoli, A. Lambe, T. Hohaus, M. Canagaratna, P. Chaabra, H. Stark, J. Kimmel, J. Jayne, D. Worsnop

Reserve paper **Quantitative single particle mass spectrometry with the Aerodyne aerosol mass spectrometer: development of a new classification algorithm and application to field data**
F. Freutel, F. Drewnick, J. Schneider, T. Klimach, S. Borrmann

10:30-12:50 Session: Particle-Lung Interactions

PM toxicity

Chairs: Otmar Schmid, Jenny Rissler
Room: E (Tycho)

10:30-10:50 **Translocation of fluorescently labelled SiO2 nanoparticles across human bronchial epithelial monolayers**
I. George, S. Vranic, S. Boland, A. Baeza-Squiban

10:50-11:10 **Air-liquid interface exposure system for in vitro toxicological studies of wood combustion aerosols**
S. Mülhopt, M. Dilger, C. Schlager, R. Zimmermann, S. Diabaté, C. Weiss, H.-R. Paur

11:10-11:30 **Effect of flue gas scrubber on the toxicological effects of particulate samples from a recovery boiler**
S. Kasurinen, O. Uski, P. Jalava, M. Happo, I. Nuutinen, M. Kortelainen, H. Koponen, J. Tirkkonen, K. Kuuspalo, A. Leskinen, K. Lehtinen, J. Jokiniemi, M.-R. Hirvonen

11:30-11:50 **Nanotoxicological studies in the Air-Liquid Interface using engineered metal NPs – Protein corona, gene analysis and dose response**
C. R. Svensson, S. Ameer, J. H. Pagels, T. Cedervall, M. Kåredal, L. Ludvigsson, K. Broberg, B. O. Meuller, M. E. Messing, J. Rissler

11:50-12:10 **Aerosol characterisation of e-cigarettes**
R. Cabot, A. Koc, C. U. Yurteri, J. J. McAughey

12:10-12:30 **Ecotoxicity of various types of urban particulate matter**
B. Jancsek-Turóczi, A. Hoffer, Á. Tóth, N. Kováts, A. Ács, A. Gelencsér

12:30-12:50 **The respiratory toxicity of coal fly ash**
T. P. Jones, P. Brown, K. A. BeruBe

Reserve paper **Trace elements bioaccessibility in fine and ultrafine particles from the industrial area of Dunkirk (France) during the NANO-INDUS project**
S. Mbengue, L. Alleman, P. Flament

12:50-14:00 Lunch break

tecora
A DIVISION OF OMNISENSE TECHNOLOGIES

Complete Solutions for Ambient Sampling

TÜV

Skypost PM HV

Sequential outdoor sampler for:
- PM10, PM2.5, PM1
- Total Particulate Matter
- Heavy metals

Delta MK2

Battery and electricity supply sampler, with built-in battery pack and integrated dry gas meter

Bravo Plus

Portable constant flowrate sampler, suitable for dust and gas sampling, both in stack and in ambient

Echo PM

PM10/PM2.5 low volume sampler, available for single filter or 2 lines sequential sampling

Echo Hi Vol

High Volume sampler for:
- IPA
- Heavy Metals
- Particulate matter

Headquarters: 211-215 rue la Fontaine - Fontenay sous Bois Cedex 94134 FRANCE
Italian Office: Via A. Volta 22 - 20094 Corsico ITALY
commercial@tecora.com www.tecora.com

Poster Session A

Monday, September 2nd
Room: Zenit + Nadir

16:00-18:00 **Authors' Presentations**
Room: Zenit + Nadir

Atmospheric Aerosols

A001 **Effective density measurements of different fresh soot types**
M. Abegglen, B. Sierau, A. A. Mensah, J. Wang, L. Durdina, M. Gysel, U. Lohmann

A002 **Atmospheric aerosol size distribution during winter period in Ostrava-Radvanice**
A. Baranova, J. Hovorka

A003 **Aerosol source analysis approach for a rural background site – identifying the chemical fingerprints of anthropogenic and biogenic aerosols**
M. Äijälä, H. Junninen, M. Ehn, T. Petäjä, M. Kajos, R. Väänänen, F. Canonaco, J. Slowik, A. Prévôt, P. Aalto, M. Kulmala, D. Worsnop

A004 **Monitoring of transatlantic particles over São Paulo (Brazil) by sun-photometry, ground-based lidar and CALIOP**
J. L. Guerrero-Rascado, F. J. S. Lopes, E. Landulfo, L. Alados-Arboledas

A005 **Measurements of aerosol light-scattering enhancement factors at the urban environment of Granada (Spain)**
G. Titos, H. Lyamani, A. Cazorla, Z.J. Wu, M. Sorribas, I. Foyo-Moreno, J. Cheng, H.J. Liu, A. Wiedensohler, L. Alados-Arboledas

A006 **Relating the wavelength dependency of the absorption coefficient and the aerosol type**
A. Cazorla, G. Titos, H. Lyamani, L. Alados-Arboledas

A007 **Evaluation of AERONET precipitable water vapour versus microwave radiometry, GPS and balloon-borne radiosondes at ARM sites**
Daniel Pérez-Ramírez, Alexander Smirnov, Hassan Lyamani, David Whiteman, Brent Holben, Lucas Alados-Arboledas

A008 **Aerosol Impact on cloud properties in Pakistan**
K. Alam, R. Khan

A009 **Remote Sensing of Aerosol optical property Over the Arabian Gulf**
F. M. Al-Kandari, H. K. Al-Jassar, K. S. Rao

A010 **Organic Fraction of Laboratory Generated Primary Marine Aerosol**
A. C. Butcher, S. M. King, T. Rosenoern, M. Bilde

A011 **Contribution of Fugitive Emissions in an Industrial Area of Portugal**
S. M. Almeida, A. V. Silva, S. M. Garcia, A. I. Miranda

A012 **Saharan dust contribution to PM10 levels and composition in Cape Verde**
S. M. Almeida, M. Almeida-Silva, C. A. Pio, T. Nunes, J. Cardoso, M. Cerqueira, M. A. Reis, P. C. Chaves, A. Taborda

A013 **Homologous series of organic compounds in aerosols impacted by sugar cane burning in São Paulo State, Brazil**
R. C. Urban, C. A. Alves, A. A. Cardoso, A. G. Allen, M. L. A. M. Campos

A014 **Emissions of carbonaceous aerosols and volatile organic com pounds by light-duty vehicles on a chassis dynamometer**
C. A. Alves, A. I. Calvo, D. Lopes, D. Custódio, S. Rocha, T. Nunes, M. Evtyugina, A. Charron, M. Goriaux, P. Tassel, P. Perret

A015 **Hydrocarbons in smoke samples from wildfire events in central Portugal in summer 2010**
A. M. Vicente, C. A. Alves, S. D. G. Acioli, A. P. Fernandes, T. Nunes, A. C. Monteiro, C. A. Pio

A016 **Evaluation of CMA as dust suppressant in Barcelona: Preliminary results from the AIRUSE LIFE+ Project**
F. Amato, A. Karanasiou, A. Alastuey, T. Moreno, F. Lucarelli, S. Nava, G. Calzolai, M. Chiari, M. Keuken, X. Querol

A017 **Temporal variation of urban atmospheric aerosol during smog episodes in Debrecen, Hungary**
A. Angyal, Zs. Kertész, Z. Ferenczi, E. Furu, Z. Szoboszlai, Zs. Török, Z. Szikszai

A018 **Aerosol profile retrieval algorithm development and validation for Sentinel-4**
A. Apituley , O. Vieitez, B. Sanders, P. Stammes, B. Veheilmann, Y. Meijer, R. Koopman

A019 **Modelling and impact of aerosols on climate variabilityover central Africa**
A. J. M.Komkoua, C. Tchawoua

A020 **Subgrid variability of CCN sized aerosol**
A. Asmi, R. Väänänen, R. Kredji, A. Minikin

A021 **Multi-criteria ranking and source apportionment of airborne particles**
G. A. Ayoko, A. J. Friend

A022 **A study of aerosol production at the cloud edge with direct numerical simulations**
N. Babkovskaia, M. Boy, S. Smolander, S. Romakkaniemi, M. Kulmala

A023 **The effect of cloudiness on new particle formation: investigation of radiation levels**
E. Baranizadeh, A. Arola, A. Hamed, T. Nieminen, A. Virtanen, M. Kulmala, A. Laaksonen

A024 **Influence of Mineral Dust Transport from North Africa in the Concentration and Size Distribution of Aerosol in León (Spain)**
E. Alonso-Blanco, A. I. Calvo, A. Castro, C. Alves, R. Fraile

A025 **UFIREG-Ultrafine particles and health**
S. Bastian, G. Löschau, J. Cyrys, J. Novak, M. Gobec, B. Mykhalchuk

A026 **Influence of stable weather on aerosol concentration and size distribution at K-puszta, Hungary**
A. Molnár, Zs. Bécsi

A027 **Wintertime distribution of PAH with aerosol particle size in two cities in the Czech Republic**
J. Bendl, J. Hovorka, J. Topinka

A028 **Hygroscopic Properties and Mixing State of Ultrafine Aerosol Particles over the Eastern Mediterranean Background Site of Finokalia**
S. Bezantakos, A. Bougiatioti, I. Stavroulas, K. Eleftheriadis, N. Mihalopoulos, A. Nenes, G. Biskos

A029 **Climatology of dust events at Mt. Cimone (2165 m a.s.l.), Italy**
L. Bourcier, G. Zaccaria, A. Marinoni, P. Cristofanelli, R. Duchi, D. Putero, T. C. Landi, F. Calzolari, P. Bonasoni

A030 **2011 Observations of Stratospheric Aerosol over Hampton, VA related to the Nabro volcanic Eruption in Africa**
N. Boyouk, P. M. McCormick, M. Hill, K. Leavor

A031 **Size-Resolved Source Apportionment of PM10 Organic Aerosol Measured with Aerosol Mass Spectrometry**
C. Bozzetti, I. El Haddad, R. Wolf, E. Bruns, A. Krepelova, K. Dällenbach, J. G. Slowik, U. Baltensperger, A. S. H. Prévôt

A032 **CANCELLED**

A033 **Lidar depolarization evolution during the CHARMEX intensive field campaign**
J. A. Bravo-Aranda , M. J. Granados-Muñoz, F. Navas-Guzmán, J. L. Guerrero-Rascado, F. J. Olmo, L. Alados-Arboledas

A034 **Ground-based observations of aerosol and cloud properties at sub-arctic Pallas GAW-station**
D. Brus, K. Neitola, E. Asmi, M. Aurela, U. Makkonen, J. Svensson, A.-P. Hyvärinen, A. Hirsikko, H. Hakola, R. Hillamo, H. Lihavainen

A035 **The concentrations of organic/elemental carbon and total protein in atmospheric aerosol of the near-ground atmospheric layer of Southwestern Siberia in the summer of 2012**
G. A. Buryak, A. S. Safatov, S. E. Olkin, I. K. Reznikova, V. I. Makarov, S. A. Popova, M. P. Shinkorenko, B. S. Smolyakov

A036 **Identification and characterization of black carbon aerosol sources in Lithuania**
S. Byčenkiene, V. Ulevicius, V. Dudoitis, J. Andriejauskiene

A037 **Influence of humidity on aerosol concentrationsin a subtropical region**
L. Caetano-Silva, A. G. Allen, M. Lima-Souza, A. A. Cardoso

A038 **CANCELLED**

A039 **Sugar markers in biomass burning particles from a Brazilian agro-industrial region**
R. C. Urban, A. A. Cardoso, A. G. Allen, M. E. C. Queiroz, C. A. Alves, M. L. A. M. Campos

A040 **Long-term time series of daily PM10 chemical composition in the area of Rome, Italy**
M. Catrambone, S. Dalla Torre, E. Rantica, T. Sargolini, C. Perrino, the Med-Particles Study Group

A041 **Organic characterization of particulate material from a Brazilian agro-industrial region impacted by biomass burning**
R. C. Urban, A. A. Cardoso, A. G. Allen, M. E. C. Queiroz, C. A. Alves, M. L. A. M. Campos

A042 **Thermal-optical analysis of elemental carbon (EC) in environmental samples – differences observed when using various protocols**
E. C. Cetintas, M. Kistler, C. Schmidl, H. Bauer, A. Kasper-Giebl

A043 **Coupling optical and chemical properties of primary and secondary carbonaceous aerosols**
F. Costabile, S. Gilardoni, F. Barnaba, M. Rinaldi, S. Ferrari, V. Poluzzi, G. P.Gobbi

A044 **Black carbon contribution to the particle matter in Madrid City during a local winter episode**
E. Coz, M. Becerril, Z. Chang, J. Pérez-Guldris, A. S. H. Prévôt, G. Ramos, B. Artiñano

A045 **Major ions particle size distribution from Baia de Todos os Santos, Northeastern Brazil**
G. O. da Rocha, J. S. S. Domingos, A. C. D. Regis, J. V. S. Santos, J. B. de Andrade

A046 **Extreme dust storms in Iceland**
P. Dagsson-Waldhauserova, H. Olafsson, O. Arnalds

A047 **Measurements of particulate matter hygroscopicity in Aerosol Exposure Chamber to prevent atmospheric corrosion in Data Center**
L. D'Angelo, G. Rovelli, L. Ferrero

A048 **Effect of the extensive use of fireplaces on carbonaceous particle concentration levels in Athens, Greece**
E. Diapouli, V. Vasilatou, S. Vratolis, M. Gini, D. Saraga, Th. Maggos, K. Eleftheriadis

A049 **Distribution of aerosol over coal strip mine**
V. Docekalova, J. Hovorka, F. Kobrzek, P. Marecek

A050 **Spatial-temporal variability of particle number concentrations between a busy street canyon and the urban background**
V. Dos Santos-Juusela, T. Petäjä, A. Kousa, K. Hämeri

A051 **Airborne Aldehydes as Altitude-Distributed Source of Particulate Matter in the Troposphere**
S. N. Dubtsov, T. A. Maksimova, G. G. Dultseva

A052 **The comparison of the light scattering coefficient measured in urban and coastal environments**
V. Dudoitis, V. Ulevicius, K. Plauškaite, G. Mordas

A053 **Variations of PM10 and its relationship with 7Be and 210Pb measurements at Malaga (Southeastern coast of Spain)**
C. Dueñas, M. C. Fernández, E. Gordo, E. Liger, S. Cañete, M. Pérez

A054 **Atmospheric fluxes of radionuclides on monthly time-scale in Malaga (Spain)**
C. Dueñas, M. C. Fernández, E. Gordo, S. Cañete, E. Liger, M. Pérez

A055 **The comparative analysis of variations of background radiation components and atmospheric electrical parameters**
M. S. Cherepnev, I. I. Ippolitov, M. V. Kabanov, P. M. Nagorsky, S. V. Smirnov, A. V. Vukolov, V. S. Yakovleva

A056 **13C measurements on organic aerosol – ambient samples versus source studies**
U. Dusek, C. Meusinger, B. Oyama, W. Ramon, P. A. de Wilde, R. Holzinger, T. Röckmann

A057 **Road Pavement Abrasion as the Source of Particulate Matter**
Dušan Jandačka, Daniela Ďurčanská

A058 **Time-resolved organic speciation at the Theodore Roosevelt National Park, North Dakota, USA**
A. Eiguren, G. Lewis, N. Kreisberg, D. R. Worton, A. H. Goldstein, S. V. Hering

A059 **Water activity measurement of pure and mixed organic/inorganic solutions**
M. M. Fard, and M. Bilde

A060 **Can lung-deposited surface area measurements serve as surrogate for black carbon?**
M. Fierz, D. Meier, C. Hüglin, H. Burtscher

A061 **Regional-scale modeling of organic aerosol composition in Europe: Insights from comparison with aerosol mass spectrometer factor analysis**
C. Fountoukis, A. G. Megaritis, K. Skyllakou, P. E. Charalampidis, C. Pilinis, S. N. Pandis

A062 **CANCELLED**

A063 **Year-round measurement of PM1 aerosol and its chemical composition in the Swiss high Alps using the Time-of-Flight Aerosol Chemical Speciation Monitor (ToF-ACSM)**
R. Fröhlich, M. J. Cubison, J. G. Slowik, A. S. H. Prévôt, U. Baltensperger, U. Rohner, M. Gonin, J. R. Kimmel, D. R. Worsnop, J. T. Jayne

A064 **Aerosol Activation and Scavenging during the Cloudy Test Campaign at the CERN CLOUD chamber**
C. Fuchs, J. Tröstl, J. Duplissy, E. Weingartner, U. Baltensperger, the CLOUD collaboration

A065 **The effect of the tramway track building on the aerosol pollution in Debrecen, Hungary**
E. Furu, I. Katona-Szabo, A. Angyal, Z. Szoboszlai, Zs. Török, Zs. Kertész

A066 **Contribution of fossil and modern carbon to PM2.5 and CO2 in the atmosphere of Debrecen, Hungary**
I. Major, E. Furu, I. Hajdas, Zs. Kertész, M. Mihály

A067 **The impact of extreme weather events on air quality in Budapest, Hungary**
V. Gácser, A. Molnár

A068 **Seasonal variation of urban aerosols in a sub-Saharan city: case study of Nairobi, Kenya**
S. M. Gaita, J. Boman, J. B. C. Pettersson, M. J. Gatari, S. Janhäll

A069 **Stable carbon isotopic values (δ13C) of biofuel in Lithuania**
A. Garbaras, A. Lipovec, A. Masalaite, V. Remeikis

A070 **Atmospheric aerosol episodes over Lithuania after the May 2011 volcano eruption at Grimsvötn, Iceland**
K. Kvietkus, J. Šakalys, J. Didžbalis, I. Garbariene, N. Špirkauskaite, V. Remeikis

A071 **Quantifying the relative contribution of different aerosol types over Eastern Mediterranean: A decadal high resolution satellite view**
A. K. Georgoulias, K. A. Kourtidis, G. Alexandri, P. Zanis, U. Pöschl

A072 **CLACE 2013: Cloud microphysics and physico-chemical characterization of ice residuals in mixed-phase clouds**
P. Kupiszewski, E. Weingartner, R. Färber, M. Gysel, E. Hammer, C. Fuchs, U. Baltensperger, P. Vochezer, M. Schnaiter, C. Linke, E. Toprak, S. Mertes, J. Schneider, T. Klimach, S. Schmidt

A073 **The UPUPA project: Ultrafine Particles in the Urban Piacenza Area, Italy**
M. Giugliano, G. Lonati, S. Ozgen, G. Ripamonti

A074 **DIAPASON: an user-oriented EC-LIFE+ Project to quantify the role of Saharan dust on European PM10 levels**
G. P. Gobbi, F. Barnaba, F. Costabile, L. Di Liberto, C. Tirelli, R. Sozzi, A. Bolignano, M. Morelli

A075 **Testing of aerosols in Barentsburg area (Spitsbergen)**
L. P. Golobokova, D. G. Chernov, U. S. Turchinovicn, V. V. Polkin

A076 **The Spanish network on environmental DMAs: the 2012 SMPS+UFP intercomparison campaign and study on particle losses in dryers**
F. J. Gómez-Moreno, E. Alonso, B. Artíñano, V. Juncal Bello, M. Piñeiro Iglesias, P. López Mahía, N. Pérez, J. Pey, A. Alastuey, B. A. de la Morena, M. I. García, S. Rodríguez, M. Sorribas, G. Titos, H. Lyamani, L. Alados-Arboledas

A077 **The potential role of ion-induced nucleation at a coniferous forest site in north eastern Bavaria**
S. G. Gonser, F. Klein, W. Birmili, J. Größ, A. Held

A078 **Analysis of aerosol hygroscopic properties by combination of lidar, microwave radiometer and radiosounding data**
M. J. Granados-Muñoz, F. Navas-Guzmán, J. A. Bravo-Aranda, J. L. Guerrero-Rascado, A. Valenzuela, J. Fernández-Gálvez, L. Alados-Arboledas

A079 **Hygroscopic growth parameterization of aerosol particles based on high humidity measurements in the Po-Valley, Italy**
J. Größ, I. Pap, W. Birmili, A. Hamed, A. Wiedensohler

A080 **Mixture of biomass-burning and urban aerosols analysis: a case study**
Marius Mihai Cazacu, Florin Unga, Adrian Timofte, Ioana Popovici, Alin Ionut Pascaru, Dan Dimitriu, Silviu Gurlui

A081 **Characterization of fine particles using Aerosol mass spectrometer during intensive campaign in three different sites in Kanto basin in summer of 2011**
H. Hagino, and T. Morikawa, S. Hasegawa, S. Yonemochi, K. Sekiguchi, K. Kumagai, N. Yamaguchi, A. Iijima, H. Shimadera, H. Hayami

A082 **Hygroscopicity of sub-6 nm sodium chloride particles**
J. Hakala, J. Kangasluoma, T. Petäjä

A083 **Semi-empirical parameterization for sub-20 nm particle growth**
S. A. K. Häkkinen, H. E. Manninen, T. Yli-Juuti, J. Merikanto, M. K. Kajos, T. Nieminen, S. D. D'Andrea, A. Asmi, J. R. Pierce, M. Kulmala, I. Riipinen

A084 **New particle formation at rural and mountain stations in north Italy: A comparative study during the joint PEGASOS and Supersito campaign**
A. Hamed, S. Decesari, S. Gilardoni, S. Niemelä, L. Tarozzi, C. Carbone, P. Vaattovaara, J. Joutsensaari, P. Cristofanelli, A. Marinoni, P. Bonasoni, G. Bonafe, D. Bacco, I. Ricciardelli, A. Virtanen, S. Ferrari, V. Poluzzi, M. C. Facchini, A. Laaksonen

A085 **Secondary New Particle Formation in Central Europe: Eight years of Aerosol Particle Size distribution data from Melpitz Site, Germany**
A. Hamed, Z. Wang, W. Birmili, G. Spindler, A. Wiedensohler

A086 **Measurement of atmospheric organic nitrate aerosols and its application in cloud events**
L. Q. Hao, S. Romakkaniemi, A. Kortelainen, A. Jaatinen, H. Portin, P. Miettinen, M. Komppula, A. Leskinen, J. N. Smith, D. Sueper, D. R. Worsnop, K. E. J. Lehtinen, A. Laaksonen, A. Virtanen

A087 **Ultrafine particle concentrations: importance of local sources and new particle formation in two central European cities**
A. Wonaschuetz, R. Wagner, I. Aschauer, R. Haindl, W. Ludwig, G. Zecha, J. Ondráček, P. Vodička, N. Ziková, V. Ždímal, J. Schwarz, R. Hitzenberger

A088 **Absorbing aerosol long-term trend at Mukteshwar, a pristine location in Central Himalayas foothills**
Rakesh K. Hooda, A.-P. Hyvärinen, V. P. Sharma, M. Komppula, E. Asmi, Y. Viisanen and H. Lihavainen

A089 **Vertical profiles of aerosol optical properties and wavelength dependent absorption at Maldives Climate Observatory Hanimaadhoo**
F. Höpner, F. Bender, P. S. Praveen, V. Ramanathan

A090 **Spatial variations and source apportionment of the marine organic aerosol over the Atlantic Ocean**
S. Huang, L. Poulain, Z. J. Wu, H. Herrmann, A. Wiedensohler

A091 **Chemical composition, concentration, size distribution and diurnal variation of atmospheric aerosol particles at the background and urban sites in Lithuania**
K. Kvietkus, J. Šakalys, J. Didžbalis, E. Meinore

A092 **Surface Aerosol Monitoring at Hada Al Sham, Western Saudi-Arabia**
A.-P. Hyvärinen, M. Alghamdi, T. Hussein, M. Khodeir, A. Shehata, H. Lihavainen, M. Kulmala, A. Laaksonen

A093 **Chemical composition, and mass closure of Siberia aerosols at ZOTTO, Russia, April 2010 to February 2011**
X. Chi, E. Mikhailov, A. Panov, M. O. Andreae

A094 **Estimation of emission rates of resuspended road dust using a mobile monitoring system**
Sehyun Han, Yongwon Jung

A095 **One-year monitoring of nitro-organic compounds in biomass burning PM10 filter samples**
A. Kahnt, S. Behrouzi, R. Vermeylen, M. Safi Shalamzari, J. Vercauteren, W. Maenhaut, M. Claeys

A096 **A case of CCN formation associated with atmospheric nucleation in eastern Mediterranean**
N. Kalivitis, V.-M. Kerminen, G. Kouvarakis, I. Stavroulas, A. Bougiatioti, A. Nenes, H. E. Manninen, T. Petäjä, M. Kulmala, N. Mihalopoulos

A097 **Nitration and oxidation of bioaerosols and allergenic proteins**
C. J. Kampf, K. Selzle, U. Pöschl

A098 **Effects of mineral dust and sea salt on global nitrate concentration field**
V. A. Karydis, A. P. Tsimpidi, J. Lelieveld

A099 **Particle size distribution of viable airborne microbes and particulate matter during pretreatment of wastewater**
E. Katsivela, E. Latos, L. Raisi, M. Lazaridis

A100 **Comprehensive studies of chemical composition of atmospheric aerosol above Lake Baikal surface area, Russia**
T. V. Khodzher

A101 **Airborne Measurements of Emissions from Oil and Gas Exploration and Production Activities in the Norwegian Sea**
J. Kim, A. Roiger, B. Weinzierl, M. Rose, A. Reiter, J. Thomas, L. Marelle, K. Law, H. Schlager

A102 **Development of Reference Film for Quality Control and Assurance for Beta Attentuation Particulate Matter Measurement**
H. H. Kim, J. Y. Lee, S. Lee

A103 **Soot on Snow (SoS) measurement campaigns 2011-2013**
N. Kivekäs, A. Virkkula, O. Järvinen, J. Svensson, A. Aarva, H. Lihavainen, D. Brus, A. Hyvärinen, O. Meinander, A. Heikkilä, R. Väänänen, J. Backman, G. De Leeuw

A104 **Characterization of particle formation in a spruce forest in north east Bavaria**
F. Klein, A. Held

A105 **Influence of different fuels and grillables on particle emissions during an outdoor barbeque**
S. H. Schmitt, C. Berberich, M. Glor, L. Güntner, T. C. Sluka, K. A. Kamili, S. G. Gonser, A. Held

A106 **Photophoretic effects for the black carbon aerosols at stratospheric altitudes**
L. B. Kochneva, S. A. Beresnev, V. I. Gryazin, M. V. Vasiljeva, K. G. Gribanov and V. I. Zakharov

A107 **Particle collection properties of high vegetation elements**
R. D. Kouznetsov, M. A. Sofiev

A108 **A scheme for particle deposition from turbulent flows above surfaces**
R. D. Kouznetsov, M. A. Sofiev

A109 **Intermodal fraction of aerosol from indoor and outdoor microenvironments**
J. Kozáková, M. Braniš

A110 **Acidic reaction products of mono- and sesquiterpenes in atmospheric fine particles in boreal forest in Hyytiälä, Finland**
M. Vestenius, H. Hellen, J. Levula, P. Kuronen, H. Hakola

A111 **Evidence for the presence of secondary phosphorus in continental fine aerosol**
K. Krassován, Z. Kertész, K. Imre, A. Gelencsér

A112 **Measurement of evaporation rates of atmospheric nanoparticles**
N. K. Kumar, S. N. Pandis

A113 **Organic compounds in PM2.5 aerosol in Ostrava (Czech Republic)**
P. Mikuška, K. Křůmal, Z. Večeřa

A114 **Laboratory characterization of a size-resolved CPC battery to infer the composition of freshly formed atmospheric nuclei**
C. Kuang, J. Kangasluoma, D. Wimmer, K. Lehtipalo, J. Wang, M. Kulmala, T. Petäjä

A115 **Detailed study of fine particulate matter during 2013 New Year's celebrations**
L. Kubelová, P. Vodička, J. Schwarz, V. Ždímal

A116 **DMA Train measurements of nanoparticle growth at a field site in Lewes, Delaware**
A. Kupc, P. M. Winkler, M. Lawler, P. H. McMurry, J. N. Smith

A117 **Source Identification and Apportionment of Finnish Arctic Aerosols**
James R. Laing, Philip K. Hopke, Eleanor F. Hopke, Liaquat Husain, Vincent A. Dutkiewicz, Jussi Paatero, Yrjö Viisanen

A118 **Forty-Seven Years of MSA Concentrations in the Finnish Arctic**
James R. Laing, Philip K. Hopke, Eleanor F. Hopke, Liaquat Husain, Vincent A. Dutkiewicz, Jussi Paatero, Yrjö Viisanen

A119 **Source apportionment of ten years' aerosol collected at Mt. Lulin in East Asia**
C.-T. Lee, S.-C. Wu, George N.-H. Lin, G.-C. Hong

A120 **On the potential of volcanic ash and powder sample investigation with FIB/SEM EBSD-EDS**
K. I. Lieke, H. Alimadadi

A121 **Analyses of long-term measurements (2005-2012) of 7Be concentrations in surface air aerosols**
E. Liger, C. Dueñas, M. C. Fernández, E. Gordo, S. Cañete, M. Pérez

A122 **Airborne measurements of ship emissions**
H. Lihavainen, E. Asmi, J.-P. Jalkanen, A. Hyvärinen, T. Laurila, J. Walden, R. Hillamo

A123 **Relationship between the tropospheric aerosol size distribution and cloud droplet effective radius in a rural region of São Paulo State**
M. Lima-Souza, A. G. Allen, L. Caetano-Silva, A. A. Cardoso

A124 **Characteristics of fine and coarse particles collected from open burning of jujube tree branches**
Chih-Chung Lin, Wen-Yinn Lin, Kuo-Lin Huang, Lien-Te Hsieh, Jen-Hsiung Tsai, Shui-Jen Chen

A125 **Investigating the Small-Scale Vertical and Horizontal Variability of the Atmospheric Boundary Layer Aerosol using Unmanned Aerial Vehicles**
B. Wehner, A. Lampert, A. Scholtz, J. Bange, A. Platis, M. Hermann

A126 **The association of children's lung function and air pollution in Kaohsiung, Taiwan**
C. L. Yeh, K. D. Mena, C. S. Ou, P. S. Chen

A127 **Seasonal physical and optical properties of atmospheric aerosol at Princess Elisabeth station, East Antarctica**
A. Mangold, H. De Backer, A. Delcloo, V. De Bock, C. Hermans, I. Gorodetskaya, W. Maenhaut

A128 **δ13C of size segregated aerosol particles collected in Preila and Baltic Sea**
A. Masalaite, A. Garbaras, V. Remeikis

A129 **Size distribution of airborne Uranium and Thorium-labelled aerosols near a UF4 processing plant**
O. Masson, G. Videau, X. Cagnat

A130 **Comparison of Aerosol Time of Flight Mass Spectrometer (ATOFMS) measurements with off-line techniques for determining metal concentration in atmospheric particles**
Eoin McGillicuddy, Robert Healy, Manuel Dall'Osto, Jean Sciare, Franco Lucarelli, Silvia Nava, Xavier Querol, Ian O'Connor, Deborah Gross, John Wenger, John Sodeau

A131 **Levels of polybrominated diphenyl ethers in the ambient air of automobile dismantling plants from southern Taiwan**
S. I. Shih, H. R. Chao, W. K. Wu, Y. Y. Guo, B. A. Jiang, C. Y. Chen, Y. M. Kuo, C. H. Tsai

A132 **Rotational Spectra and ab initio modeling of dicarboxylic acids: Succinic Acid**
Estíbaliz Méndez, Patricia Écija, Emilio J. Cocinero, Fernando Castaño, Francisco J. Basterretxea, Peter D. Godfrey, Don McNaughton, Michaela K. Jahn, K. P. Rajappan Nair, Jens-Uwe Grabow

A133 **The influence of the Sahara storm on the aerosol optical properties in Lithuania**
G. Mordas, V. Ulevicius, N. Prokopciuk

A134 **Measurements of the aerosol particle physical properties and particle chemical composition in Vilnius city**
G. Mordas, V. Ulevicius, I. Garbariene, K. Kvietkus

A135 **Exploring the effect of deep-convective cloud systems on particle mass and number: source or sink?**
B. N. Murphy, I. Riipinen, A. M. L. Ekman

A136 **Total sulphate vs. sulphuric acid monomer in nucleation studies**
K. Neitola, D. Brus, U. Makkonen, M. Sipilä, T. Jokinen, R. L. Mauldin III, K. Kyllönen, H. Lihavainen, M. Kulmala

A137 **Air mass history on 1-year long new aerosol particle formation dataset in Budapest**
Z. A. Németh, I. Salma

A138 **Comparison of particle concentrations obtained at urban and regional background environments**
J. F. Nicolás, J. Crespo, E. Yubero, R. Soler

A139 **Enhancement of the collision efficiency between basidiospores and cloud droplets by electrostatic charges carried on freshly emitted basidiospores**
M. Saar, M. Noppel, J. Salm

A140 **On the microphysical and optical aerosol properties during AMISOC-ARN campaign**
M. Sorribas, C. Córdoba-Jabonero, H. Lyamani, G. Titos, J. A. Adame, R. Fraile, B. A. de la Morena, F. J. Olmo, L. Alados-Arboledas, O. Puentedura, M. Gil

A141 **Bimodal particle concentration profile retrieved from ground-based Lidar and CIMEL measurements**
A. Quirantes, F. J. Olmo , A. Valenzuela, M. J. Granados-Muñoz, J. L. Guerrero-Rascado, J. A. Bravo-Aranda, F. Navas-Guzmán, L. Alados-Arboledas

A142 **On the contribution of ephemeral lakes to the aerosol load**
J. A. G. Orza, M. Cabello, E. Doménech, L. Pérez

A143 **Investigation of the truncation correction of the polar nephelometer Ecotech Aurora4000**
M. Paixão, T. Müller, S. Pfeifer, A. Wiedensohler

A144 **Estimation of viscosity of SOA particles based on coalescence times**
A. Pajunoja, J. Malila, L. Hao, K. E. J. Lehtinen, A. Virtanen

A145 **Studies of precipitable water vapor measurements with use of Microtops II Sun Photometer and Radiosonde RS92**
P. Pakszys, T. Zieliński, T. Petelski, P. Makuch, A. Strzałkowska, P. Markuszewski, J. Kowalczyk

A146 **Factor analysis of aerosol measurements in Tartu**
M. Palo, M. Eller

A147 **Continuous atmospheric boundary layer observations in Barcelona, Spain**
M. Pandolfi, G. Martucci, X. Querol, A. Alastuey, F. Wilsenack, S. Frey, C. D. O'Dowd, M. Dall'Osto

A148 **Hygroscopic properties of the anthropogenic aerosol in the Po-Valley, Italy**
I. Pap, J.Größ, A. Hamed, W. Birmili, A. Wiedensohler

A149 **Rainout, washout and dry deposition contributions to the total deposition flux of heavy metal aerosol onto surfaces of a small urban catchment (Pin Sec, Nantes)**
S. Percot, V. Ruban, P. Laguionie, D. Maro, P. Roupsard, D. Demare

A150 **Continuous Measurements with high Time Resolution of Semi-Volatile Components in the Atmospheric Aerosol**
H. Grimm, M. Pesch, M. Richter, A. Comouth

A151 **Mobile FINE DUST Aerosol Spectrometer**
M. Pesch, H. Grimm, M. Richter

A152 **Primary Biological DNA Database**
D. Pickersgill, J. Wehking, I. Müller-Germann, U. Pöschl, V. R. Després

A153 **Studying Atmospheric Aerosols by Acoustic Levitation: Linking Headspace Solid-Phase Microextraction (HS-SPME) with Gas Chromatography-Mass Spectrometry (GC-MS)**
S. Almabrok, G. Marston, C. Pfrang

A154 **The variation of the total aerosol particle number concentration in fog in southern and south-eastern regions of the Baltic Sea**
K. Plauškaite, N. Špirkauskaite, T. Zielinski, T. Petelski, V. Ulevicius

A155 **Autofluorescence of atmospheric bioaerosols – studies on biofluorophores and biological standard particles**
C. Pöhlker, J. A. Huffman, J.-D. Förster, U. Pöschl

A156 **CANCELLED**

A157 **Observations of cloud effects on aerosol light absorption and scattering**
A. Leskinen, H. Portin, A. Arola, S. Romakkaniemi, A.-P. Hyvärinen, A. Laaksonen, K. E. J. Lehtinen, M. Komppula

A158 **Meteorological impacts in the modification of PM10 concentration levels in the urban area of Volos, Greece**
G. T. Proias, K. P. Moustris, I. K. Larissi, P. T. Nastos, A. G. Paliatsos

A159 **Study of the Impact of the Natural Production, in the Mediterranean Sea, of Coastal Marine Aerosols on the Dynamics and Microphysical Behavior of a Convective Cloud**
R. Merrouchi, J. Piazzola, M. Chagdali, S. Mourdane

A160 **Black carbon aerosol concentrations and mixing state in Pallas, Finland**
T. Raatikainen, D. Brus, A.-P. Hyvärinen, J. Svensson, H. Lihavainen

A161 **Particle emissions from bushfires extending into the rural-urban interface**
F. Reisen, M. Bhujel, P. Selleck

A162 **Measurements of the variation in hygroscopic growth of organic aerosol with oxygen-to-carbon ratio (O/C)**
A. M. J. Rickards, R. E. H. Miles, J. F. Davies, F. H. Marshall, J. P. Reid

A163 **Overview of the French contribution to the EMEP 2012-2013 summer and winter campaigns**
V. Riffault, J. L. Jaffrezo, J. Sciare, K. Sellegri, S. Sauvage, V. Crenn, A. Waked, J. E. Petit, A. Colomb, S. Conil, J. L. Besombes, A. Setyan, E. Freney, T. Leonardis, N. Locoge, V. Gros, N. Bonnaire, R. Sarda-Estève, F. Dulac, M. Hervo, L. Chiappini, O. Favez, F. Gheusi, G. Athier, M. Mallet, T. Bourrianne, G. Roberts, N. Pascal, J. Descloitres

A164 **Dry deposition velocity measurements onto urban surfaces using atmospheric beryllium 7: development of a methodology and results**
P. Roupsard, D. Maro, A. Coppalle, V. Ruban, M. Rozet, M. Talbaut, S. Percot

A165 **Seasonality of biological aerosol particles associated with African dust storms**
Cristina Ruzene-Nespoli, Janine Fröhlich-Nowoisky, T. Nunes, J. Cardoso, C. Pio, Ulrich Pöschl

A166 **Fluorescence based real-time measurements of atmospheric PBAP in urban environment**
S. Saari, J.V. Niemi, T. Rönkkö, L. Pirjola, R. Hillamo, J. Keskinen

A167 **An observational study on air pollution conditions in two continuous haze periods in winter in Nanjing, China**
Y. J. Zhang, L. L. Tang, H. L. Zhang, L. Tang

A168 **Classification of Dust/Non-dust Particle from the Asian Dust Plumes and Retrieval of Microphysical Properties using Multiwavelength Raman Lidar System**
S. K. Shin, Detelf Müller, Y. M. Noh, D. H. Shin, K. H. Lee

A169 **Improvements to harmonize different soot measurement techniques in air quality monitoring networks**
A. Schladitz, G. Löschau, H. G. Kath

A170 **Single particle analysis of cloud residuals sampled at the research station Schneefernerhaus (2650 m) during ACRIDICON-Zugspitze 2012**
S. Schmidt, J. Schneider, T. Klimach, S. Mertes, L. Schenk, S. Borrmann

A171 **In-situ single particle composition analysis of ice residuals in mixed-phase clouds during INUIT-JFJ 2013**
S. Schmidt, J. Schneider, T. Klimach, S. Mertes, L. Schenk, U. Kästner, F. Stratmann, U. Bundke, B. Nillius, F. Frank, J. Curtius, S. Borrmann

A172 **New Homogeneous Ice Nucleation Results from Measurements at a Large Atmospheric Simulation Chamber**
T. Schmitt, O. Möhler, D. Duft, M. Haarig, K. Höhler, A. Kiselev, I. Steinke, T. Leisner

A173 **Processing of ambient aerosols during fog events**
A. Chakraborty, T. Gupta, S. N. Tripathi

A174 **Comparison of mass size distribution of PM and ions in Prague and Vienna in winter and summer**
J. Schwarz, N. Zíková , P. Vodička, I. Ševčíková, J. Kugler, A. Wonaschuetz, R. Wagner, I. Aschauer, W. Ludwig, R. Haindl, G. Zecha, R. Hitzenberger, V. Ždímal

A175 **Characteristics of Local and Regional Nucleation Events at an Urban Background Site during Summer Period in Thessaloniki, Greece**
D. Siakavaras, C. Samara, A. Kelessis, G. Biskos

A176 **Exposure of air pollutants inside vehicles while driving in road tunnels**
S. Silvergren, M. Norman, C. Johansson, B. Sjövall

A177 **Measurement capabilities of the Poland-AOD network**
A. Strzalkowska, P. Makuch, P. Pakszys, O. Zawadzka, P. Markuszewski, T. Zielinski, T. Petelski, K. M. Markowicz, I. Stachlewska, A. Ponczkowska, M. Wichorowski

A178 **Aerosol characteristics during dust storm in Middle East and South-Western Asia**
F. Subhan, K. Alam

A179 **CANCELLED**

A180 **Assessment of air pollution sources and implications for human health**
Afrim Syla

A181 **Structural analysis of fine particles using a Time-of-Flight Secondary Ion Mass Spectrometer**
A. Takami, N. Mayama, T. Sakamoto, K. Ohishi, S. Irei, A. Yoshino, S. Hatakeyama, K. Murano, Y. Sadanaga, H. Bandow, K. Misawa, M. Fujii

A182 **CANCELLED**

A183 **Estimating PM2.5 in the Stockholm region from spaceborne AOT measurements**
M. Tesche, P. Glantz

A184 **Reconciling aerosol light extinction from ground-based in-situ measurements and active satellite remote sensing**
M. Tesche, N. Rastak, P. Glantz, H.-C. Hansson, I. Riipinen, R. Charlson

A185 **Investigating the Formation of H2SO4 from ion-induced Oxidation of SO2**
N. T. Tsona, N. Bork, H. Vehkamäki

A186 **Chemical characterization of aerosol particles in Évora: comparison between summer and winter campaigns**
L. C. Tobias, N. Schiavon, K. Kandler, J. Mirão, F. Wagner

A187 **„Aerosol-fingerprint" of Europe in the atmosphere of Debrecen, Hungary**
Zsófia Török, Zsófia Kertész, Anikó Angyal, Enikő Furu, Zoltán Szoboszlai, Zita Szikszai, Ildikó Borbély-Kiss

A188 **Measurements of black carbon using the Transmissometer**
A. H. Tremper, D. C. Green, G. Fuller

A189 **Effect of organics and their hygroscopicity on cloud condensation nuclei (CCN) activity**
Deepika Bhattu, Sachchida Nand Tripathi

A190 **Estimation of source apportionment using the UNMIX model of ambient PM2.5 in Seoul area, Korea**
Yeong-Jin Jeong, Tae-Ho Lee and InJo Hwang

A191 **Ionic composition and metal content of PM10 samples collected along longitudinal and latitudinal transects in the Norwegian and Greenland Seas during the AREX 2011 cruise**
R. Udisti, S. Becagli, E. Bolzacchini, G. Calzolai, M. Chiari, L. Ferrero, D. Frosini, M. Marconi, M. G. Perrone, G. Sangiorgi, M. Severi, R. Traversi, W. Walczowski, R. Zanini, T. Zielinski

A192 **Project AEROLIT (Aerosol in Lithuania): Investigation of primary-secondary and regional-local contributions to particulate matter in the south-eastern Baltic region**
V. Ulevicius, A. S. H. Prévôt, K. Plauškaite, S. Byčenkiene, G. Mordas, V. Dudoitis, V. Remeikis, A. Garbaras, K. Kvietkus, I. Garbariene, J. Dommen, J. G. Slowik, C. Bozzetti, U. Baltensperger

A193 **Air masses types over the remote Alborán Island**
A. Valenzuela, F. J. Olmo, H. Lyamani, M. J. Granados Muñoz, J. L. Guerrero-Rascado, A. Quirantes, L. Alados-Arboledas

A194 **A LUR model for NO2 and BC to assess exposure of schoolchildren to traffic-related air pollution at their home address**
Martine Van Poppel, Evi Dons, Luc Int Panis

A195 **Košetice Observatory – The Czech Background Aerosol Supersite**
M. Váňa, J. Čech, A. Holubová, M. Pavelka, J. Ondráček, J. Schwarz, J. Smolík, N. Zíková, V. Ždímal

A196 **Source apportionment of carbonaceous PM2.5 with 14C analysis in Nagoya, Japan**
Fumikazu Ikemori, Koji Honjyo, Makiko Yamagami, Toshio Nakamura

A197 **Biomass burning in the Amazon Region: Characterization of airborne particle-phase Polycyclic Aromatic Hydrocarbons**
P. C. Vasconcellos, Nilmara de Oliveira Alves, Sofia Ellen da Silva Caumo, Paulo Artaxo, Sandra de Souza Hacon, Silvia Regina Batistuzzo de Medeiros

A198 **Optical and chemical characterization of biomass burning aerosols**
J. Vasilescu, L. Marmureanu, A. Nemuc, C. Talianu, L. Belegante

A199 **Chemical composition and hygroscopic properties of aerosol particles from Siberian boreal area**
S. Yu. Vasileva, G. N. Mironov, T. I. Rushkevich, S. S. Vlasenko, Xuguang Chi, A. V. Panov, M. O. Andreae, E. F. Mikhailov

A200 **Interpretation of Urban Particle-bound Polycyclic Aromatic Hydrocarbons Source Profiles of PMF with Known Site Specific Emission Characteristics**
E. H. Jang, M. S. Alam, R. M. Harrison

A201 **Water soluble ionic species of particulate matter in an urban road tunnel**
M. S. Vieira-Filho, R. Astolfo, J. J. Pedrotti, A. Fornaro

A202 **Determination of alkyl phenols in atmospheric aerosols by gas chromatography–ion trap mass spectrometry**
M. Visentin, M. C. Pietrogrande

A203 **Seasonal variations of organic carbon with different volatility at suburban site**
Petr Vodička and Jaroslav Schwarz

A204 **Ionic composition of PM10 and PM2.5 in the area of Thessaloniki, Northern Greece-Estimation of secondary inorganic aerosols and sea spray contribution**
D. Voutsa, C. Samara, E. Manoli, E. Gounari, D. Lazarou, P. Tzoumaka

A205 **One year analysis of sedimentation samples at Évora, Portugal**
F. Wagner, L. Tobias, K. Kandler, N. Schiavon, J. Mirão

A206 **Identification of parameters influencing the variability of particle number size distributions in Europe-a multi-site study**
C. von Bismarck-Osten, S. Weber

A207 **Vertical aerosol stratification above the Caribbean Sea near Barbados**
B. Wehner, F. Ditas, H. Wex, I. Serikov, A. Wiedensohler, H. Siebert

A208 **Methods and limits of unipolar charged aerosol inversion**
Z. N. Wei, L. Knobel, H.-J. Schmid

A209 **Alpha radioactive aerosols behavior in the ground atmosphere**
V. S. Yakovleva, M. S. Cherepnev, I. I. Ippolitov, P. M. Nagorsky, S. V. Smirnov, A. V. Vukolov

A210 **The role of condensable vapours in atmospheric new particle growth and shrinkage**
L.-H. Young, P.-S. Cheng, Y.-J. Liou, S.-H. Lee, V. P. Kanawade, T.-C. Hsiao

A211 **Evolution of n-Alkanes in PM samples collected in São Paulo, Brazil (2000-2010)**
P. C. Vasconcellos, Sofia Caumo, J. B. De Andrade

A212 **Comparison of particle number size distributions in three Central European capital cities**
N. Zíková, T. Borsós, D. Řimnáčová, J. Smolík, Z. Wagner, T. Weidinger, J. Burkart, G. Steiner, G. Reischl, R. Hitzenberger, J. Schwarz, I. Salma, V. Ždímal

A213 **CCN activation of insoluble silica aerosols mixed with soluble pollutants**
M. Dalirian, H. Keskinen, P. Miettinen, A. Virtanen, A. Laaksonen, I. Riipinen

A214 **CANCELLED**

Reserve Posters

A215 **Measurements During The South American Biomass Burning Analysis (SAMBBA) Field Experiment**
J. D. Allan, W. T. Morgan, P. I. Williams, M. Flynn, E. Darbyshire, A. Hodgson, B. T. Johnson, J. M. Haywood, S. Freitas, K. Longo, P. Artaxo, H. Coe

A216 **Characteristics of new particle formation events in Hungarian background air at K-puszta, 2008-2012**
Zs. Bécsi, Á. Molnár, K. Imre, P. P. Aalto

A217 **Long-term observations of carbonaceous aerosols and related gaseous emissions near a crude-oil plant in South Italy**
M. Calvello, M. Lovallo, F. Esposito, L. Mangiamele, G. Pavese

A218 **Wood-burning emissions within a continuous-flow photooxidation reactor: Soot-Particle Aerosol Mass Spectrometer characterization**
J. C. Corbin, A. Keller, H. Burtscher, B. Sierau, U. Lohmann, A. A. Mensah
CHANGED TO ORAL PRESENTATION

A219 **Characterising the influence of anthropogenic emissions on regional background aerosols at the puy de Dome station in France**
E. J. Freney, E. Asmi, M. Hervo, C. Rose, A. Colomb, K. Sellegri

A220 **Variations of levels of atmospheric electrical and meteorological parameters and natural radioactivity in response to heavy smog due to forest fires**
M. S. Cherepnev, A. V. Vukolov, I. I. Ippolitov, M. V. Kabanov, P. M. Nagorsky, Yu. A. Phalagov, S. V. Smirnov, V. S. Yakovleva

A221 **Road tunnels-particle properties, wet and dry conditions**
S. Janhäll, M. Gustafsson, S. Abbasi, G. Blomqvist, A. Gudmundsson, C. Johansson, M. Norman, U. Olofsson, B. Sjövall
CHANGED TO ORAL PRESENTATION

A222 **Winter particulate matter (PM10) sources for an Austrian-Slovenian border region**
M. Kistler, E. C. Cetintas, H. Bauer, A. Kasper-Giebl

A223 **Assessment of emission sources in an industrial area using instrumental and biomonitoring techniques**
J. Lage, S. M. Almeida, M. A. Reis, P. C. Chaves, M. C. Freitas, T. Ribeiro, S. Garcia, J. P. Faria, B. G. Fernández, H. Th. Wolterbeek

A224 **Relationship between oxidation level and optical properties of secondary organic aerosol**
A. T. Lambe, C. D. Cappa, P. Massoli, T. B. Onasch, S. D. Forestieri, A. T. Martin, M. J. Cummings, D. R. Croasdale, W. H. Brune, D. R. Worsnop, P. Davidovits
CHANGED TO ORAL PRESENTATION

A225 **Observations on atmospheric electricity and aerosol-cloud interactions**
Hanna E. Manninen, Hannes Tammet, Antti Mäkelä, Jussi Haapalainen, Sander Mirme, Tuomo Nieminen, Alessandro Franchin, Tuukka Petäjä, Markku Kulmala, Urmas Hõrrak

A226 **Effect of local pollutant sources on aerosol-cloud interactions at Puijo measurement station**
H. Portin, A. Leskinen, A. Kortelainen, L. Hao, P. Miettinen, A. Jaatinen, S. Romakkaniemi, A. Laaksonen, K. E. J. Lehtinen, M. Komppula

A227 **Intercomparison of sulphuric acid measurements and neutral cluster composition in the lower free troposphere**
L. Rondo, M. Simon, H. Junninen, J. Duplisy, A. Praplan, A. Adamov, A. Kürten, M. Sipilä, F. Bianchi, J. Tröstl, E. Weingartner, U. Baltensperger, M. Kulmala, J. Curtius

A228 **Air mass back trajectories and dry atmospheric aerosol mass size distributions in Prague**
J. Schwarz, L. Štefancová, W. Maenhaut, J. Smolík, W. Ždímal

A229 **Blue sky over the Ruhr – a review of the effectiveness of more than 50 years of air quality measures in Germany**
S. Wurzler, H. Hebbinghaus, P. Bruckmann, J. Friesel, U. Pfeffer

Poster Session B

Tuesday, September 3rd
Room: Zenit + Nadir

16:00-18:00 **Authors' Presentations**
Room: Zenit + Nadir

Aerosol Chemistry

B001 **Organic Aerosol Formation Photoenhanced by the Formation of Secondary Photo-sensitizers in ageing Aerosols**
Kifle Z. Aregahegn, Barbara Nozière, Christian George

B002 **H2SO4 formation from olefin ozonolysis in the presence of SO2: Influence of water vapour content and temperature**
T. Berndt, T. Jokinen, M. Sipilä, R. L. Mauldin III, H. Herrmann, F. Stratmann, H. Junninen, M. Kulmala

B003 **Development of a method to measure the δ13C for OC and EC in PM**
L. Bourcier, B. Geypens

B004 **Secondary organic aerosol formation in the ozonolysis of biogenic volatile organic compounds performed in a laminar flow reactor**
T. Braure, V. Riffault, A. Tomas, M. Duncianu, Y. Bedjanian, P. Coddeville

B005 **Geochemical anomalies in aerosol induced by mining and metallurgical activities in SW Spain**
J. de la Rosa, A. M. Sánchez de la Campa, Y. González-Castanedo, R. Fernández Camacho, J. C. Fernández Caliani, A. Alastuey, X. Querol

B006 **Synthesis and glass formation properties of compounds representative of low-volatility secondary organic aerosol particles**
H. P. Dette, M. Qi, D. C. Schröder, A. Godt, T. Koop

B007 **PM formation processes in the urban atmosphere: comparison between South and North Italy**
P. R. Dambruoso, G. de Gennaro, A. Di Gilio, P. Fermo, R. Gonzalez Turion, A. Piazzalunga

B008 **Formation mechanism and important implications of highly oxidized molecules (HOM) in the gas phase**
M. Ehn, E. Kleist, H. Junninen, M. Sipilä, T. Petäjä, I. Pullinen, M. Springer, S. Andres, M. Rissanen, J. Kontkanen, S. Schobesberger, F. Rubach, R. Tillman, B. H. Lee, F. Lopez-Hilfiker, V.-M. Kerminen, M. Kulmala, D. R. Worsnop, J. Thornton, J. Wildt, T. F. Mentel

B009 **Noise as an indicator of traffic and ultrafine particles in Huelva city**
I. M. Brito Cabeza, R. Fernández-Camacho, J. D. de la Rosa

B010 **Chemical characterization of PM2.5 belonging to a port city**
A. Genga

B011 **Temperature dependence of nopinone partitioning coefficient in organic aerosol**
B. Steitz, I. Gensch, T. Hohaus, H. Saathoff, A. Kiendler-Scharr

B012 **How did chemical composition of the Po Valley radiation fog change in the last twenty years?**
L. Giulianelli, M. C. Facchini, S. Gilardoni, S. Decesari, M. Rinaldi, C. Carbone, M. Paglione, S. Fuzzi

B013 **Speciation of metals in refinery emissions particles**
Y. González-Castanedo, D. A. Sánchez Rodas, C. Ferrer, J. de la Rosa

B014 **Thermal properties of secondary organic aerosols**
A. Lutz, E. U. Emanuelsson, Å. K. Watne, M. Hallquist

B015 **Diurnal variation of C2-C5 organosulfates detected during PEGASOS field campaign**
Yoshiteru Iinuma, Laurent Poulain, Dominik van Pinxteren, Hartmut Herrmann

B016 **Reactivity of chlorine radical on palmitic acid particles: kinetic measurements**
M. Mendez, R. Ciuraru, N. Visez, D. Petitprez

B017 **Characterization and interaction between bacterial community and chemical composition of Particulate Matter in two areas of Po Valley**
E. Innocente, G. Rampazzo, S. Squizzato, V. Bertolini, A. Franzetti, I. Gandolfi, G. Bestetti

B018 **Raman Microspectriscopic Identification and Characterization of Individual Airborne Volcanic Ash Particles**
N. P. Ivleva, S. Huckele, B. Weinzierl, C. Haisch, T. Baumann, R. Niessner

B019 **On the oxidation of gaseous iodine at elevated temperatures**
T. Kärkelä, J. Holm, A. Auvinen, C. Ekberg, J. K. Jokiniemi

B020 **Hygroscopicity of nucleated nanoparticles in the presence of sulfuric acid and organics**
J. Kim, H. Keskinen, P. Vaattovaara, P. Miettinene, J. Joutsensaari, A. Virtanen, CLOUD collaboration

B021 **Characterization of particulate matter in Kraków, Poland**
M. Kistler, L. Samek, K. Styszko, K. Szramowiat, L. Furman, M. Gerhardus, A. Kasper-Giebl

B022 **Molecular composition of PM2.5 aerosols from Cork Harbour, Ireland using ultrahigh resolution mass spectrometry**
I. Kourtchev, I. P. O'Connor, S. Fuller, K. Kristenen, W. Maenhaut, J. C. Wenger, J. R. Sodeau, M. Glasius, M.Kalberer

B023 **New experimental tools for characterization of nucleation and reactivity in small aerosols**
J. Lengyel, M. Fárník, P. Slavíček, T. Zeuch

B024 **NOx Effects on Secondary Organic Aerosol Formation of Biogenic and Anthropogenic Organic Gases**
J. H. Park, K. M. Jung, W. G. Woo, W. K. Jo, H. J. Lim

B025 **Temporal trends in the atmospheric concentration of selected metals in the PM10 aerosol collected in March-September 2010 at Ny-Ålesund (Svalbard Islands)**
M. Malandrino, A. Giacomino, O. Abollino, S. Becagli, D. Frosini, M. Severi, R. Traversi, R. Udisti

B026 **Within-city variability as a tool for source apportionment of trace elements. Application to the Barcelona metropolitan area**
M. C. Minguillón, M. Cirach, G. Hoek, B. Brunekreef, M. Nieuwenhuijsen, X. Querol

B027 **Real time chemical characterization of fine particulate matter in a Spanish regional background site**
M. C. Minguillón, A. Ripoll, N. Pérez, X. Querol, A. Alastuey

B028 **Vertical profiles and seasonal variation of aerosol particles in the PBL upon Ny Ålesund (Svalbard Islands): electron microscopy vs geochemical records**
B. Moroni, S. Becagli, E. Bolzacchini, M. Busetto , L. Ferrero, D. Frosini, C. Lanconelli, A. Lupi, M. Mazzola, R. Traversi, R. Udisti, V. Vitale, D. Cappelletti

B029 **Secondary organic aerosols (SOA) chemical characterization employing simulated NMR spectra of model compositions**
M. Paglione, F. Moretti, E. Tagliavini, E. Finessi, M. C. Facchini, S. Decesari

B030 **On the enigma of new particle formation in the atmosphere**
T.-E. Parts, A. Luts, K. Komsaare, M. Noppel, U. Hõrrak

B031 **Experimental studies of the formation of cluster ions formed by corona discharge in an atmosphere containing SO_2, NH_3 and H_2O**
Preben Hvelplund, Jens Olaf Pepke Pedersen, Kristian Støchkel, Martin B. Enghoff, Theo Kurtén

B032 **PAHs and ALKs in the Arctic (Svalbard Island) aerosol: results from the AREX2011 oceanographic campaign**
E. Bolzacchini, L. Ferrero, F. Marazzi, A. Molinelli, M. G. Perrone, G. Sangiorgi, S. Becagli, R. Traversi, R. Udisti, W. Walczowski, T. Zielinski

B033 **Chemical characterization of polar organic markers in PM 2.5 during an intensive campaign of Supersito Project in Po Valley (Italy)**
M. C. Pietrogrande, M. Visentin, D. Bacco, S. Ferrari, V. Poluzzi

B034 **Photodissociation dynamics of CF2Cl2 molecule in aerosol particles**
V. Poterya, A. Pysanenko, J. Lengyel, P. Svrčková, J. Kočišek, M. Fárník

B035 **Kinetic Measurements in Acoustically Levitated Terpene Droplets**
K. Rastogi, C. Yuan, R. Willoughby, S. Almabrok, C. Pfrang

B036 **Gas phase sampling and determination of carbonyl compounds in ship diesel emissions: Differences between light fuel oil and heavy fuel oil operation**
Ahmed A. Reda, G. Abbaszade, J. Lintelmann, H. Harndorf, R. Rabe, O. Sippula, T. Streibel, J. Schnelle-Kreis, R. Zimmermann

B037 **CANCELLED**

B038 **Regional scale oxidation of organic aerosol observed through HR-ToF-AMS measurements at Mt. Cimone (2165 m asl), Italy**
M. Rinaldi, S. Gilardoni, S. Decesari, S. Fuzzi, S. Ferrari, V. Poluzzi, M. C. Facchini

B039 **Investigation of the oxidation mechanism of limonene photosensitized by imidazole-2-carboxaldehyde and leading to aerosol growth**
S. Rossignol, L. Tinel, K. Aregahegn, L. Fine, B. Nozière, C. George

B040 **Impact on Air Quality operations cleaning and inspection of Natural Gas pipelines in Central Mexico**
L. M. Rodríguez, A. M. Sánchez de la Campa, Jesús D. Rosa

B041 **Characterization of fine particles in the near-field of a metallurgy plant: Overview of the NANO-INDUS project**
A. Setyan, P. Flament, N. Locoge, K. Deboudt, V. Riffault, L. Y. Alleman, C. Schoemaecker, J. Arndt, P. Augustin, F. Blond, F. Cazier, H. Delbarre, D. Dewaele, P. Dewalle, M. Fourmentin, P. Genevray, R. Healy, P. Le Louer, T. Leonardis, H. Marris, S. Mbengue, J. Wenger

B042 **Organic aerosol: distribution between fog water and interstitial air - a report for two mountainous sites in Germany**
S. Schüttauf, J. Matschullat, F. Zimmermann, D. van Pinxteren, H. Herrmann

B043 **Modelling the multiphase chemical processing of aerosol constituents in orographic hill cap clouds during HCCT-2010**
A. Tilgner, P. Bräuer, R. Wolke, H. Herrmann

B044 **Mass distribution of elements among four fractions of suspended dust in Zabrze, Poland**
W. Rogula-Kozłowska, K. Klejnowski, P. Rogula-Kopiec, B. Błaszczak, M. Mathews, S. Szopa

B045 **Thermal properties of SOA from Ozone and OH induced oxidation of terpenes**
J. Westerlund, Å. K. Watne, Å. M. Hallquist, M. Hallquist

B046 **Microstructural changes on the carbon functional groups of individual aerosol particles from cooking activities during photochemical oxidation**
E. Coz, I. El Haddad, S. Platt, J. G. Slowik, A. S. H. Prévôt, S. Steimer, G. Grzinic, M. Lampimäki, B. Artiñano, M. Ammann

B047 **Automatic hourly measurements of hydrocarbons (C2-C11) in Metropolitan Area of Sao Paulo: Spring campaign**
P. A. Dominutti, T. Nogueira, A. Fornaro, M. F. Andrade

B048 **Chemical composition of PM10 and PM1 at a remote mountain site in NE of Spain**
A. Ripoll, M. C. Minguillon, J. Pey, X. Querol, A. Alastuey

B049 **Profiles and seasonal-distribution of PAH and n-alkanes in the urban atmosphere of Elche, Spain**
J. Gil-Moltó, N. Galindo, M. Varea, C. Chofre

B050 **Organic and elemental carbon in the surroundings of a cement complex in southeastern Spain**
E. Yubero, N. Galindo, S. Nava, M. Chiari, J. Nicolás, G. Calzolai, F. Lucarelli, J. Crespo

B051 **ATD-GC-MS method for characterization and quantification of organic compounds associated to gunshot particles**
R. Magnusson, L. Hägglund, S. Hedenstierna, H. Wingfors

B052 **Differences between inorganic ion concentrations in an urban and a remote background station**
E. Yubero, J. F. Nicolás, N. Galindo, R. Soler, J. Crespo

B053 **Knudsen Cell measurements applied for the study of gaseous precursors and chemical process**
F. G. Di Lemma, J. Y. Colle, R. J. M. Konings

B054 **An ICP-MS analysis on aerosol from simulated nuclear fuel, to study the elemental**
F. G. Di Lemma, J. Y. Colle, G. Rasmussen, S. Van Winckel, R. J. M. Konings

B055 **Saturation vapour pressures of subcooled liquid oxodicarboxylic acids**
I. Crljenica, T. Yli-Juuti, A. A. Zardini, J. Julin, M. Bilde, I. Riipinen

B056 **Flow tube analysis of the chemical composition of freshly nucleated secondary organic aerosol particles**
S. G. Gonser , C. Berberich, A. Held

B057 **Secondary organic aerosol formation from gasoline and diesel vehicle emissions: first results from a new flow reactor**
R. J. Huang, J. G. Slowik, I. El Haddad, S. M. Platt, S. M. Pieber, A. A. Zardini, R. Suarez-Bertoa, S. Hellebust, B. Temime-Roussel, N. Marchand, L. Drinovec, G. Mocnik, C. Astorga, U. Baltensperger, A. S. H. Prévôt

B058 **Synthesis of Ag triangular nanoplates protected by glutathione and their interaction of hemoglobin**
N. Kinoshita, T. Ito, N. Nishida, H. Tanaka

B059 **First Steps in Atmospheric Particle Formation**
J. Fedor, J. Lengyel, J. Kocisek, V. Poterya, A. Pysanenko, P. Svrčková, M. Fárník

B060 **Interaction of gas-born Ag nanoparticles with DNAs of salmon testes**
M. Shibata, N. Nishida, H. Tanaka

B061 **Regional modelling of the tropospheric multiphase system using COSMO-MUSCAT: Sensitivity on detail of cloud microphysics and chemical mechanism**
R. Schroedner, A. Tilgner, R. Wolke

B062 **Extinction characteristics of SOA formed following the photolysis of 2-nitrophenol: A broadband study in the near-ultraviolet**
E. M. Wilson, J. C. Wenger, D. S. Venables

B063 **Changes of aerosol properties during the ozonolysis of unsaturated carboxylic acids in the absence and presence of oxygen**
C. Keunecke, M. Beck, T. Hoffmann, T. Zeuch

Aerosol Modelling

B064 **Long-Term Variability of Terrestrial, Terpenoid BVOC Emissions in the Last Millennium**
Juan C Acosta, Hamish Struthers, Eduardo Zorita, Annica ML Ekman, Alex Guenther, Ilona Riipinen

B065 **Applications of Multiple Regression Analysis to estimate Aerosol Optical Depth over the Arabian Gulf**
F. M. Al-Kandari, H. K. Al-Jassar, K. S. Rao

B066 **Simulation of ice nucleation in a parcel model**
C. Anquetil-Deck, C. Hoose, P. Conolly

B067 **Modelling Amazonian Biomass Burning Aerosol using WRF-Chem**
S. Archer-Nicholls, D. Lowe, W. Morgan, G. McFiggans

B068 **Modeling the chemical and radiative effects of aerosol during the wildfires of 2007 in Greece**
E. Athanasopoulou, D. Rieger, C. Walter, H. Vogel, B. Vogel, E. Gerasopoulos

B069 **Model simulations on the effects of deposition freezing in convective clouds**
K. Diehl, S. K. Mitra

B070 **On blow-up in some mathematical models related to phase transitions and turbulence**
E. I. Galakhov, O. A. Salieva

B071 **Modeling of optical properties sea-salt aerosol in the surface layer of the marine and coastal atmosphere**
G. A. Kaloshin

B072 **Coupled chemical mechanism and sectional aerosol developments within WRF-Chem**
D. Lowe, S. Archer-Nicholls, S. Utembe, D. Topping, M. Barley, R. Zaveri, G. McFiggans

B073 **WRF CHEM in the marine environment**
E. Miklos, D. Martin, C. D. O'Dowd

B074 **3D modeling of open-pored foams regarding particle deposition from aerosols**
K. Schmidt, A. Hellmann, S. Ripperger

B075 **Modelling the impact of mineral dust on air quality in Beijing during a dust event**
S. Schrader, B. Vogel, H. Vogel, K. Schaefer, R. R. Shen, R. Forkel, P. Suppan, G. Tang, Y. Wang, S. Norra

B076 **The model of propagation of acoustic signal on water surface with precipitated aerosol particles**
L. A. Uvarova, V. V. Zabolotin, I. V. Krivenko, T. V. Kazarova

B077 **Airport emissions characterized by multivariate nonlinear time series models**
G. Valotto, C. Varin, C. Gaetan, E. Pecorari, G. Rampazzo, D. Bassano, S. Sollecito, E. Rampado

B078 **Photophoresis of fractal-like aerosol particles: physical model and methodical approaches**
M. V. Vasiljeva, S. A. Beresnev, L. B. Kochneva, V. I. Gryazin

B079 **Modelling the chemically speciated PM2.5 over the French Northern region using the WRF-Chem system coupled to EMEP and regional emission inventories**
M. Mendez, V. Fèvre-Nollet, P. Lebègue, D. Petitprez, N. Visez, R. Borge

B080 **Black carbon and particle number emission factors of different vehicle types measured in real driving conditions**
I. Ježek, D. Westherdal, G. Močnik

B081 **Modelled and measured aerosol hygroscopicity for aerosol corrosion prevention and energy saving in green data center designing**
L. Ferrero, G. Sangiorgi, M. G. Perrone, M. Moscatelli, L. D'Angelo, G. Rovelli, A. Ariatta, R. Truccolo, E. Bolzacchini

B082 **CANCELLED**

B083 **The role of organic condensation on ultrafine particle growth during nucleation events**
D. Patoulias, I. Riipinen, S. N. Pandis

B084 **Computational modeling of aerosol formation and evolution using OpenFOAM®**
E. M. A. Frederix, A. K. Kuczaj, M. Nordlund, C. Winkelmann, B. J. Geurts

B085 **CANCELLED**

B086 **CANCELLED**

B087 **CANCELLED**

B088 **Modeling of long-term particle formation and growth in the planetary boundary layer**
L. Zhou, M. Boy, T. Nieminen, D. Mogensen, S. Smolander, M. Kulmala

B089 **Long range transport and chemical transformation of aerosols over the Aegean Sea during a recent Etesian period**
E. Athanasopoulou, A. Protonotariou, E. Bossioli, J. Allan, A. Dandou, G. Papangelis, H. Coe, A. Bacak, J. Kalogiros, N. Mihalopoulos, G. Biskos, M. Tombrou

B090 **On the influence of WRF schemes in reconstructing the Planetary Boundary Layer height in the Po Valley**
A. Balzarini, M. Moscatelli, F. Angelini, L. Ferrero, G. Pirovano, G. M. Riva, E. Bolzacchini

B091 **Multicomponent aerosol modelling with detailed chemical species**
A. Rusanen, M. Boy, S. Smolander, D. Mogensen, P. Roldin, E. Hermansson

B092 **Phenomenological modelling of particle resuspension on bubbling PMMA**
S. Delcour, F.-X. Ouf, N. Azema, A. Coppalle, J. Yon, L. Ferry, F. Gensdarmes, J.-M. Lopez-Cuesta

B093 **Ageing of Sodium Combustion Aerosols: a Theoretical and Experimental Study**
E. Mathé, M. P. Kissane, D. Petitprez

B094 **A modeling study of regional sources contributin to atmospheric PM2.5 of Taiwan**
Tu-Fu Chen, Wen-Yinn Lin, Ken-Hui Chang

B095 **The Contribution of Local and Regional Sources to Particulate Matter in European Megacities**
K. Skyllakou, A. G. Megaritis, C. Fountoukis, B. N. Murphy, P. E. Haralabidis, S. N. Pandis

B096 **Transport of aerosol particles from the Fukushima accident**
G. Lujaniene, S. Bycenkiene, P. P. Povinec

B097 **Cs, Am and Pu isotopes in the atmosphere: source terms and tracer studies**
G. Lujaniene, D. Valiulis, S. Byčenkiene, J. Šakalys, P. P. Povinec

B098 **Comparison of the results of two air quality models in the simulation of a turbo gas cogeneration plant PM emissions**
P. Ugolini, A.Trentini, G.Bonafé, V.Poluzzi

B099 **On an influence of a temperature jump on a molecular heat flow which is taken away from a surface of strongly heated solid spherical aerosol particle**
E. R. Shchukin, L. A. Uvarova, N. V. Malay, Z. L. Shulimanova

B100 **A novel method to determine the growth rate of a growing particle mode**
T. Anttila, J. Leppä, H. Lihavainen

B101 **Determination of geometrical length of airborne carbon nanotubes by filtration method**
Y. K. Bahk, J. Wang

B102 **Modelling of aerosol optical properties with CHIMERE and OPAC and validation with Brewer and Cimel measurements at Brussels, Belgium**
V. De Bock, A. Delcloo, A. Mangold, H. De Backer

B103 **Modelling of air quality: number of particles**
S. Deschamps, K. N. Sartelet, F. Freutel

B104 **Influence of the geometry of the aerosol conducting system on the deposition of particles from inhalable aerosols on cellular surfaces in vitro**
C. Brodbeck, D. Ritter, J. Knebel

B105 **Comparison of the atmospheric Chemistry Transport Model COSMO-MUSCAT with experimentally determined aerosol parameters**
C. Engler, R. Wolke, W. Birmili, A. Wiedensohler

B106 **Year-round modelling study on particle formation a South African savannah**
R. Gierens, L. Laakso, V. Vakkari, L. Zhou, D. Mogensen, J. P. Beukes, P. G. Van Zyl, M. Boy

B107 **Binary aerosol droplet formation**
X. Z. Zhen, H.-J. Schmid

B108 **Modelling the fine and coarse fraction of heavy metals in high resolution Spanish domains**
M. A. González, M. G. Vivanco

B109 **Measurement and 3D Simulation of NaCl aerosol deposition on electrically charged microfibers**
A. Hellmann, K. Schmidt, M. Pitz, S. Ripperger

B110 **Black carbon and organic carbon in Finland: Measurements vs. model**
A. Hienola, J.-P. Pietikäinen, D. O'Donnell, K. Saarnio, A. Laaksonen

B111 **Modelling aerosol agglomeration using molecular dynamics methodology**
G. Inci, A. Kronenburg

B112 **Identification of atmospheric PM2.5 sources using Non-negative Matrix Factorization modeling in urban-industrial mixed environments**
A. Kfoury, F. Ledoux, A. Limem, G. Delmaire, G. Roussel, D. Courcot

B113 **Mathematical study of penetration efficiency of aerosol particles for human breathing with protective facemask**
I. T. Mukhametzanov, S. K. Zaripov, A. K. Gilfanov

B114 **Diagrams for drift acceleration of inclusion in acoustic field**
D. A. Gubaidullin, P. P. Osipov

B115 **Comparison of two airports emissions and pollutants dispersion in urban areas**
E. Pecorari, G. Valotto, S. Squizzato, G. Rampazzo, D. Bassano, S. Sollecito, E. Rampado

B116 **CANCELLED**

B117 **A methodology to assess occupational exposure to MNMs by modeling**
M. Pilou, T. Oroz, C. Vaquero Moralejo, P. Neofytou, C. Housiadas

B118 **The charging of amine containing clusters using protonated acetone**
K. Ruusuvuori, P. Hietala, O. Kupiainen, T. Kurtén, H. Vehkamäki

B119 **Influence of the inlet particle diameter distribution on the experimental determination of cyclone collection efficiency**
B. Sagot, J. Giardi

B120 **CANCELLED**

B121 **Novel informatics software for automated individual aerosol component property predictions and complex ensemble predictions – an online community facility**
D. Topping, M. Bane, M. Barley, D. Lowe, R. Pinning, G. McFiggans

B122 **Modeling global secondary organic aerosol formation and growth: Integrating the volatility basis set into the EMAC chemistry climate model**
A. P. Tsimpidi, V. A. Karydis, S. N. Pandis, J. Lelieveld

B123 **Source apportionment of PM2.5 concentrations: comparison of source-oriented and receptor-oriented techniques**
G. Pirovano, C. Colombi, G. Lonati, A. Balzarini and G. M. Riva

B124 **Periodic changes in the parameters of finite coagulating systems with sources and sinks at steady state regime approach**
V. A. Zagaynov, A. Maslov, A. A. Lushnikov, I. E. Agranovski, A. B. Leontyev, Yu. G. Biryukov

B125 **Efficiency of inertial capture of aerosol particles by porous fiber in cylinder array**
S. K. Zaripov, O. V. Grigorieva, S. A. Soloviev

Aerosol-based Nanotechnology

B126 **Direct Transfer of Aerosol Particles into Liquid Suspensions**
C. Anderlohr, K. Schaber

B127 **Dependency of particle size on filtration mechanisms of nanofiber web**
H.-J. Choi, S. B. Kim, S. H. Kim, M.-H. Lee

B128 **Aerosol Synthesized Porous Catalytic Particles for Emission Control Applications**
G. Kastrinaki, M. Kostoglou, A. G. Konstandopoulos

B129 **Aerosol nanoparticles captured into colloids by using an electrospray cloud as a filter**
M. Valenti, G. Biskos, A. Kourmouli, A. Schmidt-Ott

B130 **CANCELLED**

B131 **The measurement of nanoparticle deposition efficiency in the lungs of Wistar rats**
S. G. Matveeva, A. M. Baklanov, T. G. Tolstikova, S. W. Ankow

B132 **Experimental study of homogeneous nucleation from the antimony supersaturated vapor**
O. V. Borovkova, A. M. Baklanov, S. V. Vosel, F. B. Baimasheva

B133 **CANCELLED**

B134 **Real-time Characterization of Fractal-like Aerosols**
M. L. Eggersdorfer, A. J. Gröhn, C. M. Sorensen, P. H. McMurry, S. E. Pratsinis

B135 **Potential exposure to nanoplates during blending of halloysite nanoclay powder**
E. Jankowska, J. Łukaszewska, W. Zatorski

B136 **Dustiness testing of engineered nanomaterials based on ZrO2 by vortex shaker method**
E. Jankowska, P. Sobiech, J. Łukaszewska, O. Witschger, S. Bau, B. Bianchi

B137 **An effort towards understanding the sources of impurities in generating nanoparticles via liquid-phase methods**
E. M. Faghihi, L. Morawska, C. He

B138 **New measurement system for PM and ultrafine particles**
J. Spielvogel, M. Weiß

B139 **Nanoparticles generation modes of the multi-spark discharge generator**
A. A. Efimov, V. V. Ivanov, I. V. Beketov, I. A. Volkov

B140 **Size Controlled Synthesis of Spherical Nanoparticles by Spark Discharge**
J. Feng, A. Maisser, T. Pfeiffer, G. Biskos, A. Schmidt-Ott

B141 **CANCELLED**

B142 **Fluid-Particle Dynamics of Nanoparticle Synthesis in Flame Spray Reactors**
A. J. Gröhn, S. E. Pratsinis, K. Wegner

B143 **Generation of Mn oxides nanoparticles**
P. Mikuška, Z. Večeřa, B. Dočekal, P. Moravec

B144 **Synthesis of N-modified TiO2 nano powder by plasma spray for visible light photocatalysis**
C. H. Tsai, Y. M. Kuo, Y. I. Tsai, L. C. Wang, Y. F. Wang

B145 **Experimental study of homogeneous nucleation from the sulfur supersaturated vapor: Evaluation of the surface tension of critical nucleus**
S. V. Valiulin, S. V. Vosel, A. A. Onischuk, V. V. Karasev

B146 **Cu-Ni spark discharge nanoparticles from alloy feedstock of varied composition**
M. Wagner, M. Seipenbusch

B147 **Simulation of the flow field in a nanoparticle synthesis spray flame reactor including a particle coating process**
C. Weise, I. Wlokas, A. Kempf

B148 **Emission spectroscopic investigation of the spark discharge used for Cu nano particle production**
A. Kohut, A. Metzinger, G. Galbács, L. Ludvigsson, B. O. Meuller, M. E. Messing, Zs. Márton, K. Deppert, Zs. Geretovszky

B149 **Characterization of Carbon Nano-Particles from the Clad of Nuclear Fuel in HTGR with Inherent Safety (I) - Qualitative Analysis**
H. Nishida, G. Iwanaka, H. Takano, M. Itoh

B150 **Synthesis and characterization of calcium oxide based particles for CO2 adsorption applications**
K. G. Sakellariou, G. Kastrinaki, G. Karagiannakis, A. G. Konstandopoulos

B151 **Detection of Airborne Carbon Nanotubes via Embedded Nickel Catalysts in Quasi-Real Time**
N. Neubauer, G. Kasper

B152 **Acute respiratory response on workers exposure to nanoparticles in different occupational settings**
I. Szadkowska-Stańczyk, S. Bujak-Pietrek, U. Mikołajczyk

B153 **Testing particulate matter toxicity via in vitro methods: what should be tested?**
A. J. Wlodarczyk, K. A. BéruBé

B154 **The impact of zinc oxide nanoparticles on metabolic activity in the cells of respiratory and reproductive system**
L. Zapór

B155 **A new device for continuous unattended measurements of UFP**
M. Pesch, H. Grimm, R. Albrecht, A. Edfelder

B156 **Portable device for simultaneous measurements of Nano particles and it agglomerations at workplaces**
H. Grimm, M. Pesch, M. Richter, A. Comouth

B157 **Combustion of CNT-containing composite materials in a laboratory scale incinerator**
A. M. Todea, B. Stahlmecke, C. Asbach, T. A. J. Kuhlbusch

B158 **Characterization of Polyamide Nanofiber Media for Aerosol Filtration Applications**
J. Matulevicius, L. Kliucininkas, D. Martuzevicius

B159 **Sublimation growth of 3C-SiC in induction heating of preceramic Si-C nanoparticles**
M. Miettinen, J. Hokkinen , T. Karhunen, T. Torvela, U. Tapper, J. Jokiniemi, A. Lähde

B160 **Generation of Pb/PbOx nanoparticles for inhalation experiments**
P. Moravec, J. Smolík, J. Ondráček, P. Vodička, R. Fajgar

B161 **Batch-to-batch reproducibility - a challenge for safety assessment and regulation**
H.-R. Paur, C. Adelhelm, S. Diabaté, J. Forsgren, E. Mahon, S. Mülhopt, J. P. Bagaria, V. Puntes, R. Schneider, C. Weiss, T. Wilkins, Y. Jiang

B162 **Contrasting manufactured nano objects emitted during maintenance of common particle generators with originally synthesized particles**
P. T. Nilsson, L. Ludvigsson, J. Rissler, M. E. Messing, C. Isaxon, A. C. Eriksson, M. Hedmer, H. Tinnerberg, K. Deppert, A. Gudmundsson, J. Pagels

B163 **Fragmentation of nanoparticle agglomerates by collisions in supersonic flows**
Y. Okada, N. Oshio, K. Oda, M. Yabuhana

B164 **High-throughput multi-jet electrospinning for two fluids using a coaxial grooved nozzle**
I. Park, W. Kim, S. S. Kim

B165 **Impact of size and concentration on the particle charging properties of an annular DBD**
M. Pesch, H. Grimm, T. Külz, M. Richter, R. Albrecht

B166 **Positioning of nano-sized noble metal aerosols in an organic light-emitting diode for enhanced quantum efficiency**
H.-K Sung, J.-C. Lee, J.-K. Lee, C. Kim, M. Choi

Combustion Aerosols

B167 **Penetration of Combustion Aerosol Particles through an N95 FFR Respirator Filter**
S. A. Grinshpun, X. He, J. Y. Kim, T. Reponen

B168 **Selective catalytic reduction nitrogen oxides with methane over nanosized CuO supported on Al2O3. Part 1. Materials structural characterization**
Chang-Mao Hung, Mu-Hsing Kuo, Shui-Jen Chen, Wei-Bang Lin, Wen-Liang Lai

B169 **Selective catalytic reduction nitrogen oxides with methane over nanosized CuO supported on Al2O3. Part 2. Catalytic activity and mechanism study**
Chang-Mao Hung, Mu-Hsing Kuo, Shui-Jen Chen, Wei-Bang Lin, Wen-Liang Lai

B170 **Selective catalytic reduction nitrogen oxides with methane over nanosized CuO supported on Al2O3. Part 3. Reaction kinetic behavior study**
Chang-Mao Hung, Mu-Hsing Kuo, Shui-Jen Chen, Wei-Bang Lin, Wen-Liang Lai

B171 **Characterization of aerosols emitted during the incineration of nanocomposites**
G. Ounoughene , O. Le Bihan, C. Chivas-Joly, C. Longuet, A. Joubert, C. Motzkus, D. Venditti , S. Durécu, B. Debray, J-M. Lopez-Cuesta, L. Le Coq

B172 **Particle Emission from the Aircraft Engine Testing Cycles**
J. J. Rodríguez-Maroto, V. Archilla, D. Sanz-Rivera, E. Rojas-García, M. Pujadas, J. L. Mosquera, D. Mercader, A. Gonzalez (ISDEFE), A. Jimenez, J. Mena, A. Entero (ISDEFE), J. M. Fernández-Mainez, J. C. Bezares

B173 **Gas-droplet flows in fire safety engineering**
K. Volkov, V. Emelyanov

B174 **The nanofraction of fly ashes in Swiss waste incineration plants (WIP) and the respective modelled contributions of engineered nanomaterials (ENM)**
J. Buha, N. Müller, B. Nowack, A. Ulrich, J. Wang

B175 **Tandem-DMA measurements of gases and particles in large-scale biomass combustion and gasification**
D. Gall, M. Pushp, C. Forsman, K. O. Davidsson, M. Hallquist, J. B. C. Pettersson

B176 **Condensing Heat Exchanger for Fine Particle Precipitation and Efficient Heat Recovery in Small Scale Wood Combustion**
J. Grigonyte, O. Sippula, I. Nuutinen, T. Koponen, H. Lamberg, T. Kaivosoja, J. Jokiniemi

B177 **Effect on pore size distribution on filtration performance of ceramic filter media**
J.-U. Kim, H.-J. Choi, S.-H. Kim, M.-W Lee

B178 **Characterizing physical properties of aerosol particles in a bubbling fluidized bed boiler**
H. Kuuluvainen, P. Karjalainen, J. Maunula, J. Kauppinen, M. Räsänen, R. Taipale, P. Vainikka, J. Roppo, J. Keskinen, T. Rönkkö

B179 **Diagnostics of burning tungsten particles by two-color imaging pyrometry**
S. G. Orlovskaya, F. F. Karimova, M. S. Shkoropado

B180 **Fate of hazardous elements from biomass burned in stoves and boilers**
Torben Seidel, Hans Ruppert

B181 **Biomass Combustion in Stoves - Influence on Emissions and Toxic Potential of Particles**
C. Schön, H. Hartmann, J. Gerth

B182 **Ultrafine particulate matter emissions from a gasoline direct injection engine**
B. R'Mili, A. Boréave, W. Y. Hernandez, M. N. Tsampas, N. Charbonnel, L. Retailleau-Mevel, B. D'Anna, ¨ P. Vernoux, M. Leblanc, S. Zinola, S. Raux

B183 **Fractional cabin air recirculation: A simple and robust way to reduce PM exposure for passengers**
H. Jung, M. Grady

B184 **Particle emissions of a heavy duty diesel engine fuelled with fossil diesel and hydrotreated vegetable oil**
P. Karjalainen, J. Heikkilä, T. Rönkkö, M. Happonen, F. Mylläri, L. Pirjola, T. Lähde, D. Rothe, J. Keskinen

B185 **Particle number and size distribution of Euro 5 and Euro 6 passenger cars at 22°C and -7°C**
F. Riccobono, U. Manfredi, G. Martini

B186 **Investigations on the removal of volatile components from diesel exhaust**
B. Kiwull, J. C. Wolf, R. Niessner

B187 **Effects of severe congestion on PAH emissions from a heavy vehicle diesel engine**
M. Vojtisek-Lom, M. Pechout, M. Mazač, J.Topinka

B188 **Emissions of gases and PM2.5 during combustion of wood logs in a stove or a fireplace**
V. Martins, A.I. Calvo, C. Alves, T. Nunes, R. Hillamo, K. Teinilä, M. Duarte, L. Mendes, L. A. C. Tarelho

B189 **Combustion of forest residues in a bubbling fluidised bed: characterisation of particulate matter emissions**
A. I. Calvo, L. A. C. Tarelho, E. R. Teixeira, R. Modolo, C. Alves, T. Nunes, M. Duarte, E. Coz, D. Custódio, A. Castro, B. Artiñano, R. Fraile

B190 **Prospecting analysis of soot for post-fire investigation**
A. Bellivier, M. Meneceur, H. Bazin

B191 **Nanoparticles Emissions from Pottery Manufacturing**
A. Voliotis, S. Bezantakos, M. Giamarelou, G. Biskos

B192 **Wildfires in North Spain: Smoke aerosol and its radiative effects**
A. Castro, E. Alonso-Blanco, A. I. Calvo, V. Pont, M. Mallet, C. Alves, R. Fraile

B193 **Influence of biodiesel-to-diesel addition on major ions and trace elements in fine particulate matter exhausted by a diesel engine**
G. O. da Rocha, J. V. S. Santos, A. C. D. Regis, L. Tormen, A. L. N. Guarieiro, J. D. S. da Silva, A. J. Curtis, J. B. de Andrade

B194 **Effective density of particulate matter emitted from aircraft gas turbine engine sources**
L. Durdina, B. Brem, M. Abegglen, B. Sierau, J. Wang

B195 **Particulate matter generated by heating/cooking plants in traditional homes of Mt. Everest region in central southern Himalaya (Nepal)**
P. Fermo, A. Piazzalunga, R. Gonzalez, D. Comunian, G. Tartari, F. Salerno, G. Viviano, P. Ielpo

B196 **New CO2 Mitigation Process with Diesel Dynamo Power Plant Associated by Optimized Aerosol Driven Technique**
K. Fukamizu, H. Takano, M. Itoh

B197 **Investigating the aethalometer model to estimate black carbon and airborne particles from wood burning**
G. W. Fuller

B198 **CANCELLED**

B199 **Reduction of PAHs emitted from a generator fuelled by waste-edible-oil-biodiesel with acetone and isopropyl alcohol addition**
Jen-Hsiung Tsai, Shui-Jen Chen, Wen-Yinn Lin, Kuo-Lin Huang, Chih-Chung Lin, Yung-Shun Chen

B200 **Cytotoxicity of exhaust emissions from a generator fuelled by waste-edible-oil-biodiesel with acetone and isopropyl alcohol addition**
Jen-Hsiung Tsai, Shui-Jen Chen, Kuo-Lin Huang, Wen-Yinn Lin, Yi-Chu Huang, Te-San Chen

B201 **Characteristics of SO2 removal by using CaCO3 sorbent particle in an oxy-PC combustion system**
Seongha Jeong, Kang Soo Lee, Sang In Keel, Jin Han Yun, Sang Soo Kim

B202 **Dry absorption of SO2 with hydrated lime in spout-bed circulating dry scrubber system**
Young-Ok Park, Seong-Min Cheon, Yong-Ha Kim

B203 **Real-time chemical composition analysis of particle emissions from woodchip combustion**
A. Kortelainen, J. Joutsensaari, P. Tiitta, A. Jaatinen, P. Miettinen, L. Hao, J. Leskinen, A. Virén, T. Torvela, J. Tissari, J. Jokiniemi, D. R. Worsnop, A. Laaksonen, A. Virtanen

B204 **Ash behaviour and emission formation in co-combustion of wood and two agricultural fuels**
M. Kortelainen, J. Tissari, T. Torvela, T. Karhunen, H. Lamberg, I. Nuutinen, O. Sippula, J. Jokiniemi

B205 **Characteristics of the particulate matter from road tunnel environment**
R. Licbinsky, J. Huzlik, J. Faimon, K. Kreislova

B206 **On the relation between aerodynamic and mobility diameter distributions for aggregates consisting of few monomers**
A. Melas, M. Kostoglou, P. Baltzopoulou, Y. Drossinos, A. G. Konstandopoulos

B207 **Immunomodulatory effects of short-term exposure to fine particulate matter from smog episode in Ostrava region: in vitro study**
T. Brzicová, I. Lochman, P. Danihelka, A. Lochmanová, K. Lach, V. Mička

B208 **PAH, PCDD/F and HCB emissions from residential wood combustion**
K. Mõts, M. Maasikmets, E. Teinemaa, K. Vainumäe, L. Lehes, T. Arumäe, V. Kimmel

B209 **Toxicological Responses to Ozone Aging of Aerosols from Small-scale Biomass Combustion**
E. Z. Nordin, O. Uski, R. Nyström, P. Jalava, J. Genberg, A. C. Eriksson, C. Bergvall, R. Westerholm, C. Boman, J. Jokiniemi, J. Pagels, M.-R. Hirvonen

B210 **Fourier-transform-ion-cyclotron-resonance mass spectrometry with laser-desorption-ionization of primary ship diesel exhaust particles**
C. Rüger, T. Schwemer, M. Sklorz, R. Zimmermann

B211 **Removal Characteristics of Iron Particles by Ceramic Candle Filters and the Effect of the flue Gas Inlet Configuration in Particulate Collectors**
Y. O. Park, N. Hasolli

B212 **Chemical profile of wood burning PM2.5 and PM1 in the two largest cities of Greece, Athens and Thessaloniki**
St. Pateraki, Th. Maggos, D. A. Sarigiannis, M. Kermenidou, S. K. Karakitsios, V. D. Assimakopoulos, A. Zagkos, D. N. Asimakopoulos

B213 **Emissions of volatile organic compounds from ritual burning practices**
Shamsh Perver, Rajan Chakrabarty, Barbara Zielinska, Shippi Dewangan

B214 **Particle and gas phase distribution of toxic metals during biomass combustion**
D. Pudasainee, H.-R. Paur, A. Bologa, H. Seifert

B215 **Laboratory particle-phase emissions from sugarcane burning: chemical and mutagenicity**
E. R. Dias, K. F. Souza, D. A. Morales, F. Kummrow, G. A. Umbuzeiro, L. R. F. Carvalho

B216 **Characterisation of different soot types regarding morphology and black carbon content**
H. Saathoff, A. Comouth, B. Altstädter, C. Linke, A. Kiselev, K.-H. Naumann

B217 **Characterization of indoor and outdoor aerosol during extreme pollution events from winter heating in single-family home districts**
I. Stasiulaitiene, E. Krugly, L. Kliučininkas, T. Prasauskas, M. Tichonovas, A. Garbaras, D. Martuzevičius

B218 **Verifying modified EAD (MEAD) used in measuring metal fume nanoparticle and charactering its exposure concentration during gas metal arc and flux cored arc welding processes**
P. J. Tsai, Y. F. Wang

B219 **Particle size distributions of PAHs in workplace atmospheres and their exposure concentrations to workers in a steal and iron manufacturing factory**
Y. F. Wang, P. J. Tsai

B220 **Comprehensive analysis of anthropogenic aerosol using automated classification for GCxGC-TOF analysis**
B. A. Weggler, J. Orasche, T. Groeger, R. Zimmermann

B221 **Physical and chemical characterisation of PM emissions from in-operation ship engines**
J. Moldanová, E. Fridell, H. Winnes, J. Boman, V. Tishkova, B. Demirdjian, S. Joulie, H. Bladt, N. Ivaleva

B222 **Exposure to airborne (1-3)-B-D-glucans during metalworking processes**
M. Cyprowski, A. Lawniczek-Walczyk, R. L. Górny

B238 **Nanoparticle release from nanostructured powders during low- and high-energetic dry dispersing processes**
D. Göhler, M. Stintz

B239 **Characterization of Carbon Nano-Particles from the Cladof Nuclear Fuel in HTGR with Inherent Safety(II) –Quantitative Analysis**
G. Iwanaka, H. Nishida, H. Takano, M. Itoh

B240 **Risk assessment of airborne engineered nanomaterials**
A. J. Koivisto, A.-K. Viitanen, T. Hussein, T. Kanerva, T. Tuomi, H. Stockmann-Juvala, K. Hämeri

B241 **Stability of nanoparticle agglomerates in flames - First results of investigations on the release during waste incineration**
I.-M. Liesen, W. Baumann, M. Hauser, H. Mätzing, H.-R. Paur, H. Seifert

Reserve Posters

B223 **Uptake of N2O5 to citric acid aerosol particles**
G. Gržinić, T. Bartels-Rausch, A. Türler, M. Ammann

B224 **Pressure dependency of ozonolysis product formation of α-pinene focusing on low volatile compounds such as organic acids and dimeric compounds**
M. Beck, C. Keunecke, T. Zeuch, T. Hoffmann

B225 **Dry deposition of electrosprayed liquid suspensions**
S. Martin. B. Martinez-Vazquez, P. L. Garcia-Ybarra, J. L. Castillo

B226 **Effect of Nucleation Precursors on the Atmospheric Oxidation of Organic Compounds**
J. Elm, M. Bilde, K. V. Mikkelsen
CHANGED TO ORAL PRESENTATION

B227 **Quantitative single particle mass spectrometry with the Aerodyne aerosol mass spectrometer: development of a new classification algorithm and application to field data**
F. Freutel, F. Drewnick, J. Schneider, T. Klimach, S. Borrmann

B228 **Smoke particle morphology for different fire types determined by equivalent ratio tube furnace method**
Jaehark Goo

B229 **Industrial by-products as precursors for gas-phase nanoparticle synthesis**
T. Karhunen, A. Lähde, T. Torvela, J. Jokiniemi

B230 **Dilution affects particle properties originating from residential biomass combustion**
H. Lamberg, T. Kaivosoja, J. Leskinen, M. Kortelainen, A. Viren, H. Koponen, V. Tiihonen, M. Miettinen, J. Pyykönen, J. Jokiniemi, J. Tissari

B231 **A novel set-up for source characterization and human exposures of biomass combustion aerosols**
R. Nyström, E. Z. Nordin, J. H. Pagels, A. Blomberg, T. Sandström, C. Boman

B232 **Synthesis of tailored organic-inorganic nanostructures by charge controlled coagulation**
S. Sigmund, E. Akgün, J. Meyer, M. Wörner, G. Kasper

B233 **Contribution of Inorganic aerosols and trace gases due to biomass burning during cooking hours at a rural site in India**
Sudha Singh, Gyan Prakash Gupta, Bablu Kumar, U. C. Kulshrestha

B234 **Dependence of Aircraft Smoke Number on Black Carbon Size Distribution**
M. E. J. Stettler, J. J. Swanson, A. M. Boies

B235 **Characterisation of solid and semi-volatile gas-turbine particulate matter using a catalytic stripper**
J. J. Swanson, T. J. Johnson, J. S. Olfert, M. P. Johnson, P. I. Williams, G. J. Smallwood, A. M. Boies

B236 **Impact of biogenic emissions on PM2.5 concentration over Europe**
E. Tagaris, R. E. P. Sotiropoulou, N. Gounaris, S. Andronopoulos, D. Vlachogiannis

B237 **Climate and biofuels in Brazil**
H. Vuollekoski, R. Makkonen, A. Asmi, R. Hillamo, T. Petäjä, M. Kulmala

Poster Session C

Thursday, September 5th
Room: Zenit + Nadir

16:00-18:00 **Authors' Presentations**
Room: Zenit + Nadir

Electrical Effects

C001 **Incineration of the diesel particulate matter using the dielectric barrier discharge on the electrostatic precipitator**
Y. Ehara, M. Kobayashi, H. Muramatsu, A. Zukeran, H. Kawakami, T. Inui

C002 **Manipulation of aerosol particles with nonlinear polarizability**
K. V. Generalov, D. V. Korneev, V. M. Generalov, M. V. Kruchinina, B. N. Zaycev

C003 **An ESP nanoparticle generator**
C. W. Lin, W. Y. Lin, T. C. Hisao, Y. M. Kuo, C. C. Chen

C004 **Experimental study of a louvered electrostatic precipitator**
Hso-Chi Chaung, Tsai-Yun Wu

C005 **Open Channel Electrospray System**
J. S. Kang, J. H. Jung, G.-N. Bae

C006 **Effect of aperture rate on improving collection efficiency in hole-type electrostatic precipitator**
H. Kawakami, A. Osako, Y. Watanabe, Y. Ehara, Y. Nitta, A. Zukeran, T. Inui

C007 **The Effect of Surface Charge on Characteristics of Fibrous Membrane**
Y. R. Jhong, H. Y. Lin, S. K. Chan, T. M. Tu, Y. C. Cheng, Y. Y. Chang, C. W. Chen, W. Y. Lin

C008 **Characterization of an ion jet unipolar electrical aerosol diffusion charger**
Wen-Yinn Lin, Ken-Hui Chang, Chih-Chieh Chen, Shao-Hao Lu, Yuan-Yi Chang, Jin-Yuan Syu

C009 **SO2 Reduction by water condensation for marine diesel**
A. Zukeran, K. Ninomiya, Y. Ehara, K. Yasumoto, H. Kawakami, T. Inui

Fundamentals

C010 **Modifications to the bipolar charging theory for spherical particles**
J. L. de La Verpillière, J. J. Swanson, A. M. Boies

C011 **Restructuring of Aggregates and their Primary Particle Size Distribution during Sintering**
M. L. Eggersdorfer, S. E. Pratsinis

C012 **Acoustic waves in vapour-gas mixtures with polydispersed particles and droplets**
Yu. V. Fedorov, D. A. Gubaidullin, D. D. Gubaidullina

C013 **Multiscale design of aerosol synthesis of materials: Effect of structure on TiO2 & SiO2 particle growth by coagulation and sintering**
E. Goudeli, M. L. Eggersdorfer, S. E. Pratsinis

C014 **Dynamics of aerosols and particles at nonlinear oscillations in tubes**
D. A. Gubaidullin, R. G. Zaripov, L. A. Tkachenko

C015 **De-agglomeration and bounce of the iron oxide agglomerates due to the impaction**
M. Ihalainen, T. Lind, T. Torvela, J. Ruusunen, A. Lähde, P. Tiitta, J. Jokiniemi

C016 **Propagation of acoustic disturbances in N-fractional gas-liquid systems**
D. A. Gubaidullin, A. A. Nikiforov, E. A. Teregulova, R. N. Gafiyatov

C017 **Experimental investigation dynamics of aerosols at oscillations in tubes in a no shock-wave mode**
D. A. Gubaidullin, R. G. Zaripov, L. A. Tkachenko

C018 **Calculation of deposition on fibrous filters due to impaction – critical trajectories**
S. J. Dunnett, C. F. Clement

C019 **Study of filtration performances of fibrous media: comparison between flat and industrial-geometry prototypes filters**
L. F. Gonzalez, A. Joubert, Y. Andrès, C. Delahaye, N. Berthelot, X. Chaucherie, L. Le Coq

C020 **Degradation of glass fiber filter media exposed to acidic and alkaline contaminants**
Myong-Hwa Lee, Jeong-Uk Kim, Eunsol Kim

C021 **Filtration characteristics of air filter loaded with differently charged particles**
H. S. Park

C022 **Influence of particle and filter charge on collection efficiency of air filters in an externally applied electric field**
H. S. Park

C023 **The analytical description of the dynamics of the impurity redistribution in the composite particles by coagulation**
D. V. Tsaplin, V. N. Piskunov

C024 **Detection of the negative thermophoresis phenomenon in microgravity experiments**
A. A. Vedernikov, S. A. Beresnev, A. V. Markovich

C025 **Contribution to the study of particle resuspension kinetics during thermal degradation of polymers**
S. Delcour, F.-X. Ouf, N. Azema, A. Coppalle, J. Yon, L. Ferry, F. Gensdarmes, J.-M. Lopez-Cuesta

C026 **Determining the mass accommodation coefficient of dicarboxylic acids using molecular dynamics simulations**
Jan Julin, Ilona Riipinen

C027 **Size dependence of incorporation of gas molecules into aerosol nanoparticles**
V. V. Levdansky, J. Smolík, V. Ždímal, P. Moravec

C028 **Influence of size effect on chemical reactions on surface of aerosol nanoparticles**
V. V. Levdansky, J. Smolík, V. Ždímal, P. Moravec

C029 **Evolution of Size and Temperature of Droplets in the Process of Bulk Condensation**
N. M. Kortsenshteyn, A. K. Yastrebov

C030 **Nucleation near critical supersaturation**
Z. Kožíšek, P. Demo

C031 **Heterogeneous nucleation on partially wettable charged conducting seed particle**
M. Noppel, H. Vehkamäki, P. M. Winkler, M. Kulmala, P. E. Wagner

C032 **The Role of Highly Oxidized Organics in New Particle Formation**
I. K. Ortega, H. Vehkamäki

C033 **Linking Neutral and Charged Sulfuric Acid - Ammonia and Sulfuric Acid - Dimethylamine Clusters**
I. K. Ortega, O. Kupiainen, T. Olenius, V. Loukonen, T. Kurten, H. Vehkamäki

C034 **Determination of Nanoparticles Surface Tension from Experimental Data on Homogeneous Nucleation of Ibuprofen Vapors**
A. V. Samodurov, A. M. Baklanov, S. V. Vosel

C035 **Development of an Experimental Flow Configuration for the Study of the Effects of Mixing on the Nucleation and Growth of Liquid Droplets**
G. Scribano, A. O. Alshaarawi, K. Zhou, A. Attili, F. Bisetti

C036 **Systematic correlation between aerodynamic shape factor and optical properties**
S. Pfeifer, T. Mueller, A. Wiedensohler

C037 **CANCELLED**

C038 **Experiments on neutral cluster generation and detection below 2 nm size**
J. Kangasluoma, H. Junninen, M. Sipilä, M. Kulmala, T. Petäjä

C039 **A method to determine the size distribution of recombination products from atmospheric measurements**
J. Kontkanen, T. Nieminen, H. E. Manninen, K. Lehtipalo, V-M. Kerminen, K. E. J. Lehtinen, M. Kulmala

C040 **Generation of sub-Nanometer Atomic Clusters in the Aerosol Phase using Spark Discharge Generation (SDG)**
A. Maisser, K. Barmpounis, M. B. Attoui, G. Biskos, A. Schmidt-Ott

C041 **Calculation of dynamic properties of fractal aggregates in the transition regime**
A. D. Melas, A. G. Konstandopoulos, L. Isella, Y. Drossinos

C042 **Analysis of the Current Models of Aerosol Dry Deposition**
V. N. Piskunov

C043 **CANCELLED**

Instrumentation

C044 **Comparisons of Rman- and WALI- derived aerosol optical properties during HyMeX**
M-L. Boytard, P. Royer, P. Chazette, J. Totems, X. Shang, F. Marnas

C045 **Determining effective density of nanostructured particles by tandem electrical mobility and mass measurement (tandem DMA/APM): application to thermal spraying fumes**
S. Bau, A. Charvet, D. Bémer, D. Thomas

C046 **Direct analysis of secondary organic aerosol using atmospheric-pressure glow discharge mass spectrometry**
M. Brüggemann, T. Hoffmann

C047 **Aerosol detection and ranging: fast laser imaging optical emission spectroscopy (DARLIOES)**
S. Mitachi, M. M. Cazacu, A. Timofte, D. Dimitriu, S. Gurlui

C048 **Measurement of solid particle concentration is aided by catalytic stripper technology**
J. J. Swanson, H.-J. Schulz

C049 **A new Instrument to Observe Contact Freezing of Single Supercooled Levitated Water Droplets**
H.-J. Tong, F. D. Pope, M. Kalberer

C050 **On-board study of nano- and micrometer-particle characteristics of a running electric train**
S. Abbasi, U. Olofsson, T. Tritscher, T. Krinke

C051 **A new device for the investigation of nucleation, dynamic growth and surface properties of single ice crystals**
J. Voigtländer, C. Chou, H. Bieligk, T. Clauss, P. Herenz , D. Niedermeier, J. Z. Ulanowski, F. Stratmann

C052 **A real-time analyzing and weighing system**
D. Weidauer, C. Bey, F. Freyer, N. Derenda

C053 **Review of the field experiments on the transfer of pollution in urban areas in 1979 and 2003**
Yu. S. Balashov, V. N. Piskunov

C054 **Comparing particle number size distributions and number concentrations for airborne nanoparticles measured by SMPS, FMPS and UWCPC**
S. Bau, V. Hase, P. Danihelka, O. Witschger

C055 **UFP measurement: comparison of commercial equipments using different measuring principles**
B. Bergmans, F. Lenartz, J. Mertens, N. Faniel, T. Krinke

C056 **Comparison among un-denuder filter based, denuder filter pack and continuous techniques for inorganic artefact assessment**
P. R. Dambruoso, G. de Gennaro, A. Di Gilio, P. Fermo, R. Filardi, A. Piazzalunga, R. Gonzalez Turion, R. Vecchi

C057 **Comparison of On-line and Off-line methods for the quantification of particle bound Reactive Oxygen Species**
S. J. Fuller, F. P. H. Wragg, M. Kalberer

C058 **Inter-comparison of size distribution measurements in cloud expansion studies**
E. Järvinen, M. Schnaiter, P. Vochezer, K. Höhler, N. Hiranuma, O. Möhler

C059 **Validating SMPS-measured size distribution of double-mode spherical Silica nanoparticles by Transmission Electron Microscope (TEM)**
E. M. Faghihi, L. Morawska, G. Johnson, T. Bostrom

C060 **Application and recalibration of a GRIMM spectrometer in the monitoring of Sahara dust**
C. Pio, J. Cardoso, T. Nunes, C. Alves, M. Cerqueira, S. M. Almeida, M. Almeida-Silva, M. C. Freitas

C061 **Description of the aerosol size distribution of the atmosphere during a Saharan dust intrusion over South Spain with airborne and ground based instrumentation: AMISOC**
N. Seoane Vieira, J. Andrey-Andrés, M. Sorribas, A. Corrales Sierra, R. González-Armengod, M. Gil, B. de la Morena, B. Marqués

C062 **Model 3088 Advanced Aerosol Neutralizer: Comparisons with Previous Generation**
J. H. Scheckman, S. Elzey, J. E. Farnsworth, B. Osmondson

C063 **Black carbon measurements in snow with the single particle soot photometer**
J. Svensson, D. Brus, A.-P. Hyvärinen, H. Lihavainen

C064 **RADES (RAdiological Dispersion Events Set-up) set-up and result from the characterization of the aerosol from simulated RDE´s (Radiological Dispersion Events)**
F. G. Di Lemma, J. Y. Colle, H. Thiele, M. Ernsteberg, R. J. M. Konings

C065 **A laboratory evaluation of four commercial particle sizers under several aerosol types**
G. C. Dragan, J. Schnelle-Kreis, E. Karg, R. Zimmermann

C066 **On-line Diagnostics for Particle Size in Nanoparticle Manufacturing**
A. J. Gröhn, M. L. Eggersdorfer, S. E. Pratsinis, K. Wegner

C067 **XPS analysis of size-segregated aerosol collected in an urban background site in Lecce (Italy)**
M. R. Guascito, P. Ielpo, D. Cesari, A. Genga, C. Malitesta, D. Chirizzi, D. Contini

C068 **Characterization of filter materials for aerosol research – size resolved penetration**
J. Ondráček, N. Zíková, V. Ždímal

C069 **Data Merging of Size Distributions from Electrical Mobility and Optical Measurements**
T. Tritscher, A. F. Zerrath, S. Elzey, H. S. Han

C070 **Tandem of Differential Mobility Analyzer and Centrifugal Particle Mass Analyzer: application to hygroscopic growth of aerosol particles**
S. S. Vlasenko, E. F. Mikhailov

C071 **Steady-state mass-mobility measurements of cigarette smoke using a CPMA**
T. J. Johnson, R. Cabot, C. Treacy, C. Dickens, J. McAughey, C. U. Yurteri, J. P. R. Symonds, J. S. Olfert

C072 **Assessment of Voltage Shift in Tandem DMAs by Brownian Particle Trajectory Simulation**
M. Alonso, F. J. Alguacil, J. P. Santos, V. Gómez

C073 **Instrumental optimization of the compact laser mass spectrometer LAMPAS 3 for on-line single particle analysis under various field conditions**
K.-P. Hinz, A. Fendt, B. Spengler

C074 **Multi-Element Scanning Thermal Analysis (MESTA) of Aerosols and Nano-Carbon Particles**
Y. P. Hsieh, G. Bugna, K. Robertson

C075 **Study on particle capture characteristics and numerical analysis for impaction sizer**
C-H Huang, C-J Wu, Y-Y Chang

C076 **Consistency of Long-term Black Carbon Trends from Thermal and Optical Measurements in the U.S. IMPROVE Network**
L.-W. A. Chen, J. C. Chow, J. G. Watson, B. A. Schichtel

C077 **Black Carbon in Dust and Geological Material: Reconciling Thermal/Optical and Spectral Quantification Methods**
L.-W. A. Chen, Y. M. Han, J. A. Robles, J. C. Chow, J. J. Cao, J. G. Watson

C078 **Airspace Dimension Test (ADT) – A novel technique for diagnosis of chronic obstructive pulmonary disease with nanoparticles**
J. Jakobsson, J. Kumlin, J. Hedlund, P. Wollmer, J. Löndahl

C079 **Remotely operated PLUS-octocopter used as an aerosol measurement platform**
P. Madl, C. Oberauer, F. Steinhäusler

C080 **A CAPS-Based Single Scattering Albedo Monitor**
T. B. Onasch, P. Massoli, P. L. Kebabian, A. Freedman

C081 **Performance Enhancements to TSI Water-based Condensation Particle Counters**
J. H. Scheckman, S. Morell and F. Quant

C082 **Evaluation and development of Scanning Flow CCN Analysis**
C. Wittbom, B. Svenningsson, S. Sjogren, E. Swietlicki

C083 **Generation and growth of aerosol particles on nucleus of radioactive decays**
V. A. Zagaynov, N. A. Klyachin, N. P. Kalashnikov, A. A. Lushnikov, I. E. Agranovski, Yu. G. Biryukov

Particle-Lung Interactions

C084 **Biological response in lung cells by brake dust from a novel set-up to generate one source wear particles**
S. Abbasi, B. Ekstrand-Hammarström, U. Bergström, A. Bucht, U. Olofsson, U. Sellgren, A. Jansson

C085 **A multiculture cell exposure chamber for the assessment of airborne and engineered nanoparticles effects on health**
A. Asimakopoulou, E. Daskalos, N. Lewinski, E. Papaioannou, A. G. Konstandopoulos

C086 **Effect of flow rate on fiber deposition in the model of human lungs**
M. Bělka, F. Lízal, M. Jicha, J. Jedelsky

C087 **A portable device to measure puffing behaviour and tobacco smoke exposure**
C. Graham, S. Slayford

C088 **In vivo measurements of nanometer-sized particle deposition in the nasal cavities of Taiwanese adults**
D. J. Hsu and C. W. Lee

C089 **Role of size and composition of traffic and wood burning aerosols in the molecular responses induced in airway epithelial and pulmonary artery endothelial cells**
L. Boublil, M. Lisbonne-Autissier, M. Thierry-Mieg, M. Leroux, J. P. Savineau, L. Martinon, J. Sciare, K. Andreau, A. Baeza-Squiban, I. Baudrimont

C090 **In vitro efficiency measurements of the deposition of pMDI generated aerosols in a realistic central airway geometry**
A. Kerekes, A. Nagy, M. Veres, D. Oszetzky, A. Czitrovszky

C091 **Aerosol Deposition Measurement in the Model of Human Lungs**
F. Lízal, J. Jedelský, J. Adam, M. Bělka, M. Jícha

C092 **Airspace dimension test (ADT) with nanoparticles for identification of patients with respiratory disease**
J. Löndah, J. Jakobsson, T. Andersson, P. Wollmer

C093 **CANCELLED**

C094 **Experimental investigation of the transport and deposition of ambient aerosols in the human airways**
A. Nagy, A. Kerekes, A. Czitrovszky

C095 **Coincidental study of inhalation and intratracheal instillation for hazard assessment of nanoparticles**
T. Oyabu, Y. Morimoto, M. Horie, Y. Yoshiura, M. Shimada, M. Kubo, B. W. Lee, T. Okada, T. Myojo

C096 **HEAPS study design: Health Effects of Air Pollution in Antwerp Schools**
E. Dons, M. Van Poppel, S. De Prins, L. I. Panis, G. Koppen

C097 **Differential uptake kinetics of nitrogen dioxide on various pollen grains**
N. Visez, G. Chassard, S. Gosselin, M. Choël, D. Petitprez

C098 **Characterisation of an analysis system used to quantify health-relevant reactive oxygen species (ROS) in atmospheric aerosol particles**
F. P. H. Wragg, S. J. Fuller, M. Kalberer

Indoor and Working Place Aerosols

C099 **Analysing biological activity of dust from moisture damaged buildings: Relation of microbial components with toxicity**
K. Huttunen, J. Tirkkonen, E. Krop, M. Täubel, J. Pekkanen, A. Hyvärinen, D. Heederik, J.-P. Zock, M.-R. Hirvonen

C100 **Environmental monitoring to inform built environments vulnerability to airborne disease transmission**
Z. A. Nasir, L. Campos, M. Canales, L. Ciric, I. Colbeck

C101 **Air concentration of ultra-fine particles released from the Diesel engines**
S. Bujak-Pietrek, U. Mikołajczyk, I. Szadkowska-Stańczyk

C102 **Workers exposure to carbon black dust containing nano-sized particles**
U. Mikołajczyk, S. Bujak-Pietrek, I. Szadkowska Stańczyk

C103 **Tests of the personal respiratory protective equipment using radioactive aerosols**
P. Otahal, J. Vosahlik, I. Burian

C104 **Verification of airflow patterns and leakage of contaminants from fume cupboard**
T. Jankowski

C105 **Effect of air exchange rate on the removal of aerosol in a test chamber**
T. Prasauskas, L. Gagyte, A. Jurelionis, D. Ciuzas, E. Krugly, L. Seduikyte, D. Martuzevicius

C106 **Coarse and fine particulate emissions from drilling activity**
F. Azarmi, P. Kumar, M. Mulheron

C107 **Particle concentrations and radon equilibrium ratios in an occupied auditorium**
I. Bilska, M. R. Dudzinska, K. Kozak, J. Mazur, B. Polednik

C108 **Assessment of fungal aerosol in different type of residential buildings located in the city free of flood**
K. Bródka, M. Sowiak, M. Wojtania, A. Kozajda, I. Szadkowska-Stańczyk

C109 **Indoor air in child homes related to selected home characteristic**
M. Sowiak, K. Bródka, A. Kozajda, M. Wojtania, I. Szadkowska-Stańczyk

C110 **Indoor particles collected passively in urban and rural primary schools of Portugal**
N. Canha, S. M. Almeida, M. C. Freitas, H. T. Wolterbeek

C111 **Filtration of an ultrafine aerosol produced by thermal spraying using a granular bed**
D. Bémer

C112 **Physical parameters of powders and release of aerosol**
P. Görner, R. Wrobel, M. Knider, A. Boivin, F. Clerc

C113 **PM10 and PM2.5 air pollution in Chinese village homes in the Xuanwei region**
Fengxia Li, Jürgen Schnelle-Kreis, Gülcin Abbaszade, Bernhard Michalke, Ralf Zimmermann, Jing Wang, Shao Longyi

C114 **Indoor particle load caused by burning of different types of candles and incense**
C. Heuck, S. A. Hofmann, A. Hubach, J. Mehlhorn, S. Titel, K. Wissmüller, K. A. Kamilli, S. G. Gonser, A. Held

C115 **Influence of food surface area on PM2.5 and particle number concentration during frying**
M. Amouei Torkmahalleh, Y. Zhao, P. K. Hopke, A. Rossner, A. R. Ferro

C116 **Air Quality in London Paddington Train Station**
U. Chong, J. J. Swanson, A. M. Boies

C117 **Source characterisation and estimation of daily residential exposure to ultrafine particles**
C. Isaxon, A. Wierzbicka, E. Z. Nordin, A. Dahl, G. Wieslander, M. Bohgard

C118 **VOC and particle emissions from a household cleaning product**
A. W. Nørgaard, J. D. Kudal, I. K. Koponen, P. Wolkoff

C119 **Radon progeny particle concentration changes in an air-conditioned auditorium**
B. Polednik, M. R. Dudzinska, K. Kozak, J. Mazur, D. Grzadziel

C120 **Exposure to indoor air pollutants during physical activity in gymnasiums**
C. A. Ramos, S. M. Almeida, H. T. Wolterbeek

C121 **Investigation of particulate matter from wave soldering processes at a printed circuit board manufacturing company**
Z. Szoboszlai, Zs. Kertész, Z. Szikszai, A. Angyal, E. Furu, Zs. Török, L. Daróczi, Á. Z. Kiss

C122 **Comparative study of indoor aerosols collected at educational institutions: kindergarten, elementary school, and secondary grammar school**
Z. Szoboszlai, E. Furu, A. Angyal, Zs. Török, Zs. Kertész

C123 **Seasonal behavior of indoor and outdoor PAHs in different microenvironments of Rome, Italy**
M. P. Gatto, A. Gordiani, P. Romagnoli, C. Balducci, M. Perilli, A. Cecinato, M. Gherardi

C124 **Indoor/outdoor ratio and percent distribution behaviours of PAHs in Rome, Italy**
P. Romagnoli, C. Balducci, M. Perilli, A. Cecinato, M. Gherardi, M. P. Gatto

C125 **Seasonal and weekly modulations of Psychotropic Substances (PSs) in Rome, Italy**
P. Romagnoli, F. Sacco, C. Balducci, M. Perilli, A. Cecinato

C126 **Spatial and seasonal variation of nitrogen dioxide and ozone in modern office buildings**
T. Szigeti, V. G. Mihucz, P. M. Bluyssen, P. Carrer, A. Cattaneo, D. Cavallo, H. J. M. Cornelissen, S. Dimitroulopoulou, S. Fossati, C. Mandin, E. Oliveira de Fernandes, K. K. Kalimeri, Y. de Kluizenaar, R. Pereira, Y. Sakellaris, D. E. Saraga, J. G. Bartzis

C127 **Indoor air quality in Lahore, Pakistan**
I. Colbeck, Z. A. Nasir, Z. Ali, S. Safdar

C128 **Indoor air quality in university**
S. W. Chen, K. D. Mena, P. S. Chen

C129 **Concentrations of Indoor Submicrometer and Supermicrometer Particulate Matter in a Primary School in Prague**
J. Stolcpartova, M. Branis, J. Hromadka

C130 **PM2.5 in modern office buildings: elemental characterization and oxidative potential**
T. Szigeti, C. Dunster, F. J. Kelly, Zs. Kertész, A. Cattaneo, Gy. Záray, V. G. Mihucz

C131 **Characterization of the bacterial and fungal bioaerosols in three elementary schools in Kaohsiung**
M. C. Wang , K. D. Mena, P. S. Chen

C132 **Exposure Assessment of Ozone in Elementary Schools in Kaohsiung, Taiwan**
Y. C. Lin, K. D. Mena, P. S. Chen

C133 **Real-time Monitoring Of PM2.5 In Primary School**
Y. C. Lin, K. D. Mena, P. S. Chen

C134 **Ultrafine particles counts in elementary school in Taiwan**
M. C. Wang, K. D. Mena, P. S. Chen

C135 **The distribution of PM10, PM2.5, and PM1 concentrations in primary schools in Kaohsiung, Taiwan**
S. W. Chen, K. D. Mena, P. S. Chen

C136 **Clean air delivery rate (CADR) analysis based on energy consumption for different air flow rates of air cleaners**
B. Han, J. S. Kang, H. J. Kim, Y. J. Kim

C137 **Characterization of particular matters in subway HAVC system**
S. Huang, Y. M. Jo

C138 **The effect of controlled indoor activities on the particulate matter mass and number**
S. E. Chatoutsidou, N. Serfozo, I. Kopanakis, T. Glytsos, M. Lazaridis

C139 **Survivability of yeast in an electrodynamic balance**
Y. M. Kuo, S. H. Huang, W. Y. Lin, S. C. Teng, C. C. Chen

C140 **Evaluation on removal performance of air cleaning devices against airborne allergen particles using an optical particle counter and ELISA method**
H. J. Kim, B. Han, Y. J. Kim

C141 **Aerosol Particles in the Indoor Environment of the Týn Church in Prague**
L. Mašková, J. Smolík

C142 **Air Quality in Different Types of Archives**
L. Mašková, J. Smolík

C143 **Alveolar dose of ultrafine particles for children in urban environments**
M. Mazaheri, S. Clifford, M. A. Megat Mokhtar, F. Fuoco, G. Buonanno, L. Morawska

C144 **Subway platform air quality: assessing the influences of tunnel ventilation, train "piston effect" and station design**
T. Moreno, N. Pérez, C. Reche, E. de Miguel, M. Capdevila, S. Centelles, J. Jaume, A. Alastuey, X. Querol

C145 **The effect of biomass burning on PM exposure during wintertime**
D. A. Sarigiannis, S. Karakitsios, M. Kermenidou

C146 **Particle release from open ethanol fireplaces into the indoor environment**
T. Schripp, E. Uhde, S. Wientzek, M. Wensing, T. Salthammer

C147 **Nanoparticle Enhanced PCR Detection of Bacterial Aerosols**
Siyu Xu, Maosheng Yao

C148 **Direct Viral Aerosol Inactivation by Microwave Irradiation and its Mechanisms**
Yan Wu, Maosheng Yao

C149 **Improving the Efficiencies of Andersen Impactors Using Mineral-Oil-Spread Agar Plate**
Maosheng Yao, Zhenqiang Xu, Kai Wei, Yan Wu, Fangxia Shen, Qi Chen, Mingzhen Li

C150 **Cancer risk assessment for the inhalation exposure to particulate matters and polycyclic aromatic hydrocarbons from household cooking in northern Taiwan**
K.-P. Yu, K. R. Yang, S. C. Lung, C.-H. Liu

C151 **Enhancement effect of O3 on the antifungal efficacy of nano-metals supported TiO2 on resistant mold spores**
K.-P. Yu, Y.-T. Huang, S.-C. Yang

C152 **Organic composition of indoor/outdoor particles in an elementary school**
C. A. Alves, R. C. Urban, P. N. Pegas, T. Nunes

C153 **Indoor air quality in school buildings in the city of Sosnowiec, Poland**
P. Z. Brewczyński, E. Krakowiak, J. Kurek, A. Wlazło, M. Zaciera

C154 **Assessing the contribution of indoor particulate matter sources in residential homes in a northern province of Italy**
P. Fermo, A. Piazzalunga, J. Tarlassi, A. Cattaneo, P. Urso, M. G. Perrone

C155 **Assessment of population exposure to PM2.5 and PM10 in the Athens metropolitan area**
V. Aleksandropoulou, M. Lazaridis

C156 **Measurement of Non-Volatile Particulate Matter Mass Emission Indices of Aircraft Gas Turbine Sources**
B. T. Brem, L. Durdina, J. Wang

C157 **CANCELLED**

C158 **Dynamic Changes of the Aerosol Composition and Concentration During Different Burning Phases of Wood Combustion**
M. Elsasser, C. Busch, J. Orasche, C. Schön, H. Hartmann, J. Schnelle-Kreis, R. Zimmermann

C159 **PM10 chemical composition in at street canyon and urban locations in London, UK**
D. C. Green, A. H. Tremper

C160 **Particles in road and railroad tunnel air - properties, sources and abatement possibilities**
M. Gustafsson, S. Abbasi, G. Blomqvist, A. Gudmundsson, S. Janhäll, C. Johansson, M. Norman, U. Olofsson, B. Sjövall, H. Wilhelmsson

C161 **Study on design optimization of HI-FILTER SYSTEM by using CFD**
Youn Suk Kang, Hye Mi Lim, Cheol-Gyu Lee, Du-Hun Jang

C162 **PM trends, chemical composition and source apportionment of particulate matter in Mediterranean countries: Results from the Med-Particles project**
A. Karanasiou, X. Querol, A. Alastuey, C. Perrino, J. de la Rosa, G. Berti, B. Artiñano, J. Sunyer, F. Forastiere, M. Stafoggia, the Med-Particles Study Group

C163 **Overview of the AIRUSE project: Testing and Development of air quality mitigation measures in Southern Europe**
A. Karanasiou, F. Amato, T. Moreno, A. Alastuey, M. Viana, F. Lucarelli, S. Nava, G. Calzolai, C. Pio, C. Alves, T. Nunes, K. Eleftheriadis, E. Diapouli, V. Vasilatou, E. Monfort, I. Celades Lopez, R. M. Harrison, D. Beddows, X. Querol

C164 **Particle size distributions of combustion aerosol of various local fuel mixtures**
E. Krugly, E. Puida, K. Buinevičius, L. Kliučininkas, I. Stasiulaitiene, A. Minikauskas, D. Martuzevičius

C165 **Analysis of intrapersonal variance of hourly PM exposures**
P. Lipponen, O. Hänninen, J. Kolomazníková, M. Braniš

C166 **Real-time relationship between digital visibility and PM2.5 at the middle of Taiwan**
C.-H. Luo, S. Yang

C167 **On the fine and the coarse fractions of atmospheric aerosol**
M. Manigrasso, A. Febo, P. Avino

C168 **Nanoparticle contribution to elemental concentration in atmospheric particulate matter**
S. Canepari, M. L. Astolfi, M. Marcoccia, D. Frasca, C. Perrino

C169 **Primary aerosols from ship diesel engine exhaust within the framework of HICE measurement campaign**
L. Mueller, G. Jakobi, M. Elsasser, B. Stengel, R. Rabe, O. Sippula, E. Karg, M. Sklorz, T. Streibel, J. G. Slowik, A. S. H Prevot, J. Schnelle-Kreis, R. Zimmermann

C170 **Study of the aerosol elemental composition with high time resolution: preliminary results from the AIRUSE LIFE+ Project**
S. Nava, G. Calzolai, M. Chiari, F. Lucarelli, F. Amato, A. Karanasiou, X. Querol, C. Alves, M. Duarte, T. Nunes, C. Pio, K. Eleftheriadis, D. Beddows, R. M. Harrison

C171 **Characterisation of winter aerosols in the Helsinki region by TEM/EDX individual particle analysis**
J. V. Niemi, S. Saarikoski, K. Saarnio, A. Frey, A. Kousa, H. Kuuluvainen, L. Pirjola, T. Rönkkö, R. Hillamo

C172 **Development of a non-destructive method based on infrared analysis for quantification of ionic components in atmospheric particulate matter**
A. Piazzalunga, D. Ballabio, V. Bernardoni, P. Fermo, U. Molteni, P. Prati, R. Vecchi, G. Valli

C173 **Micromarkers of source-specific combustion aerosols**
O. B. Popovicheva, E. D. Kireeva, N. M. Persiantseva

C174 **Meteorological and chemical factors triggering an exceptional PM pollution episode in wintertime in the Po Valley, Italy**
V. Poluzzi, D. Bacco, G. Bonafé, C. Maccone, S. Ferrari, R. Vecchi, S. Decesari, I. Ricciardelli

C175 **Comparison of particle number concentration and PM2.5 chemical species in urban and rural sites in Po Valley (I) during measurement program in the Supersito project**
I. Ricciardelli, D. Bacco, F. Scotto, A. Trentini, A. Vagheggini, V. Poluzzi

C176 **Organic aerosols from residential wood burning emissions analysed by Ultra-high resolution mass spectrometry**
A. G. Rincón, C. Alves, M. Dietzel, M. Kalberer

C177 **A highway study of PM and black carbon (BC) in Flanders (Belgium)**
D. Roet, J. Vercauteren, C. Matheeussen, E. Roekens

C178 **Urban organic aerosols ultrafine particles compositions: a high-resolution mass spectrometry characterization**
G. Salque-Moreton, R. Jacob, D. Voisin, F. Donnaz, J.-L. Jaffrezo, J.-L. Besombes, R. Thissen

C179 **Organic and elemental carbon associated to PM10 and PM2.5 in the urban atmosphere - Estimation of secondary organic carbon**
C. Samara, D. Voutsa, A. Kouras, K. Eleftheriadis, Th. Maggos, D. Saraga, M. Petrakakis

C180 **Study of Trace Metals and Free Radical Generation in Particulate Matter in Pune**
P. G. Satsangi, Suman Yadav, Amruta P. Kodre, Ritwika Roy

C181 **The influence of children jumping on the bed on PM10/PM2.5/PM1 concentration profile**
C. L. Yeh, K. D. Mena, P. S. Chen

C182 **Summer and winter time aerosol levels at an urban Mediterranean environment: Impacts of biomass burning**
M. Psichoudaki, E. Kostenidou, A. Bougiatioti, S. Bezantakos, G. Biskos, A. Nenes, S. N. Pandis

C183 **An integrated source apportionment study: Positive Matrix Factorization vs. the Chemical Transport Model CAMx**
M. C. Bove, P. Brotto, F. Cassola, E. Cuccia, D. Massabò, A. Mazzino, P. Prati

C184 **Characterization of PM10 sources in the central Mediterranean Basin**
G. Calzolai, S. Nava, M. Chiari, F. Lucarelli, S. Becagli, R. Traversi, M. Marconi, F. Rugi, R. Udisti, A. di Sarra, G. Pace, D. Meloni, C. Bommarito, D. M. Sferlazzo

C185 **Size-segregated source apportionment of aerosol using water soluble components**
D. Cesari, D. Contini, A. Genga, M. Siciliano, P. Ielpo, M. R. Guascito, M. Conte

C186 **The Impact of Select Pollutant Sources on Air Quality for Ostrava and the Moravian-Silesian Metropolitan Region by the Positive Matrix Factorization model**
L. Černikovský, J. Novák, H. Plachá, B. Krejčí, I. Nikolova, E. Chalupníčková, T. Conner, G. Norris, K. Kovalcik, D. Olson, J. Turlington, C. Croghan, R. Willis, R. Williams

C187 **Source apportionment of PM2.5 at Abu Dhabi sites**
C. Hak, S. López-Aparicio

C188 **Comparison of PMx collected at sites with different level of air pollution using iron oxides as magnetic tracers**
E. Petrovský, B. Kotlík, A. Kapička, M. Mikešová, R. Zbořil, H. Grison

C189 **Seasonal variability of the PMx chemical composition and ammonia concentration in loose-housing cowshed**
M. Maasikmets, A. Kaasik, A. Ruus, E. Teinemaa

C190 **Contribution from wood burning to the PM10 aerosol at four urban background sites in Flanders, Belgium**
W. Maenhaut, R. Vermeylen, M. Claeys, J. Vercauteren, C. Matheeussen, E. Roekens

C191 **Characterization of submicron organic aerosol in Prague by ME 2 factor analysis of summer AMS data**
O. Makeš, P. Vodička, J. Schwarz, F. Canonaco, A. S. H. Prévôt, V. Ždímal

C192 **Source apportionment in suburban environment during summer**
L. Marmureanu, J. Vasilescu, D. Nicolae, F. Canonaco, J. G. Slowik, A. S. H. Prévôt

C193 **The contribution of winter sanding to PM10 concentrations at traffic stations in the Czech Republic in 2011**
L. Matoušková

C194 **Size distributed metallic elements in submicron and ultrafine atmospheric particles from urban and industrial areas: a source assessment**
S. Mbengue, L. Alleman, P. Flament

C195 **Estimation of Non-Exhaust Emissions in PM10 Road Dust in Birmingham, UK**
Pallavi Pant, R. M. Harrison

C196 **Elemental composition and source identification of PM0.09-0.26 in European air pollution hot-spot**
P. Pokorná, J. Hovorka, P. K. Hopke

C197 **PM2.5 chemical composition and source apportionment in the Po Valley: the Med Particles and Supersito projects preliminary results**
F. Scotto, S. Ferrari, I. Ricciardelli, R. Vecchi, G. Valli, A. Piazzalunga, V. Poluzzi

C198 **Traffic-generated changes in the chemical composition of 13 fractions of PM in an urban area of Upper Silesia, Poland**
W. Rogula-Kozłowska

C199 **PM1 chemical and mineralogical characterization near a crude oil pre-treatment plant (Agri Valley) during an emergency procedure**
S. Trippetta, R. Caggiano, S. Margiotta, S. Sabia, A. Speranza, V. Summa

C200 **Sources and trends of atmospheric pollutants at Pallas, Finland, during 1996-2009**
M. Vestenius, P. Anttila, S. Leppänen, K. Hansson, E. Brorström-Lunden, H. Hakola

C201 **High-time resolved characterization of PM1.0 in a peri-urban site near Rome, Italy**
R. Salzano, M. Giusto, M. Montagnoli, M. Catrambone, E. Rantica, T. Sargolini, C. Perrino

Reserve Posters

C202 **Urban particulate matter monitoring on a mobile platform: a real time experiment on a long term scale**
B. Moroni, E. Scocchera, A. Piazzalunga, M. G. Ranalli, S. Castellini, D. Cappelletti
CHANGED TO ORAL PRESENTATION

C203 **Characterisation of the aerosol sources in Brindisi (Italy) harbour area within the CESAPO project: an overview of the experimental results**
D. Contini, D. Cesari, A. Donateo, A. Gambaro, A. Genga, G. Giovanelli, R. Giua, F. M. Grasso, E. Gregoris, P. Ielpo, S. Masieri, E. Merico, E. Morabito, A. Nocioni, T. Pastore, M. Siciliano

C204 **An experimental approach to measure particle deposition in large circular ventilation ducts**
G. Da, E. Géhin, M. Ben-Othmane, M. Havet, C. Solliec, C. Motzkus

C205 **PMF source apportionment for fine and coarse PM in Athens, Greece: Evolution of source contributions over the last decade**
K. Eleftheriadis, E. Diapouli, A. Karanasiou, S. Vratolis, V. Vasilatou, M. Gini, D. Saraga, S. Pateraki, Th. Maggos

C206 **Toxicological effects of the particulate emissions from diesel engines and wood combustion are affected by used technology**
P. I. Jalava, M. S. Happo, T. Brunner, I. Obernberger, T. Murtonen, P. Aakko-Saksa, J. Mäki-Paakkanen, J. Jokiniemi, M-R. Hirvonen
CHANGED TO ORAL PRESENTATION

C207 **Diurnal variation of small and large ion concentrations in an urban location**
E. R. Jayaratne, X. Ling, L. Morawska

C208 **Particulate Matter in Indoor Aor in two Schools in Vienna, Austria**
A. Kasper-Giebl, N. Jankowski, K. Kassin, E. Can Cetintas, H. Bauer, H. Grothe

C209 **Organic aerosol speciation with in-situ thermal desorption gas chromatography: a brief history of the TAG instrument**
N. M. Kreisberg, S. V. Hering, A. P. Teng, G. Isaacman, Y. Zhao, D. R. Worton, A. W. H. Chan, B. J. Williams, J. T. Jayne, A. T. Lambe, T. Hohaus, J. R. Kimmel, D. T. Sueper, W. Brooks, L. R. Williams, A. M. Trimborn, D. R. Worsnop, A. H. Goldstein

C210 **Particle characterization during abrasive treatment of composite material containing fibres by Cryo HRTEM**
K. I. Lieke, M. Levin, K. A. Jensen, I. K. Koponen

C211 **Trace elements bioaccessibility in fine and ultrafine particles from the industrial area of Dunkirk (France) during the NANO-INDUS project**
S. Mbengue, L. Alleman, P. Flament

C212 **Free energy barrier in the growth of sulfuric acid clusters**
T. Olenius, O. Kupiainen, I. K. Ortega, H. Vehkamäki

C213 **Evaporation and growth dynamics of layered droplets: Theory and experiments**
H. H. Tu, A. K. Ray

C214 **Atmospheric tar balls: primary droplets from biomass burning?**
Á. Tóth, A. Hoffer, I. Nyírő-Kósa, M. Pósfai, A. Gelencsér

Aerodyne Research, Inc. (ARI) has provided research and development (R&D) services to commercial and government clients working to solve national and international problems since 1970. Our R&D staff is organized into six technology centers which address such critical issues as global and regional environmental quality and development of clean and efficient energy and propulsion technologies.

In conjunction with ARI's research activities, we also manufacture and sell high sensitivity, fast time response instrumentation for environmental air quality monitoring and atmospheric research. These instruments include Aerosol Mass Spectrometers, Quantum Cascade Laser Trace Gas Detectors, Aerosol Chemical Speciation Monitors (ACSM), Particle Optical Extinction (CAPS PMex) monitors, and ultrasensitive nitrogen dioxide (CAPS NO2) monitors.

ARI also designs, builds and utilizes remote sensing, surveillance, image processing, tracking and recognition systems for commercial and environmental applications and national defense.

Aerosol d.o.o.

Website: **www.aerosol.si**

Magee Scientific Aethalometers, instruments for measurement of Black Carbon, are manufactured at "Aerosol d.o.o." in Ljubljana, Slovenia. The Aethalometers provide an on-line measurement of aerosol absorption on up to 7 wavelengths: 370, 470, 520, 590, 660, 880, 950 nm. Black Carbon is the second most important climate forcer and highly correlated with detrimental health effects of air pollution. Measurements by the Aethalometer of aerosol absorption at different wavelengths of light provide information specific to sources and enable discrimination between biomass and fossil fuel combustion aerosols by ambient measurements, and detection of mineral dust events.

The 'Next Generation' Aethalometer®, Model AE33, incorporates scientific and technical advances designed to offer improved measurement performance, user features, communications and interface, and the ability to perform routine performance tests to verify correct operation. Most importantly, the new instrument incorporates the patented DualSpot™ measurement method. This provides two significant advantages: elimination of the changes in response due to 'aerosol loading' effects; and a real-time calculation of the 'loading compensation' parameter which offers insights into aerosol optical properties.

AethLabs

Address: **2180 Folsom St, 3rd Floor**
San Francisco, CA 94110
United States of America

Phone: **+1 (415) 529-2355**
Website: **www.aethlabs.com**

AethLabs is the manufacturer of the microAeth® Model AE51 for measuring Aerosol Black Carbon. The microAeth® is battery powered, easy to use, and small enough to fit in your pocket. With Aethalometer® measurement technology inside, the microAeth® is built on proven technology that has been used world-wide for 30 years.

Airmodus Ltd.

Fax: **+44 1223 210190**
Email: **cambustion@cambustion.com**
Web: **www.cambustion.com**

New in 2013, Cambustion's UDAC is a standalone unipolar diffusion charger, capable of placing a high level of charge on aerosols, and forming a building block of many laboratory experiments.

A novel application (the subject of an AS&T letter) combines a UDAC, a Cambustion Centrifugal Particle Mass Analyzer (CPMA) and an aerosol electrometer, to provide an aerosol mass standard.

The CPMA continues to find new applications as an aerosol laboratory tool, with a growing group of researchers publishing around the world since 2012.

Cambustion's aerosol product range continues to develop, with the addition of an aerosol flow meter accessory for the UDAC/CPMA and a standalone electrostatic precipitator.

Our established DMS series instruments offer the fastest real-time electrical mobility size/number spectra available (from 200 ms T10-90% at 10Hz); particle size measurement range from 5nm – 2.5μm, with unrivalled sensitivity. Applications include ambient monitoring, combustion aerosol, workplace exposure and engineered nanoparticle research.

With fully integrated sampling and dilution options, DMS series instruments can be used for both ambient applications and straightforward direct sampling of high concentration aerosol sources through software selection of appropriate dilution.

Meet us at the Cambustion exhibit – booth No. 14

Catalytic Instruments GmbH & Co. KG

Address: **Lug ins Land 53**

Email: **hans-joachim.schulz@catalytic-instruments.com**

Catalytic Instruments is a German company specializing in the production of innovative aerosol instruments based on "catalytic stripper" technology. A catalytic stripper is a heated catalytic element used to remove the particle and gas phase semi-volatile fraction of an aerosol. Applications include measurement of diesel, locomotive, and gas turbine exhaust.

Current products include the CS08 and CS015 - catalytic strippers designed for aerosol flowrates of 8 and 1.5 L/min, respectively. A CVF100 or Catalytic Vapor Filter is also offered for the removal of CPC exhaust vapor. For unique applications, Catalytic Instruments will work with the customer to provide individual solutions.

Comde-Derenda GmbH

Address: **Kieler Strasse 9**
14532 Stahnsdorf
Germany

Phone: **+49 3329 690 27 10**
Fax: **+49 3329 690 27 19**
Email: **info@derenda.de**
Website: **www.comde-derenda.de/index.php/en**

Comde-Derenda GmbH was originally founded under the name of Norbert Derenda Engineering Office in Berlin in the year of 1972. Today the company is located in Stahnsdorf near Berlin where new facilities were erected in the year of 2007. The firm's products are being used to an ever increasing extent within the European Union to monitor outdoor air quality.

In the years 1999 and 2000 the company was certified as per the DIN EN ISO 9001 quality assurance standards. In 2002 the quality management system was audited to the requirements set forth in DIN EN ISO 9001:2000. Norbert Derenda, the owner of the company, has, since the year 2000, also been a member of the Sponsors' Circle for the Commission on Air Quality Maintenance (KRdL) in the VDI and DIN organizations.

In October of 2007 Norbert Derenda was appointed to membership in "KRdL Working Group 4/2/09 on Measurement of Particles in Outdoor Air".

The product range now includes complete sampling systems and measurement instruments for direct and continuous analysis of gas and particle concentrations in the atmosphere.

In detail the available products are the following:

Equipment and systems for sampling and measuring fine dust from the ambient air. Low volume sampler (reference devices in compliance with CEN standards). Automatic dust sampling systems for low-, medium- and high-volume sampler units. Air pollution monitors (on-line) for direct and continuous determination of the concentration of suspended dust particles. Automatic weighing systems for gravimetric evaluation of dust-loaded filters or other sample carriers. Air monitoring stations for up to 8 immission values (fine dust and gases) for environmental monitoring purposes. Gas collection units for exposing gas absorption tubes.

Comde-Derenda GmbH employs highly competent and dedicated personnel who can also be set to work on special solutions and custom equipment at any time.

Copley Scientific Limited

Address: **Colwick Quays Business Park**
Private Road No. 2
Colwick, Nottingham
NG4 2JY, United Kingdom

Website: **www.copleyscientific.com**

Copley Scientific is considered the world's leading manufacturer of test equipment for Metered-Dose Inhalers (MDIs), Dry Powder Inhalers (DPIs), Nebulizers and Nasal Sprays. In cooperation with aerosol characterisation equipment experts, MSP Corporation (MN, USA), Copley Scientific also offers a comprehensive range of aerosol sampling and particle sizing equipment for use in industrial and academic applications. This includes the world-renowned MOUDI and Nano-MOUDI range of cascade impactors, the Wide Range Particle Spectrometer Model 1000XP, the Real-Time Fibre Monitor Model 7400AD and Water-based Condensation Particle Counters (WCPCs). Copley Scientific has offices and product experts based in Nottingham, UK and Basel, Switzerland, serving the European market.

Dekati Ltd.

Address: **Tykkitie 1**
36240 Kangasala
Finland

Phone: **+358 3357 8100**
Email: **sales@dekati.fi**
Website: **www.dekati.com**

Dekati Ltd. develops, manufactures and markets instrumentation needed in fine particle measurement and sampling. In 1995, Dekati introduced the world's first real-time fine particle concentration and size distribution measurement instrument, ELPI™. Since then, our product line has been continually expanding and it now includes several instruments for both particle detection and aerosol sample conditioning and dilution. The latest addition in the Dekati® Product Line is the Dekati® Bipolar Charge Analyzer (BOLAR™) for particle bipolar charge size distribution measurements.

Dekati develops new products in close co-operation with the world's leading universities and companies. Our mission is to provide our customers with innovative fine particle measurement solutions that guarantee accurate results even in demanding environments.

Dekati instruments are used for example in the following application areas:

- Combustion Processes (Diesel, Gasoline, Oil, Coal, Bio-fuels etc.)
- Environmental Ambient Aerosol Research and Monitoring
- Occupational Health and Safety Measurements
- Pharmaceutical Drug Screening and Inhalator R&D
- Nanotechnology and Material Processing

Visit www.dekati.com for more details on our company and our products, or contact us at sales@dekati.fi for further information.

DIGITEL Elektronik AG

Address: **Alte Gasse 18**
CH-8604 Hegnau
Switzerland

Phone: **+41 44 908 20 30**
Fax: **+41 44 908 20 31**
Email: **info@digitel-ag.com,**
Website: **www.digitel-ag.com**

Since 1970 Digitel Elektronik AG designs and manufactures successfully measurement instrumentation for environmental monitoring. Digitel Elektronik AG is located in Switzerland and sells worldwide over a network of local resellers. Their experience and the state-of- the- art production processes stand for approved first-class quality products.

Digitel provides a full range of High and Low Volume sampler products for immission measurement such as PM10 according to the directives EN12341 and PM2,5 according to the directives EN 14907 as well as for other measuring purposes with different flow rates and cut-off point characteristics.

In addition to their standard products Digitel offer customer-specific solutions with specialised know-how and profound experience of over 40 years as environmental professionals. Digitel sets high quality standards and is well know to be the leading company when it comes to precision and reliability. All instruments made by Digitel hav a long lifetime, low power consumption and a low noise level.

Digitel Enviro-Sense – We Care

Ecotech PTY Ltd.

Address: **1492 Ferntree Gully Road**
Knoxfield, VIC, 3180
Australia

Phone: **+613 9730 7800**
Email: **info@ecotech.com**
Website: **www.ecotech-research.com**

Ecotech's tailored and innovative monitoring solutions assist our customers in quantifying environmental impacts all around the world. From our range of gas analysers through to our particulate instrumentation and also our sophisticated data software, Ecotech provides solutions that ensure air quality and climate data are accessible to everyone.

Our series of integrating nephelometers ranges from single to multiple wavelength versions and incorporates both polar and particle correlating options. Ecotech's Aurora range of integrating nephelometers are gaining a world-wide reputation for quality and reliability.

The newest addition to our aerosol family is the Aerosol Conditioning System (ACS1000). By exposing the aerosol to different relative humidity, the system enables their hygroscopic properties to be measured and analysed by a wide range of instrumentation. The dual channel provides real-time comparison between humid and dry samples.

Visit our booth at the EAC to view both our polar nephelometers and ACS1000. We will also be conducting an open workshop on Saturday 7th September at the Clarion Congress Hotel to discuss these instruments and much more. Register your interest at our booth today.

Grimm Aerosol Technik GmbH & Co. KG

Address: **Dorfstrasse 9**
83404 Ainring
D – Germany

Phone: **+49 (0)8654 / 578-0**
Fax: **+49 (0)8654 / 578-35**
Website: **www.grimm-aerosol.com**

The company GRIMM Aerosol Technik has been established 30 years ago by Hans Grimm in Bavaria/Germany. Meanwhile, GRIMM Aerosol Technik is one of the worldwide leading companies in the field of particle sizing and counting down to a few nanometers due to its innovative developments and manufacturing.

The company offers a product range of portable and stationary solutions for the continuous measurement of fine and ultrafine aerosols, for applications such as Environmental Dust Monitors, Aerosol Spectrometers, Particle Counters and Sizers, Filter and Motor Testers, as well as appropriate Aerosol Generators. Our products and technologies are of newest technology, such as wireless data transfer and logging, remote control, automatic operation. Specialists in-house will advise about the correct instruments for particular applications, e.g. for ambient air, emission, occupational health, filter efficiency and exhaust gas measurements, for quality control and for pharmaceutical, atmospheric or epidemiological studies.

Worldwide direct customer support and service is offered through our subsidiaries in the US, Canada, UK, Middle East and Asia, Australia, etc. and supplemented by our strong network of international representatives.

GRIMM Aerosol Technik:

- Environmental Dust Monitors
- Portable Dust Monitors and Aerosol Spectrometers
- Nanoparticle measuring systems (portable, mobile, stationary)

IONER®

a trademark of RAMEM S.A.

Address: **C/ Sambara, 33**
28027 - Madrid
Spain

Phone: **+34 91 404 45 75**
Fax: **+34 91 403 45 96**
E-mail: **sales@ioner.eu**
Websites: **www.ioner.eu, www.ramem.com**

RAMEM-IONER® is a Spanish company devoted to the development of innovative aerosol instruments. RAMEM-IONER has a main goal: taking the DMA technology and applications to the smaller particles possible. RAMEM-IONER develops DMAs based on patented parallel plate technology and with different chargers and ion sources. Very high resolutions are reached with high sheath flows. Complete DMAs with sheath flow and aerosol flow control, chargers and electrometers are commercialised. Also, separate modules like ElectroSpray sources, Corona discharge sources, High Voltage sources or modules for flow control are sold.

RAMEM, the main branch of the company, designs and manufactures special needs of prototypes in scientific instrumentation or scientific installation. Short series or even single prototypes can be considered.

The latest RAMEM-IONER project is GANS: A DMA for early stage of nucleation studies. In this project, RAMEM-IONER ion sources for organic compounds and for inorganic compounds are coupled to a high resolution DMA (or HRIMS) for ions. The detection stage is done coupling a Particle Size Magnifier (PSM) with a Condensation Particle Counter (CPC) developed by Airmodus. Further information about GANS project and RAMEM-IONER can be found in: http://www.gans-project.eu/

Matter Aerosol

matter aerosol
a testo company

Address: **Bremgarterstrasse 62**
CH-5610 Wohlen
Switzerland

Phone: **+41 (0)56 618 66 30**
Fax: **+41 (0)56 618 66 39**

Matter Aerosol continues its successful specialization in the measurement and characterization of nanoparticles from combustion processes and nanoparticles in ambient air.

Matter Aerosol combines over 50 years experience in instrument design and development with latest research results about nanoparticles, for application in laboratories to real-world problems.

Matter Aerosol's NanoMet3 is a new Portable Emissions Measurement System – PEMS for nanoparticle counting and classification. Come and see yourself!

MCV, S.A.

Address: **Highway A-2, km 575**
ES08293 Collbató (Barcelona)
Spain

Phone: **+34 93 777 05 00**
Fax: **+34 93 777 05 50**
Email: **cial@mcvsa.com,**
Website: **www.mcvsa.com**

MCV is a company established for more than 30 years in order to design and develop instrumentation, equipment and systems related to the environment, especially in the areas of air quality control and meteorology. The main field of activity of the company includes the design of equipments, management, control and monitoring systems, data acquisition systems, software and civil works.

MCV due to its experience and leadership in the environmental engineering field offers their clients the development of customize solutions to their needs.

The facilities of the company allow us to face any kind of project as the construction of mobile units, monitoring stations for automatic networks, radars and meteorological towers, production of equipments for the sampling of gases and particles or data acquisition systems.

MCV has the certifications for quality and environmental management systems ISO9001, ISO 14001 and EMAS.

MCV develops, manufactures and distributes equipment to measure and control the air quality as: HVS (PM10, PM2.5, PM1, HAP, TSP heads), VOC's samplers, Calibration systems with aire zero generator and automatic analysers for SO2, NOx, O3, CO, H2S, BTX…

MCV carries out tasks of maintenance, repairmen, verification and calibration of the measurement instruments either on site or in the company features. Our team possesses the means and technical resources to give and effective response to the customer requirements and incorporates the last updates and innovations. MCV supports their customers with its features and technical assistance in order to give an integral service.

This company will not be present at the Conference.

Met One Instruments, Inc.

Address: **Met One Instruments Inc**
1600 Washington Blvd
Grants Pass, Oregon, 97526
United States of America

Phone: **+1 (541) 471-7111**

Email: **sales@metone.com**
Website: **www.metone.com**

Met One Instruments, Inc. located in Oregon, USA designs and manufactures meteorological instruments, handheld/portable particle counters, aerosol monitors, and regulatory particulate matter (PM) samplers/monitors. Our BAM-1020 Monitor is the first continuous PM measurement method to receive both PM2.5 and PMcoarse U.S. EPA Federal Equivalence Method designation. It also passed the newest European Equivalency testing for PM10 and PM2.5 and is certified to EN 15267 the highest EU quality standard for ambient monitors.

We are committed to meet the needs of our worldwide customers for ambient and indoor monitoring requirements and offer specialized solutions for various applications including data logging and software instruments. We are in business since more than 20 years and bring our experience to work for you.

See the new additions to our aerosol instrumentation product line at www.metone.com.

Metrohm Applikon B.V.

Address: **P. O. Box 149,**
3100 AC Schiedam
The Netherlands

Phone: **+31 (0)10 29 83 555**
Fax: **+31 (0)10 437 96 48**
Email: **ELe@metrohm-applikon.com**
Website: **www.metrohm-applikon.com**

Metrohm Applikon, headquartered in Schiedam, the Netherlands has more than 35 years experience in delivering solutions for laboratory, at-line and on-line wet chemical analysis. Part of the worldwide Metrohm AG group, Metrohm Applikon has access to Metrohm's know-how and expertise in ion analysis.

MARGA (Monitor for AeRosols and Gases in ambient Air) is an on-line ion chromatograph that measures the concentration of soluble inorganic species in aerosols and their related gas phase components in ambient air. Hourly simultaneous results for gases and aerosols can be accessed from a remote workstation, with result quality being maintained by an internal standard and detailed system diagnostics.

Jointly developed with ECN, The Netherlands, MARGA is distributed world-wide through Metrohm Applikon's distributor network; most members of which belong to the Metrohm group of companies.

Naneos Particle Solutions GmbH

Address: **Dorfstrasse 69**
CH-5210 Windisch

Phone: **+41 56 560 20 70**
Website: **www.naneos.ch**

Naneos builds nanoparticle detectors that are easy to use, small and reliable. They can be used in workplace safety, for ambient monitoring and health studies.

Palas® GmbH

Address: **Greschbachstr. 3b**
76229 Karlsruhe
Germany

Phone: **+49 (0)721 96213-0**
Fax: **+49 (0)721 96213-33**
Email: **mail@palas.de**
Website: **www.palas.de**

With more than 60 submitted patents, the Palas® GmbH has effectively set standards in the aerosol technology since 1983. Today, Palas® offers a complete product range for the continuous aerosol generation and measurement from 5 nm to 100 μm.

Our innovations result in superior quality and durability of the products that lead to unique technical and economic advantages for our customers.

Our core competencies are:

- Particle generation
- Particle measurement systems (for high pressures up to 10 bar, temperatures from -120°C up to 470°C, processes, environment and workplace, inhalation)
- Nanoparticle measurement systems (U-SMPS, UF-CPC etc.)
- Filter test and filter media test systems
- Continuous fine dust monitoring systems
- Dilution systems
- Cleanroom particle technology
- Calibration systems

Well-known industrial enterprises and research institutions worldwide have decided in favour of Palas® products and have thus established Palas® as a worldwide market leader.

Sunset Laboratory Inc.

Address: **10180 SW Nimbus Avenue**
Suite J/5
Tigard, OR 97223-4341

Phone: **503-624-100**
Fax: **503-620-3505**
Website: **www.sunlab.com**

Sunset Laboratory Inc. has specialized in the analysis of air pollution for carbon aerosols since 1984. As well as performing the OCEC analysis, Sunset Laboratory also provides instrumentation for carbon aerosol analysis. Our equipment is suitable for the laboratory or in the field, and ready for use with the NIOSH method 5040, IMPROVE-A, and EUSAAR 2 protocols.

Clients include researchers working for government regulatory agencies, private companies, commercial laboratories, and universities.

Topas GmbH

Address: **Oskar-Röder-Str. 12**
01237 Dresden
Germany

Phone: **+49 (351) 21 66 43-0**
Fax: **+49 (351) 21 66 43 55**
Email: **office@topas-gmbh.de**
Website: **www.topas-gmbh.de**

Topas GmbH Dresden is a specialist company in the field of aerosol and particle technology.

Our standard product range comprises:

- aerosol generators (mono- and polydisperse, solid and liquid particles)
- particle size measuring instruments for aerosols and liquids
- aerosol dilution systems
- electrostatic aerosol neutralizers
- process aerosol monitors
- filter testing technology and instruments
- clean room measuring equipment
- pore size measuring instruments

Topas also provides solutions for special applications like the dispersion of complex powders, test systems for particle filters and for adsorptive filters, filter media testing, blow-by measuring etc. Our corporate philosophy allows us to meet a variety of customer needs. Many years of experience, our know-how as well as close cooperation with universities, research centres and industrial partners is the ideal basis for the development of new and innovative solutions. Our reliable measuring and testing equipment has proven successful worldwide.

TSI GmbH Germany

Address: **Neuköllner Strasse 4**
52068 Aachen
Germany

Phone: **+49 241-52303-0**
Fax: **+49 241-52303-49**
Email: **answersEU@tsi.com**
Website: **www.tsi.com**

As an international leader in measurement technology for over 50 years, TSI Incorporated (www.tsi.com) designs and manufactures precision instruments used for aerosol research, contamination control, indoor air quality and serves the needs of industry, governments, research institutions and academia.TSI researchers and engineers have developed instruments that are recognized worldwide. During EAC 2013 in Prague TSI's team will show new products like the Model 3938 which is the 3rd generation of the SMPS; trusted by researchers for over 30 years. The new generation has an improved accuracy, does not require an external computer, and offers new features like fast size measurements with scan times below 10s.

Stop by our booth and learn more about the new.

Multi-Instrument-Software (MIM), Highlights of Sizing Nanoparticles with NanoScan SMPS and OPS Combination System Model 3914 and our 30 % CPC Trade-In offer for selected CPCs.

We look forward to seeing you at our booth.

ECM ECO Monitoring

ECM ECO Monitoring

Address: **Nevädzová 5**
821 01 Bratislava
Slovak Republic

Phone: **00421 2 4342 9417**
Fax: **00421 2 4342 7465**
Email: **ecm@ecm.sk**

ECM is a TSI company operating in area of Central/Eastern Europe and CIS countries. Besides of TSI particle monitoring products also OC/EC, carbon black and complex analytic solutions for monitoring of gases, liquids and particles are provided.

For detailed information in different languages refer to www.ecomonitoring.com

URG Corporation

Adress: **116 South Merritt Mill Rd.**
Chapel Hill,
North Carolina
27516 USA

Phone: **919-942-2753**
Email: **info@urgcorp.com**
Website: **www.urgcorp.com**

URG Corporation manufactures the Ambient Ion Monitor (AIM) System for the continuous direct measurement of particulate Cl-, NO3-, SO42-, NH4+, NA+, K+, CA2+, MG2+ in PM2.5 plus gas measurements of HCl, HNO3, HNO2, SO2, NH3. The AIM System analyzes particles, gases and organics. The AIM System incorporates Thermo Scientific Dionex Reagent-Free Ion Chromatographs. The AIM System has detection limits of 0.05μg/m3 for each of the required analytes. The multi-pollutant data is instantly available on an hourly basis and with the option of every 15-30 minutes.

URG provides a wide variety of instruments for indoor and outdoor air sampling. Our Annular Denuder System (ADS) collect both acidic and basic gases and is designed to meet USEPA's Compendium Method IO-4.2. URG's complete collection of aluminum cyclone inlets are Teflon© coated, a patented process that minimizes the losses of reactive gases such as HNO3 and NH3 to the internal surfaces of the cyclone. URG provides stainless steel cyclones and filter holders for diesel emissions.

URG air sampling instrumentation is used in Europe, Asia, North America, Australia, Antarctica, Africa and South America.

Plenary lecture: Aerosol particles in the marine environment

by Merete Bilde

Aerosol particles in the marine environment

M. Bilde

Department of Chemistry, Aarhus University, Langelandsgade 140, DK-8000 Århus, Denmark

Keywords: Sea spray aerosol, CCN, soot.
Presenting author email: bilde@chem.au.dk

Aerosol particles in the marine environment stem from several sources including primary production of sea-spray particles via wind-driven air-entrainment and subsequent bubble bursting, transport from land sources, new particle formation and emissions from ships.

Large uncertainties are associated with the source strength, properties and climate impact of particle from these different sources.

This talk provides a general introduction to aerosol particles in the marine environment with focus on particle properties. The results presented address properties of particles generated from bubble bursting processes in a laboratory environment. In addition, properties of particles sampled from a low-speed ship engine will be presented. Outcomes will be discussed in the context of atmospheric science.

Methods

In *Sea-spray experiments* particles were generated by air-entrainment and bubble bursting processes in laboratory tanks. Bubbles were generated either by aeration through a diffuser or by water jet impingement on the water surface of the tank. Particle properties were determined using a suite of aerosol instruments including SMPS systems and CCN-counter.
In *ship-engine experiments* particles were collected during a 3-week measurement campaign at a MAN B&W low-speed ship engine on test bed in Copenhagen and analyzed using Transmission Electron Microscopy.

Results

Sea-spray aerosols constitute a major fraction of marine aerosols. They can be formed when air bubbles entrained in ocean water as a result of breaking waves rise and burst at the surface (e.g. de Leeuw et al. 2011). Sea-spray aerosol has been shown to contain not only sea salt but also organic molecules and field studies (O'Dowd et al. 2004) have suggested that smaller sub-micron particles are enriched in organic material compared to the ocean water.

In this work a series of laboratory experiments were performed to investigate the mechanism of sea-spray aerosol formation, organic enrichment and physico-chemical properties of sea-spray aerosols. For example, the effect of bubble residence time in the bulk seawater solution on particle size and CCN activity was investigated for artificial seawater containing different organic molecules. CCN activity of particles produced from water jet impingement was compared with CCN activities of particles produced from aeration through a diffuser and suggests a considerable amount of organic enrichment in the particles produced via jet-impingement when the salt water contained an organic surfactant (sodium laurate) (King et al. 2012).

Another type of complex aerosol particles in the marine environment are particles emitted from marine diesel engines. Results will be presented from a study comparing particle properties before and after an exhaust gas recirculation scrubber for a low-speed ship engine on test bed.

Brown carbon (BrC), which may include secondary organic aerosol (SOA), can be a significant climate-forcing agent via its optical absorption properties. However, the overall contribution of SOA to BrC remains poorly understood. Here, correlations between oxidation level and optical properties of SOA are examined. SOA was generated in a flow reactor in the absence of NO_x by OH oxidation of gas-phase precursors used as surrogates for anthropogenic (naphthalene, tricyclo[5.2.1.$0^{2,6}$]decane [JP-10]), biomass burning (guaiacol), and biogenic (α-pinene) emissions. SOA chemical composition was characterized with a time-of-flight aerosol mass spectrometer. The mass spectra yielded oxygen-to-carbon (O/C) ratios, used as a measurable surrogate for SOA oxidation level, that ranged from 0.29 to 1.29.

SOA mass-specific absorption cross sections (MAC) and refractive indices were calculated from real-time cavity ring-down photoacoustic spectrometry (CRD-PAS) measurements at 405 and 532 nm and from UV-Vis spectrometry measurements of methanol extracts of filter-collected particles (300 to 600 nm). At 405 nm, SOA MAC values and imaginary refractive indices ranged from $<$0.001 to 0.088 $m^2\ g^{-1}$ and 1.9×10^{-4} to 3.6×10^{-3}, respectively, increasing with SOA oxidation level. SOA light absorption decreased with increasing wavelength, leading to negligible absorption at 532 nm. Real refractive indices (n) of SOA at 405 nm ranged from 1.45 to 1.66 and for a given precursor changed at a rate of $\Delta(n)/\Delta(O/C)$ = -0.055 to -0.11. Comparison with literature studies suggests that under typical polluted conditions the effect of NO_x on SOA absorption is small. SOA may contribute significantly to atmospheric BrC, with the magnitude dependent on both precursor and oxidation level.

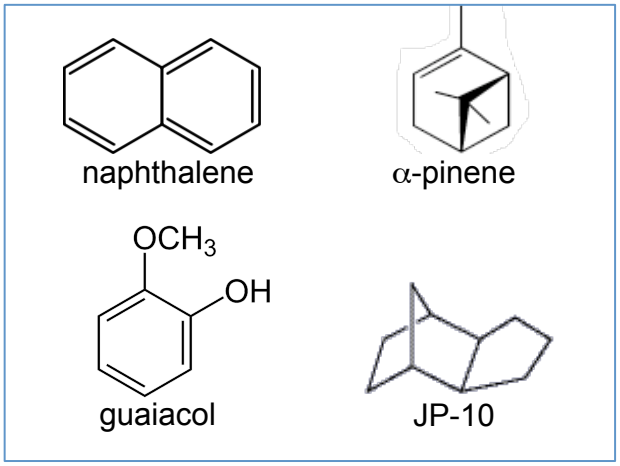

Figure 1: Molecular structures of SOA precursors used in this work.

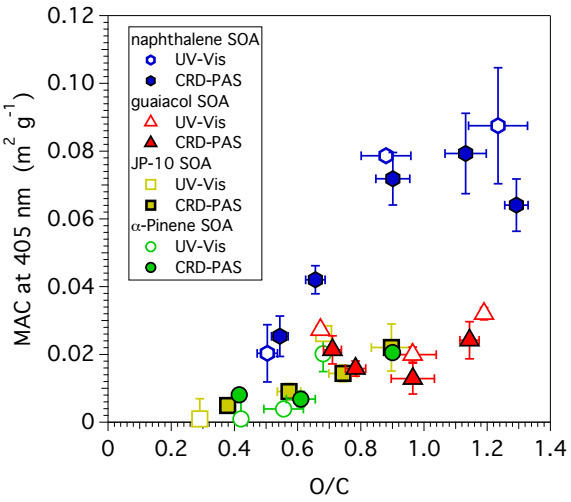

Figure 2: Mass-specific absorption cross sections (MAC) of SOA obtained at λ = 405 nm as a function of O/C ratio. MAC values are calculated from CRD-PAS and UV-Vis spectrometer measurements.

Aerosol particles influence the Earth's radiation balance directly by scattering or absorbing incoming solar radiation. Improving our knowledge of Arctic aerosols and their radiative impacts is important, particularly at present day when albedo is decreasing due to reductions in sea ice and snow cover. Realistic simulations of aerosol radiative forcing at the top of the atmosphere and at the surface require knowledge of the aerosol optical thickness (AOT).

In this study 9 years (2003-2011) of MODIS-Aqua aerosol observations have been combined with ground-based long-term sun-photometer and dry nephelometer measurements as well as with climate model simulations to examine the accuracy in estimations of aerosol optical properties in the Svalbard region (82°N-75°N, 10°W-40°E). MODIS 555-nm AOT was compared to ground-based sun-photometer measurements. For the 642 matches that was obtained it was found that MODIS AOT on the whole varies within the expected uncertainty for one standard deviation of the retrieval over ocean ($\Delta AOT = \pm 0.03 \pm 0.05 \cdot AOT$).

Figure 1 shows the annual variation of MODIS median 555-nm AOT, for the period under investigation,

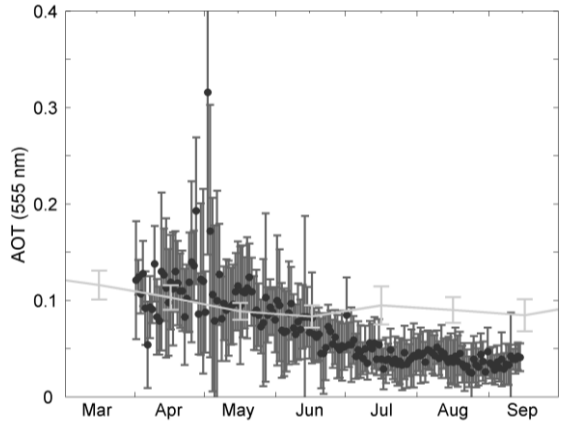

Figure 1. MODIS median AOT at 555 nm (black circle) and one standard deviation (dark gray line) averaged over all pixels that correspond to a day of the year in the 9-years period of observations (2003 – 2011). The light grey solid line denotes CAM3-Oslo model simulation of clear-sky AOT, using boundary conditions representative of the year 2000 and IPCC AR5 aerosol emissions.

compared to clear-sky AOT as simulated with the CAM3-Oslo global climate model. The latter values were obtained at 555 nm wavelength and averaged over the area investigated. Figure 1 shows that reasonable agreement occurs for the spring season while the simulated AOT is approximately a factor of 2 higher than the MODIS observations for the summer season.

Table 1 compares mean tropospheric AOT at 555 nm obtained in the framework of this study with AOT at 533 nm as obtained at Svalbard in the 1990's (Herber et al., 2002). The tropospheric AOT for the time period 2003-2011 was screened for the contribution of volcanic events by subtracting stratospheric AOT from Odin/OSIRIS measurements. In the present study we found June to mark the transition between spring- and summer-time aerosol conditions. Fig. 7 in Herber *et al.* (2002) on the other hand suggests that the transition occurred over a rather short period in late May in the 90's. The difference in AOT between June and July/August for the present period is statistical significant at the 99.9% confidence level (unpaired t-test) for all three platforms. This change in aerosol conditions suggests that Arctic was isolated during a longer period in the 90's compared to the last decade, in in line with weakened zonal winds and increased wave amplitude during 2000-2010, thus, moving the Rossby waves poleward (Francis and Vavrus, 2012).

Table 1. Tropospheric mean AOT at 555 nm (this study) and 532 nm (Herber et al. 2001, 1991 – 1999) resolved according to different times of the year.

Operational boundary layer height determination with in-situ and ground-based remote sensing instruments: validation and first climatology on the Swiss plateau.

C. Praz, **M. Collaud Coen,** A. Haefele, and D. Ruffieux

MeteoSwiss, 1530 Payerne, Switzerland
Keywords: PBL, Lidar, Windprofiler, Radiometer, parcel and bulk Richardson, NWP model.
Presenting author email: martine.collaudcoen@meteoswiss.ch

The planetary boundary layer (PBL) is the lowest part of the troposphere that is directly influenced by the Earth's surface and concentrates the major part of aerosols as well as others pollutants. Continuous determination of PBL height is of prime importance for air quality analysis, for predicting aerosols, pollens and pollutants dispersion, and for local meteorological climate comprehension.

The top of the PBL is characterized by a strong decrease of the aerosol concentration and humidity content as well as by strong turbulences. It can be consequently estimated by measuring various physical parameters such as the aerosol scattering ratio (ASR) measured by the Raman-lidar, the RH gradient measured by the radiosonde (RS) or the Raman-lidar, or the turbulence signature in the signal to noise ratio (SNR) of the windprofiler. The radiosonde and the microwave radiometer provide temperature profiles to which both Parcel Method (PM) and bulk Richardson (bR) can be applied to detect the PBL height by the elevation of air masses adiabatically raised by convection. The numerical weather prediction (NWP) model COSMO-2 also used the bulk Richardson method to determine the PBL height.

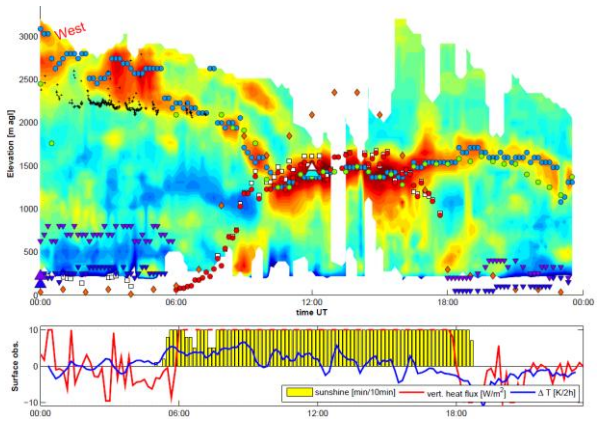

Figure 1: PBL height detected by the PM (red circles + triangle) and the bR (white squares +triangle) applied on the radiometer and radioSonde T profiles, on the SNR (blue circles) on the ASR (green circles) and nocturnal SBL height detection (blue and violet triangles), as well as COSMO-2 output (orange diamond), 31 July, 2012 at Payerne. The sunshine duration, the vertical heat flux and the temperature gradient are plotted on the second panel.

All the PBL height detection methods are operationally applied to all instruments in Payerne (491 m asl) and Schaffhouse (437 m asl) situated on the Swiss plateau. The 2012 data were used to validate the detection methods taking the PM applied on the radiosonde or the radiometer T profiles as a reference method and to calculate a climatology of both the CBL and the SBL at both measuring sites. Figure 1 presents an example of clear sky convective day, where 1) the convective boundary layer (CBL) height's increase and decrease can be detected by the PM applied to the radiometer data, 2) all detection methods show a very good agreement for the CBL height during the afternoon, 3) the residual layer is detected by both the windprofiler and lidar, 4) the nocturnal stable layer (NSL) is evaluated by the radiometer and radiosonde T profiles, and 5) the COSMO model shows a clear overestimation of the CBL height for this day.

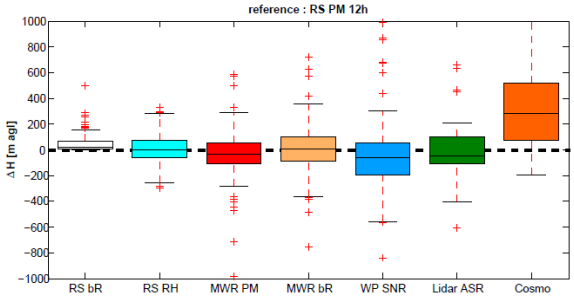

Figure 2: Boxplots of ΔH between PBL height computed at 12:00 UT with various methods and the reference RS PM. The central mark is the median, the edges of the box are the 25th and 75th percentiles q1 and q3, the whiskers extent covering 99% of data assuming a normal distribution, and the red crosses are the outliers.

The validation (Fig. 2) done on 107 convective days during January-October 2012 shows that all the detection methods based on remote sensing and radiosonde measurements are in very good accordance (mean at ± 50m, 25th and 75th percentiles at ± 200 m). The COSMO CBL height being on the contrary regularly overestimated for part of the summer days.

One year climatology shows that both in Payerne and Schaffhouse, the PBL height obeys a remarkable annual cycle, varying between about 400 m agl in winter up to nearly 1400 m agl in July. The PBL maximal height appears to be reached from May to August.

Assessment of parameterizations of optical properties and hygroscopic growth of aerosols

Atmospheric aerosols affect the Earth's climate both directly, through the scattering and absorption of radiation, and indirectly, via changes to cloud microphysics and properties. In order to estimate the "direct effect", climate models generally require aerosol optical properties such as the extinction coefficient, the single scattering albedo and the asymmetry parameter. And for these, they need to quantify first the spectral refractive index, the size distribution, the influence of relative humidity and the mixing state of atmospheric aerosols. This complexity of the atmospheric aerosols requires synergistic use of models and measurements in order to provide the information needed in climate models.

The Facility for Airborne Atmospheric Measurements (FAAM) BAe-146 aircraft has recently provided a new body of measurements of the chemical composition, microphysical, optical and hygroscopic properties of the atmospheric aerosols (Johnson *et al.*, 2000; Osborne *et al.*, 2007), which allow us to explore the agreement between models and measurements of the aerosol optical properties.

In this work we have used a flexible framework for assessing parameterizations of optical properties and hygroscopic growth of aerosols. We have used this framework to calculate aerosol optical properties at a given relative humidity based on composition, and then we have compared with measured values of the same. For this, we have used data collected by the FAAM BAe-146 aircraft over Western Europe during the EUCAARI-ADIENT project (Kulmala *et al.*, 2009) and over the South East Pacific region during the VOCALS-UK project (Wood *et al.*, 2011).

The methodology used in this work consists in using the measurements of the aerosol composition made by a Time-of-Flight Aerosol Mass Spectrometer (ToF-AMS) and a Single Particle Soot Photometer (SP2) and the measurements of the size distribution made by a Passive Cavity Aerosol Spectrometer probe (PCASP-100x) together with volume weighted mixing rules, best estimates of refractive indices and assumptions about the growth factors of the aerosol components to determine the ambient size distribution and the refractive indices of an internally mixed aerosol at a given relative humidity. The scattering and absorption by the internally mixed aerosol can be then calculated using a Mie scattering code (Wiscombe, 1979). Finally, the resulting scattering and absorption are compared against coincident scattering and absorption measurements from a TSI 3563 integrating nephelometer and a Particle Soot Absorption Photometer (PSAP) (Figure 1).

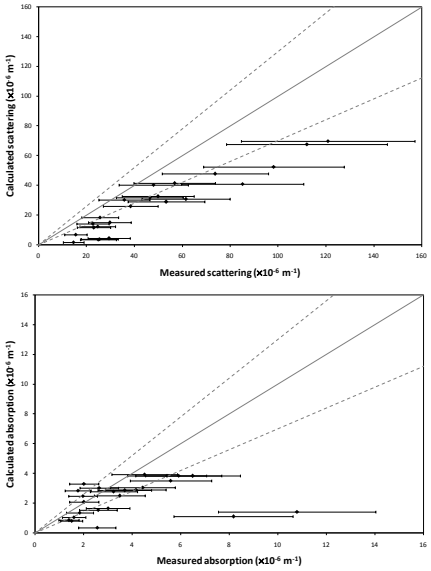

Figure 1. Comparison of modelled and measured scattering and absorption during the EUCAARI-ADIENT project.

Keywords: Aerosol particles, Amazonia, biosphere-atmosphere interactions, Biomass Burning,
Presenting author email: Artaxo@if.usp.br

Amazonia is one of the most pristine continental areas in the wet season, with very low aerosol particles concentration. Over the last 20 years, the Large Scale Biosphere Atmosphere Experiment in Amazonia (LBA) has implemented research projects aiming to study aerosol optical properties (Davidson et al., 2012). Three aerosol components are the most visible: 1) The natural biogenic emissions of aerosols; 2) Secondary organic aerosols from biogenic VOCs emissions; and 3) the biomass burning component. Long term monitoring of aerosols and trace gases were performed in two sites: a background site in Central Amazonia, 55 Km North of Manaus (called ZF2 ecological reservation) and a monitoring station in Porto Velho, Rondonia state, a site heavily impacted by biomass burning smoke. Recently, two new sites are providing new information on aerosol optical properties: the so called ATTO (Amazon Tall Tower Observatory) that is a very clean site North of Manaus and the EMBRAPA site, 50 Km NE of Manaus, with the long term operation of a Raman Lidar and other instruments. At these sites, detailed aerosol characterization is being performed, with the measurements of aerosol size distribution from 10 to 600 nm, spectral light absorption measured with Aethalometer and MAAPs, light scattering with the use of TSI and Ecotech 3 lambda nephelometers. In parallel, aerosol composition is being measured for inorganic components (measured using XRF) and organic and elemental carbon determined with a Sunset OC/EC instrument. We are also operating a network of 6 CIMEL sunphotometers from AERONET and the use of MODIS AOD allows to obtain the large scale aerosol distribution. Combination of MODIS and CERES allowed the calculation of top of the atmosphere large scale aerosol radiative forcing.

Aerosol optical depths (AOD) of more than 4 at 550nm was observed frequently over biomass burning areas, while in the wet season, central Amazonia shows very low AOD of about 0.05 to 0.1 at 550 nm. At the ZF2 site, dry particle median scattering coefficients at the wavelength of 550 nm increased from 6.3 Mm−1 to 22 Mm−1, whereas absorption at 637 nm increased from 0.5 Mm−1 to 2.8 Mm−1 from wet to dry season. Angstrom exponents for scattering were lower during the wet season (1.6) in comparison to the dry season (1.9), which is consistent with the shift from fine mode biomass burning aerosols, to biogenic aerosols, predominant in the coarse mode. Single scattering albedo (SSA), calculated at 637 nm, did not show a significant seasonal variation, averaging 0.86±0.08 for dry particles. AERONET SSA at 550 nm for the region shows an average of 0.91±0.04. A detailed analysis of aerosol optical properties was provided in Rizzo et al., 2012.

Combined analysis of MODIS and CERES for a 10 years study shows that the mean direct radiative forcing of aerosols at the top of the atmosphere (TOA) during the biomass burning season was $-5.6\pm1.7 Wm^{-2}$. It was observed that for high AOD (larger than 1 at 550 nm) the maximum daily direct aerosol radiative forcing at the TOA may be as high as $-20 Wm^{-2}$ locally. Details of this analysis can be found in Sena et al., 2012.

At the ATTO site, very low aerosol light scattering and absorption was observed, with a wet season light scattering typical values of 6 Mm-1 at 550 nm, while BC typical values are in the range of 70-100 ng/m³. The average SSA at ATTO is about 0.89, a value slightly higher than observed at the ZF2 site (0.86).

Elemental composition of aerosols shows that sharp increases in Al, Si, Ti and Fe are associated with Sahara dust input into Central Amazonia that is also easily observed with our Raman Lidar.

This work presents a general description of the aerosol optical properties in Amazonia, both during the Amazonian wet and dry seasons.

We would like to thank the INPA LBA central office in Manaus for logistical support for the ZF2 and ATTO sites. This research was funded by the FAPESP Thematic project AEROCLIMA, 2008/58100-2, and CNPq/INCT projects.

In-situ absorption measurement of HULIS and mineral dust components as well as winter time ambient aerosol using multi-wavelength photoacoustic instrument. A laboratory and a field study

T.Ajtai[1], N. Utry[1], Á. Filep[1], Z. Bozóki[1], G. Szabó[1]

Department of Optics and Quantum Electronics, University of Szeged, Hungary
Keywords: Aerosol absorption, minerals, HULIS, photoacoustic
Presenting author email: ajtai@physx.u-szeged.hu

Aerosol can interact with solar radiation via absorption and scattering. While backward scattering directly cooling the atmosphere, forward scattering redistribute the electromagnetic energy without affecting the annual global average of atmospheric temperature. The absorption processes directly heat the atmosphere. The net effect is cooling, but the accuracy of its amplitude is really questionable, in part since, the lack of the reliable instrumentation for in-situ absorption measurement (Lack et al., 2006). The only method which could directly measure light absorption by aerosol is photoacoutic, but it is not widespread in its application yet (Meinrat. O. Andreae, 2005). Very recently, multi-wavelength photoacoustic instruments become available for in-situ spectral characterisation of aerosol and open up a new perspective for reliable and selective in-situ carbon content identification (Lewis et al, 2008 , Ajtai et al, 2010).

In this study we present mass specific light absorption coefficient of re-dispersed dust components such as illit, caolinite, quartz, calcite, rutile, hematite as well as HULIS aerosols in the whole climate relevant and the photochemically active UV region. The measurements were made by our state-of-the-art multi-wavelength photoacoustic instrument (4λ-PAS, Ajtai et al, 2010). Based on the photoacoustic absorption measurement we calculated the two wavelengths Absorption Angström Exponent (AAE) of the investigated aerosols refer to UV, VIS, and Near-IR spectral region. We experimentally demonstrated that the absorption feature of mass specific aerosol absorption (MAC) could be used as chemically selective parameter. We also demonstrated that the selectivity of the composition identification through in-situ measured absorption feature might be increased by taking into account the wavelength dependency of AAE. Moreover, we demonstrate that forcing calculation based on the wavelength dependent AAE is more accurate than forcing calculation used the commonly applied single wavelength AAE approach.

We also present here results of in-situ spectral responses of ambient aerosol under wintry conditions in urban environment. The hourly concentration of gaseous pollutants (CO and NOx), trace elements (i.e. K, Ca, Fe, and Si) as well as the size distribution of ambient aerosol were also analyzed during the whole measurement campaign. The levoglucosan measurement was made to confirm that the daily fluctuation of ambient AAE governed by the changes in the relative strength between the traffic and residential heating emission. Finally, we demonstrate correlations between the measured two wavelengths AAEs and the concurrently measured other aerosol variables such as size distribution, gas and trace elements concentrations. All the correlations are quantified using both single wavelength and wavelength dependent AAE.

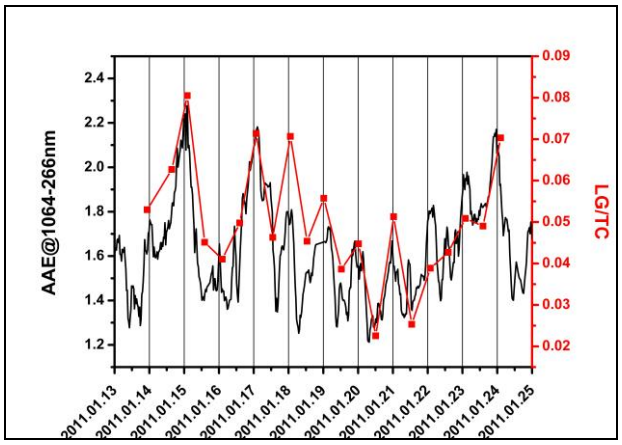

Figure 1. The time series of AAE and the relative strengths of levoglucosan/TC concentration

Black carbon aerosol concentrations and mixing state in Pallas, Finland

T. Raatikainen[1], D. Brus[1], A.-P. Hyvärinen[1], J. Svensson[1] and H. Lihavainen[1]

[1]Finnish Meteorological Institute, Helsinki, Finland
Keywords: SP2, black carbon, soot particles, aerosol coating.
Presenting author email: tomi.raatikainen@fmi.fi

Black carbon (BC) aerosols have various climate effects. In addition to directly absorbing solar radiation, they have an effect on aerosol-cloud interactions and snow and ice albedo. Single Particle Soot Photometer (SP2) detects BC by using laser-induced incandescence and non-absorbing particles are identified from the scattered light (Stephens et al, 2003). Absorbing particles, with or without coating, are quickly heated to the incandescence temperature and the resulting peak signal, which is seen before evaporation, is proportional to the BC mass. Sizes of the purely scattering particles can be calculated from the peak intensity of the scattered light, which is seen when the particle is at the centre of the laser beam. However, particles containing both BC and scattering material heat up rapidly so that the scattering material evaporates before the centre of the laser beam. In this case, the initial scattering particle size can be extrapolated.

Two commonly used methods to extrapolate scattering sizes for evaporating particles are Leading Edge Optimization (LEO; Gao et al, 2008) and Normalized Derivative Method (NDM; Moteki and Kondo, 2008). The NDM is computationally demanding, and both methods can fail when, for example, the sample flow rate fluctuates. Significant flow rate fluctuations were observed in the SP2 measurements conducted at Pallas station in northern Finland during winter 2011-2012. To improve the coating thickness calculations, we have improved the NDM method so that the computationally heavy a priori estimate of the scattering signal is replaced by a linear fit to the normalized derivative and a fast posteriori likelihood test.

Figure 1 shows number concentrations of the different particle types. Concentrations are low in this pristine environment, but about 10 % of the observed (150-500 nm) particles contain BC. In addition, practically all BC particles are coated.

Figure 2 shows coating thickness distributions based on the original scattering sizes and those calculated with LEO, NDM and the new method. Due to the fluctuating flow rate, the NDM often fails to find a solution. The LEO method can find a solution, but it could overestimate coating thickness. The new method finds a reasonable solution for most particles (4715 of 5973) and the results show that most particles are thinly coated (68 % have less than 50 nm coating). This finding is in good agreement with the observation that 73 % of these particles experienced rapid coating evaporation determined from the lag time between scattering and incandescence peak signals. Further calibration experiments with mixed particles will be used to show that the new method finds the correct scattering size.

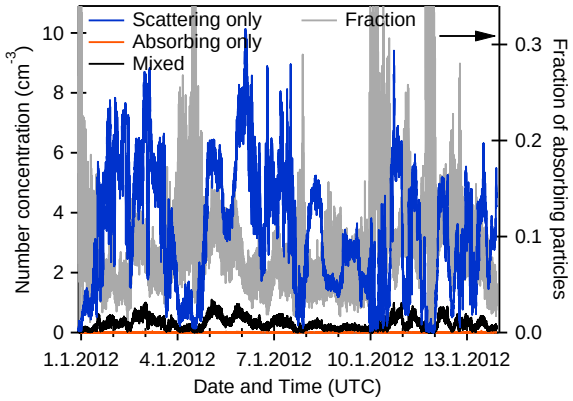

Figure 1. Total concentrations of scattering, absorbing and mixed particles from the 150-500 nm size range, and the fraction of absorbing particles.

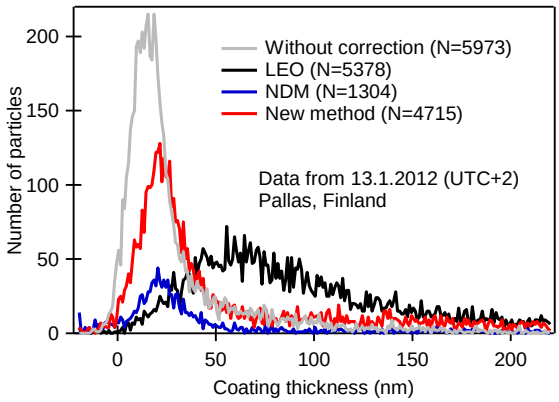

Figure 2. Coating thickness distributions for mixed particles which BC core diameter is 150-170 nm.

Session: Atmospheric Aerosols,
SOA and aerosol hygroscopicity

Vapour pressures of substituted polycarboxylic acids are much lower than previously reported

The formation and fate of secondary organic aerosol (SOA) is governed by the partitioning of compounds between the aerosol and gas phase. This gas-particle partitioning of SOA is generally represented by an equilibrium partitioning model. A key physical parameter which governs gas-particle partitioning is the pure component vapour pressure (p^0) over the liquid state, which is difficult to accurately measure at atmospheric temperatures for low- and semi-volatile organic compounds such as polycarboxylic acids. Subcooled liquid state vapour pressures of substituted polycarboxylic acids inferred from measurements made in the solid state differ by many orders of magnitude from the predictions of current vapour pressure estimation methods, leading to large uncertainties in predictions of SOA partitioning. In this study, vapour pressures are inferred from the evaporation rate of single liquid particles levitated in an electrodynamic balance.

We present measurements of the liquid pure component vapour pressure for 2-Methylmalonic (isosuccinic) acid, 2-Hydroxymalonic (tartronic) acid, 2-Methylglutaric acid, 3-Hydroxy-3-Carboxyglutaric (citric) acid and 2,3-Dihydroxysuccinic (tartaric) acid which were measured in the subcooled liquid state (Huisman et al, 2013). Here we report also on measurements for 2-Oxoglutaric acid and compare those with literature data.

While the measurements of isosuccinic and 2-Methylglutaric acids agree with previous measurements, the data for tartaric and citric acid are 6 orders of magnitude lower than those previously reported, see Fig. 1. Also, our data of tartronic acid and 2-Oxoglutaric acid are significantly lower (2-3 orders of magnitude) lower than those inferred from measurements in the solid state by Booth et al. (2010). Please note that the agreement between our data and those of the vapour pressure estimation method by Compernolle et al. (2011) is significantly better when neglecting the empirical correction terms introduced to model the inexplicably high vapour pressures of some of substituted dicarboxylic acids reported by Booth et al. (2010). This holds particularly true for tartaric and citric acid.

We conclude first, that vapour pressure measurements should be performed in the liquid state whenever possible, second, that the empirical correction term introduced within the estimation model by Compernolle et al. (2011) should not be used and third, that more measurements using different techniques are needed to elucidate the reason for the many order of magnitude differences between our measurements and those of Booth et al. (2010).

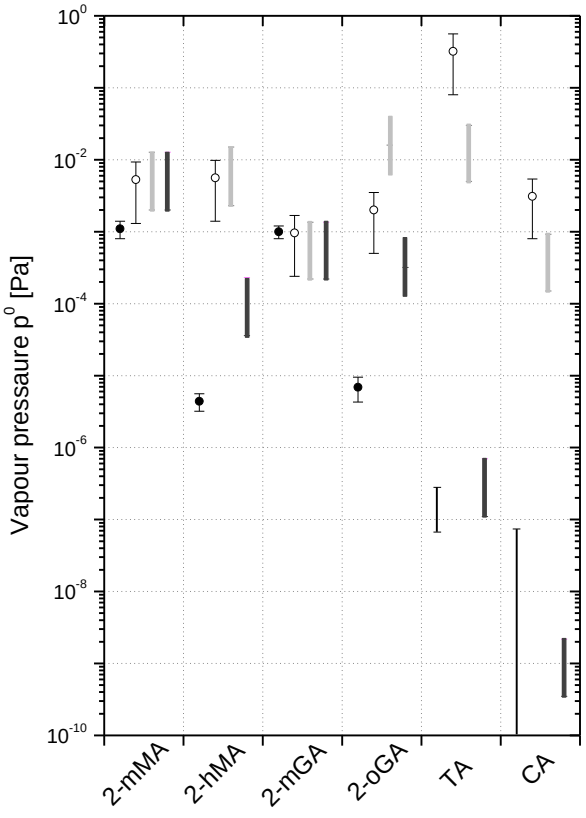

Fig. 1. Vapour pressures (T=298 K) of the liquid for 2-Methylmalonic acid (2-mMA), 2-Hydroxymalonic acid (2-hGA), 2-methlyglutaric acid (2-mGA), 2-oxoglutaric acid (2-oGA), tartaric acid (TA), and citric acid (CA), from this work (solid symbols and bars, when only a data range is reported), Booth et al. (open symbols), model prediction (Compernolle et al.) with correction (light gray) and without empirical correction term (dark gray).

Keywords: SOA, phase state, viscosity, VOC.
Presenting author email: aki.pajunoja@uef.fi

Secondary organic aerosol (SOA) formed from partitioning of oxidation products of volatile organic compounds (VOC) accounts for a significant portion of atmospheric particulate matter. Behaviour of SOA particles in the atmosphere is affected by the phase of particles; not heeding these effects can result in errors when the atmospheric implications of SOA particles are predicted. Phase change of the particles can be induced e.g. by temperature change, absorption of water, or other solvent, or by chemical aging.

The phase state of SOA particles cannot be measured directly. Present studies show that particle bounce correlates with the phase state of particles (Virtanen et *al.* (2010), Saukko et *al.* (2012a), Saukko et *al.* (2012b)). A similar but modified method was employed in this study. The schematic of the new measurement system is shown in Figure 1. The system consists of a size classification DMA (selected sizes 70-150 nm), humidity control unit, a single MOUDI-type impactor stage (cut-off size 67 nm) and two CPCs. Upstream and downstream pressures of the impactor stage were stabilized to 0.85 bar and 0.7 bar.

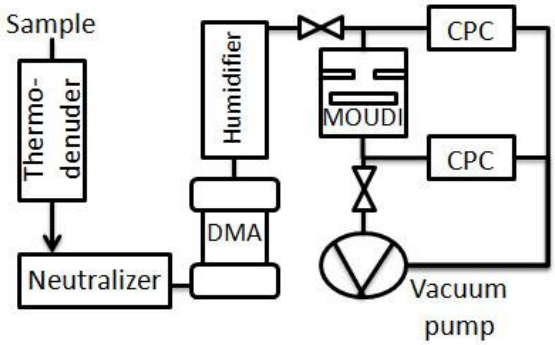

Figure 1: Schematic representation of the measurement system.

The chamber experiments were performed in the Manchester Photochemical Aerosol Chamber (Alfarra et al., 2012). In these experiments both biogenic and anthropogenic precursors were used (α-pinene, 1,3,5-trimethylbenzene, β-caryophyllene, limonene and n-heptadecane). The measurement schedule for different VOC mixtures is shown in Table 1. Mixtures of one to three precursors were investigated with and without the presence of ammonium sulphate seeds.

The oxidation conditions in the chamber were altered, namely the NO_x-level (20-115 ppb) and the UV exposure (filter on/off) while the O_3 level and relative humidity (RH) in the chamber were constantly 40 ppb and 60%, respectively. The exposure to light (visible and UV) varied between 0 and 5 hours.

The particle bounce was investigated for RH between 5 and 80% in the impactor. These RH scans were conducted for several thermodenuder temperatures (25 - 75°C).

Table 1. Chamber experiment schedule for four VOCs and specific NO_x and O_3-levels (ppb). X means the existence of ammonium sulphate seeds or usage of UV filter.

1	2	3	NO_x	O_3	seed	filter

n-hept			50	80		

In this paper, results of the particle bounce measurements will be compared to findings from measurements of particle composition and sub- and super-saturated water uptake determined by high resolution AMS, HTDMA and CCNc, respectively. Clear effects of chemical composition and aging, hygroscopicity and relative humidity on the phase state of the SOA particles were observed. In addition differences between the bounce fractions in the SOA-coated seed experiments with different temperatures and aging times were found.

Impact of semi-volatiles on hygroscopic growth and CCN activity of secondary organic aerosol

A. Buchholz[1], M. R. Alfarra[1,2], W.T. Hesson[1] and G. McFiggans[1]

[1]Centre for Atmospheric Sciences, The University of Manchester, Manchester, M13 9PL, UK

Presenting author email: angela.buchholz@manchester.ac.uk

Secondary organic aerosols (SOA) are an important constituent of the global aerosol load. They are formed via gas to particle conversion of low- and semi-volatile oxidation products of volatile organic compounds (VOCs) from both biogenic and anthropogenic sources. In smog chamber studies semi-volatile compounds may play an important role. These compounds could be over-represented at the beginning of experiments because of relatively high precursor concentrations and the limited volume of chambers. As an additional complication, these compounds might leave the particle phase when subjected to higher temperatures e.g. in measurement instruments. In this paper we focus on the influence of semi-volatiles on the microphysical properties (i.e. the hygroscopic growth and cloud condensation nuclei (CCN) activity) of SOA. Knowledge of the microphysical properties is important to understand the impact of atmospheric aerosols on climate.

Experiments were conducted in the Manchester Aerosol Chamber (Alfarra et al., 2012) using biogenic (α-pinene, β-caryophyllene, limonene) and anthropogenic precursor VOCs (1,3,5-trimethylbenzene (TMB), n-heptadecane) both individually and in binary or ternary mixtures. In some experiment ammonium sulphate was used as seed aerosol. In order to produce SOA with a range of different composition and properties the oxidation conditions were varied (namely the NO_x to VOC ratio, the starting O_3 concentration, and the spectrum of the UV lamp). All experiments were conducted at approx. 25°C and under humid conditions (RH ~60%).

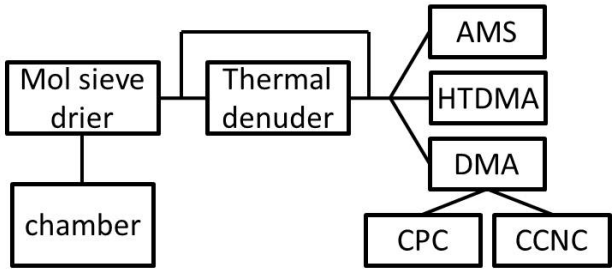

Figure 1. Schematic representation of instrument set up

The aerosol was treated in a thermal denuder (TD) at temperatures between 25 °C (room temperature) and 100 °C to investigate the influence of semi-volatile compounds on the properties of the particles (see Fig. 1). This alternated with sampling directly from the chamber to fully characterise the SOA. The chemical composition was investigated with an Aerodyne Time-of-Flight Aerosol Mass Spectrometer (HR-ToF-AMS). The hygroscopic growth at 90% RH was measured with a hygroscopicity tandem differential mobility analyser (HTDMA). A differential mobility analyser (DMA) was coupled with a CPC to measure the size spectra and with a Droplet Measurement Technology cloud condensation nuclei counter (CCNC).

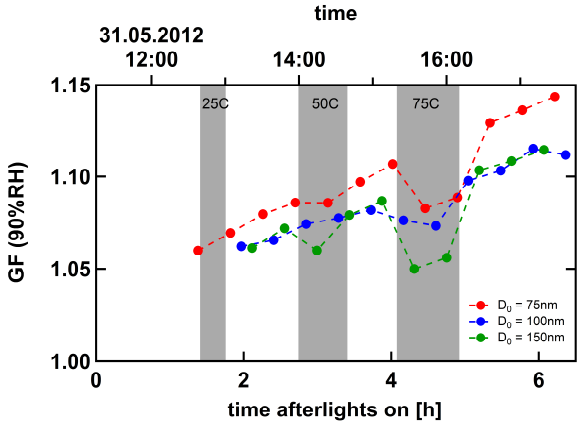

Figure 2. Time series of GF(90%) for an α-pinene experiment.

Figure 2 shows an example for one of the α-pinene experiments. In this case hygroscopic growth was reduced for particles which passed through the TD. A similar effect could be seen for the CCN activity of these particles. We will investigate how the HTDMA and CCNC reconciliation varies with TD temperature and if this can be related to changes in the AMS mass spectra.

This work was supported by the UK Natural Environment Research Council (NERC) through the ACIDPRUF programmes.

We use data from a high-resolution time-of-flight chemical ionization mass spectrometer (HRToF-CIMS, Yatavelli et al 2012) to derive chemical formulas for aerosol particles and gas-phase acids measured continuously for a 10-day period during August 2011 in a Ponderosa Pine forest in South-Western Colorado, USA. This study was part of the "Bio-hydro-atmosphere interactions of Energy, Aerosols, Carbon, H2O, Organics & Nitrogen - Rocky Mountain Biogenic Aerosol Study" (BEACHON-RoMBAS) project focused on the study of secondary organic aerosol (SOA) precursors, and their transformations and impacts in the atmosphere.

The newly developed MOVI technique (Yatavelli *et al*, 2010) was used to simultaneously study gas phase and aerosol particles. The use of acetate as reagent ion (Veres et al, 2008) in combination with the HRToF-CIMS allowed us to selectively and simultaneously measure the entire population of inorganic and organic acids at the same time. Data were acquired at 2Hz, MOVI cycles were repeated every 90 min. Data analysis was performed using the analysis package "Tofware", embedded within the commercial data analysis program "Igor Pro" (Wavemetrics, Inc.).

We will describe the specific methods developed to assign chemical formulas to all ion peaks measured in each mass spectrum, resulting in more than 1800 different unique formulas. The formulas, together with their ion peak areas, were used to perform elemental analysis and derive chemical properties such as elemental ratios (e.g. O:C, H:C, N:C) and average carbon oxidation state (OS_c), both for the bulk composition as well as a function of carbon number.

Figure 1 shows a diagram of approximate oxidation state as a function of carbon number for the aerosol during a 24-hr period of the campaign ("Kroll diagram", Kroll et al, 2011).

These data help to understand the volatile organic compound (VOC) emissions from a Ponderosa Pine forest, their gas-phase chemical transformations as well as the formation of secondary organic aerosol (SOA).

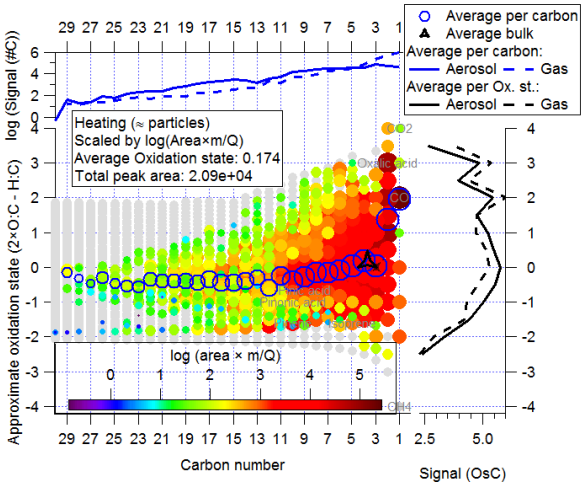

Figure 1: "Kroll diagram" for 24-hour average of "heating" (≈ aerosol) on August 20th, 2011. Colored circles: individual data; blue circles: average data per carbon number, sized by log(ion peak area×m/Q), black triangle: bulk average OS_c, blue line: avg. log(ion peak area×m/Q) vs. carbon number: solid: aerosol, dashed: gas phase, black line: avg. log(ion peak area×m/Q) vs. oxidation state: solid: aerosol, dashed: gas phase; grey circles: expected possible data range

The data show wide ranges of carbon numbers and oxidations states, suggesting a variety of VOC emissions and chemical processing. In general, gas-phase signals show higher signal at lower carbon numbers and higher bulk oxidation states than aerosol signals.

We also compare our results for acids to total organic aerosol mass (OA), measured by the AMS, and find that a significant fraction of OA consists of acids.

Ultrafine aerosol particles in the atmosphere affect the global climate by absorbing and scattering radiation and by acting as Cloud Condensation Nuclei (CCN). Due to the high variability of their physical and chemical properties, however, quantifying the contribution of airborne particles on climate is a challenging task. Particle properties may change depending on the activity of their sources and the meteorological conditions. In addition their mixing state can vary with time and location. Having information about the variation of the properties and the mixing state is therefore very important for understanding the contribution of atmospheric particles on climate.

In this work we report in situ measurements of the hygroscopicity and the mixing state of the particles observed in the atmosphere over two urban background sites in Greece: one in Patras and one in Athens. Measurements were conducted from 8 to 27 June in Patras and from 4 to 25 July 2012 at the NCSR Demokritos Global Atmosphere Watch (GAW) in Athens using a Hygroscopic Tandem Differential Mobility Analyzer (HTDMA; Rader & McMurry, 1986). In brief, dried aerosol particles having mobility diameter of 40, 60, 80, 100, and 120 nm were selected by the first DMA of the system. The monodisperse particles downstream of DMA-1 were conditioned at a relative humidity (RH) of 87±2% and measured by the second DMA and the CPC. A curve-fitting algorithm was used to fit up to three lognormal distributions depending on the spread of the selected monodisperse size distributions, revealing the aerosol's mixing state.

Figure 1 shows the HTDMA measurements of particles having dry diameter of 120 nm in Patras and in Athens. Particles observed over the Athens GAW station were more hygroscopic and more frequently externally mixed. The measured hygroscopic growth factors ranged from 1.01 to 1.63 with an average value of 1.26 and from 1.01 to 2.0 with an average value of 1.37, over the urban background sites of Patras and Athens respectively.

Table 1 provides a summary of all the HTDMA measurements recorded during the campaign.

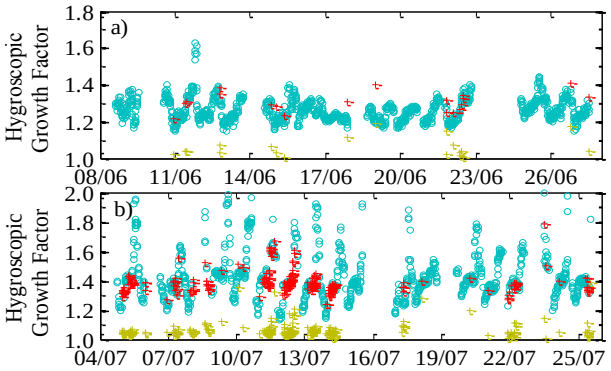

Figure 1. Particle hygroscopic growth factors in (a) Patras and (b) Athens. The growth factors correspond to particles having dry mobility diameter of 120 nm when exposed to 87±2% RH. Circles indicate internally mixed particles and crosses externally mixed particles (bimodal).

Table 1: Summary of the HTDMA measurements. Key: d_{dry} is the mobility diameter selected by DMA-1; P_u and P_b are the relative frequencies of occurrence for unimodal and bimodal distributions, respectively; g_1, g_{21}, and g_{22} are the average growth factors ± one standard deviation for the measurements showing unimodal and two bimodal distributions, respectively.

Aerosol particles influence the Earth's radiation budget by interacting with the incident sunlight. If they directly scatter or absorb the incoming solar radiation it is referred to as *aerosol direct effect*. The magnitude of this effect depends on several factors, including the chemical composition and size of the particles as well as their ability to take up water. If the particles are hygroscopic, this will itself lead to an increased size and change in index of refraction which will significantly vary their optical properties (Zieger et al., 2011). In addition, aerosols can exist in different mixing states that are usually described as internal and external mixtures. While an internal mixture implies that all particles of the same size have an identical chemical composition, an external mixture is composed by different substances that are chemically and physically independent. By analyzing the water uptake, the mixing state can be inferred. An internally mixed aerosol will grow uniformly with increasing relative humidity (RH), whereas the different species present in the external mixture will lead to a polymodal or broad size distribution. Since the chemical composition and ambient RH are known to change with altitude (Morgan et al., 2010), vertical profiles are important to quantify the actual optical properties and mixing states which particles have at different heights. This information is finally needed to e.g. determine the direct aerosol radiative forcing or to validate remote sensing with in-situ data.

Within the **P**an-**E**uropean **G**as-**A**ero**so**ls-climate interaction **S**tudy (PEGASOS) a Zeppelin is used to explore the planetary boundary layer. Two main measurement campaigns took place in the Netherlands and in the Po-Valley in Italy in 2012. As a new way to explore hygroscopic and optical properties on the platform, the white-light humidified optical particle spectrometer (WHOPS) was developed. Due to its ability to record data each second, it is highly suited for airborne measurements. The working principle can be explained as follows: First, the particles are dried and led through a differential mobility analyzer to select particles with a specific mobility diameter (d_{mob}). This monodisperse aerosol is then exposed to a defined high RH (typically 94%) and the new size is detected with a white-light optical particle spectrometer (WELAS). In this way, the hygroscopic growth factor can be determined. In addition, the humidification system is periodically bypassed. This allows retrieving information on the particle's effective refractive index by comparing the particle's dry mobility diameter with the optical response from the WELAS.

In this work we will present the hygroscopic growth and mixing state of aerosols, measured during the PEGASOS campaign in the Po-Valley in Italy in June 2012. Figure 1 shows an example for such a profile flown above San Pietro Capofiume (SPC), where the response of the WHOPS to dry, monodisperse particles (d_{mob}= 300 nm) is shown. The lower graph depicts the size distribution of the humidified particles and clearly shows a bimodal distribution with a more and a less hygroscopic mode. This is a clear indication of an externally mixed aerosol. Comparing the results for the two selected heights (i.e. 100 m and 700 m above ground), a similar behavior can be seen. Different results (i.e. non hygroscopic particles) were found for the larger sizes (d_{mob}= 500 nm) on days with Saharan dust intrusions.

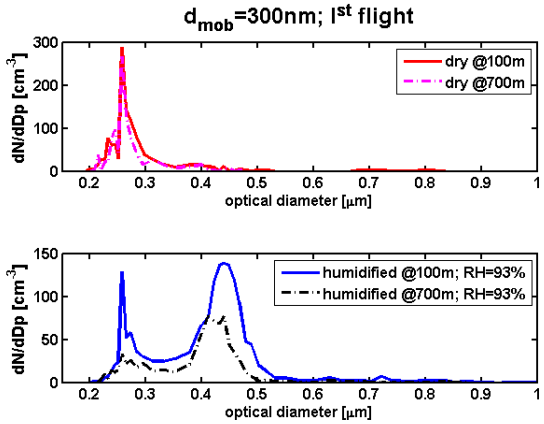

Figure 1: Data from a flight at SPC on the 20th of June 2012; for both plots a dry d_{mob} of 300 nm was selected; solid and dashed lines: flights at 100m and 700m above ground, respectively; the upper and lower graph show the dry and wet size distributions, respectively.

Keywords: atmospheric electricity, small ions, earth's electric field, lightning, aerosol-cloud interactions.
Presenting author email: hanna.manninen@helsinki.fi

Atmospheric ions play an important role in the fair weather electricity. Atmosphere's fair weather condition concerns the electric field and the electric current in the air as well as the air conductivity. On the other hand, atmospheric ions are important for Earth's climate, due to their potential role in secondary aerosol formation. This can lead to increased number of cloud condensation nuclei (CCN), which in turn can change the cloud properties. Our aim is to quantify the connections between these two important roles of air ions based on field observations and existing data archives.

When studying atmospheric electricity, the air ions are essential. Small ions, or charged molecular clusters, carry electric currents in the atmosphere. These small ions are continuously present, and their lifetime in lower atmosphere is about one minute. It's essential to find out a connection between the production rate of cluster ions, ion-ion recombination, and ion-aerosol attachment, and their ambient concentrations, in order to understand electrical properties of air istelf.

Currently, there's an intensive discussion about the connection between the atmospheric electricity and climate change. Recently, changes in atmosphere's electric properties caught new interest, as a possible connection between ionizing galactic cosmic rays, cloud cover and climatic effects was suggested (Carslaw, Harrison and Kirkby, 2002; Kirkby et al. 2011). The most significant factor of uncertainty in climate research is caused by atmospheric aerosols, especially due to small particle effects. Secondary formation of new particles through a process of gas-to-particle conversion, beginning with a few gas molecules colliding to form a cluster of 1-2 nm in diameter, is believed to be the dominant source of aerosol particles in the atmosphere. Some studies suggest that the contribution of air ions is important or even dominant to secondary aerosol formation, whereas other studies show that their role is negligible.

We studied the interactions between atmospheric electricity (air conductivity, electric field, and ambient concentartion of small ions), aerosol particles, and cloud properties. In other words, the correlations and trends in atmospheric ionization, electricity, aerosols, and CCN properties were studied. Most of the work here is based on analysis of already existing data archives, and some new measurements are established as a part of already existing measurement networks. The electrical properties of the atmosphere have been measured over a century now, whereas the longest continuous time series of aerosol particle data available is little over decade old. Tammet (2009) has collected a dataset, which comprises the measurements of atmospheric electric field, positive and negative conductivities, air ion concentrations, and accompanying meteorological measurements at 13 stations, including 7 stations of the former World Data Centre network on Atmospheric Electricity at the Main Geophysical Observatory, St. Petersburg, Russia.

The ongoing field observations of atmospheric aerosols are mainly performed at Hyytiälä SMEAR site, Southern Finland (Station for Measuring Ecosystem-Atmosphere Relations). Hyytiälä provides extensive dataset of measured aerosol particle (physical, chemical, and optical) properties, external and radon radiation, CCN properties, trace gases, meteorological parameters, different flux measurements (micrometeorology), and forest ecology observations. The atmosphere's electricity is measured with the air ion spectrometers (Manninen et al. 2010) to determine air conductivity and with the electric field mills, which measures the strength of atmospheric electric field. The plan is to extend the measurements of atmospheric electricity to the Finnish Meteorological Institute (FMI) site at Pallas, Northern Finland, and to SMEAR site at Järvselja, Estonia. Hyytiälä and Pallas stations are part of ACTRIS (Aerosols, Clouds, and Trace gases Research InfraStructure Network) and GAW (Global Atmosphere Watch) networks.

The lightning activity and ion concentration was also investigated. The lightning flash counter data for Hyytiälä, Pallas, and Järvseljä is collected by FMI. The systematic ground lightning observations are performed with eight ground-based sensors in Finland. The Norwegian, Swedish, and Estonian sensors have been integrated, completing the coverage up to the whole Nordic countries.

The support by the Finnish Cultural Foundation and the Academy of Finland Centre of Excellence program (project no. 1118615) are gratefully acknowledged.

Atmospheric aerosols are known to affect climate and human health. The organic component of aerosol particles comprises about one half of the fine-particle mass on average. Recent work has shown that most of the organic-aerosol mass is oxygenated organic aerosol (OOA) (Zhang et al., 2007), which is expected to be formed mostly as secondary organic aerosol (SOA) from the oxidation of biogenic and anthropogenic volatile and semi-volatile organic compounds (VOCs and SVOCs). Air-quality models currently under-predict the concentrations of organic aerosol in the atmosphere, especially in the summer and in urban areas (Volkamer et al., 2006), suggesting that anthropogenic SOA formation is still not well understood.

A wide range of SOA mass yield values have been reported in the literature for a number of the most commonly studied anthropogenic VOCs (e.g. toluene and 1,3,5-trimethylbenzene). In this paper, we present results suggesting that the ability of key anthropogenic precursors to form SOA may have been over-estimated in the literature. The paper will discuss a series of smog chamber experiments conducted using single anthropogenic and biogenic precursors, as well as mixtures of anthropogenic and biogenic VOCs at different experimental conditions. Investigated compounds included touluene, 1,3,5-trimethylbenzene (TMB), n-heptadecane, α-pinene, β-caryophyllene and limonene. Among the studied parameters, the influence of different characteristics of chamber light spectrum on SOA formation will be discussed and related to previous anthropogenic SOA studies.

The experiments reported in this paper were conducted at the Manchester aerosol chamber (Alfarra et al., 2012), which is an 18 m^3 photochemical batch reactor designed to study atmospheric processes of multicomponent aerosols under controlled and realistic conditions. An array of state-of-the-art instruments measuring aerosol composition and properties as well as VOC precursors and their oxidation products were employed. The chemical composition of the formed SOA was measured on-line using an Aerodyne Time-of-Flight Aerosol Mass Spectrometer (HR-ToF-AMS). A hygroscopicity tandem differential mobility analyser (HTDMA) and a cloud condensation nuclei (CCN) counter were used to probe the hygroscopic properties and CCN activity of the aerosols in the sub- and super-saturated regimes, respectively. A proton transfer reaction mass spectrometer was used to study the evolution of the gas-phase oxidation products. The phase-state of the formed particles was inferred using a particle bounce method (Virtanen et *al.* (2010), Saukko et *al.* (2012)). A thermodenuder was used to study the volatility of secondary organic aerosol at 50 and 75 ^oC.

Particles from a range of experiments were collected on filters for off-line chemical speciation by liquid-chromatography coupled to mass spectrometry (LC/MS-MS). Results from this detailed analysis will be used to investigate the contribution of specific precursors to the formed SOA, and will also be linked to the particle phase state and precursor type.

This work was supported by the UK Natural Environment Research Council (NERC) through the ACIDPRUF programmes. The particle phase-state studies were performed as part of a EUROCHAMP-2 transnational activity.

Presenting author email: puneet@aerodyne.com

We present gas-phase measurements of laboratory generated oxidized organic compounds using acetate chemical ionization mass spectrometry (Acetate-CIMS). This relatively new detection scheme uses acetate ions ($CH_3C(O)O^-$) to initiate proton transfer reactions with trace organic and inorganic acids with gas-phase acidities higher than that of acetic acid (Veres *et al*, 2008; Bertram *et al*, 2011). This technique has been used in conjunction with recently developed aerosol inlets to study secondary organic aerosol in both the field and laboratory (Yatavelli *et al*, 2009, 2012).

Here, we present acetate-CIMS spectra of oxidized organic vapors generated from the ozonolysis of α-pinene and photooxidation of α-pinene, isoprene, and naphthalene in a Potential Aerosol Mass (PAM) flow reactor over multiple days of equivalent atmospheric OH oxidation (Lambe *et al*, 2011). By taking advantage of the high-resolution capabilities of the Tofwerk HToF on the CIMS, we are able to explore the elemental composition of the oxidized organic vapors as a function of OH exposure and precursor. Such vapors are of interest because low volatility organics have been implicated in aerosol nucleation processes (Riipinen *et al*, 2012).

Within the range of our measurements, we investigate commonly used metrics for oxidation level such as the average oxygen to carbon (O/C) ratio, carbon oxidation state (OS_c), and carbon number (C_n) of the oxidized vapors relative to C_n of the precursor. Figure 1 shows O_{sc} as a function of C_n of oxidized vapors produced from the ozonolysis of α-pinene, referred to here as a Kroll diagram (Kroll *et al*, 2011). Average O/C ratios and OS_c values typically range from 0.7 to 1.1 and -0.1 to 0.9, respectively, across the entire simulated OH exposure.

To gain insight into the relative acidity of these oxidized organic vapors, we compare acetate-CIMS spectra with NO_3-CIMS spectra obtained for the same systems in the laboratory and for ambient measurements obtained during the Southern Oxidant and Aerosol Study (SOAS) at the forest supersite in Centreville, AL. The NO_3-CIMS method is specific to species with gas-phase acidities higher than that of nitric acid, thus producing spectra that represent a subset of the acetate-CIMS spectra.

The oxidation of biogenic volatile organic compounds (BVOCs) yields a wide range of oxidation products with multifold functional groups. Depending on the chemical and physical properties of the formed products they are able to undergo gas to particle conversion contributing significantly to the formation of secondary organic aerosol (SOA). Although several studies exist about the formation of SOA originating from the monoterpene oxidation (see review by Hallquist *et al.*, 2009) there is a gap in the knowledge about the involved species. To overcome this issue, the condensation growth and impacting system (C-GIS, Sierau *et al.*, 2003) was connected to the aerosol chamber LEAK (Leipziger Aerosol Kammer) that enables a time-resolved sampling and analysis of chamber generated SOA.

Several experiments were conducted examining the oxidation of monoterpenes (α- and β-pinene) and their first generation oxidation products (pinonaldehyde and nopinone). The oxidation was carried out using OH radicals originated from the photolysis of hydrogenperoxide (H_2O_2) as well as from the ozonolysis of tetramethylethylene (TME). All experiments were conducted in the presence of acidic seed particles (78 mM NH_4HSO_4). The generated SOA was sampled during the course of the experiment for 10 minutes using C-GIS. The suitability of C-GIS was evaluated conducting a comparison between filter measurements and C-GIS using three SOA compounds (Table 1) terpenylic acid, pinic acid, and 3-methyl-1,2,3-tricarboxylic acid (MBTCA).

Table 1. Mean value of the deviation between filter and C-GIS measurements

Compound	Deviation [%] (n=3)
Terpenylic acid	39 ± 2
Pinic acid	21 ± 4
MBTCA	48 ± 3

Despite the underestimation the data obtained by C-GIS show only small deviations from the mean value (below 5%) indicating the suitability of C-GIS for the time-resolved SOA analysis.

From the analysis of the C-GIS samples a time profile of the three SOA compounds can be obtained. It was found that terpenylic acid and pinic acid are early generation oxidation products whereas MBTCA is formed secondary.

These observations are in consistence to the literature (Claeys *et al.*, 2009, Christoffersen *et al.*, 1998). In addition, a correlation was found between the time-profile of the terpenylic acid concentration and the particle growth ΔM (Figure 1) indicating a central role of terpenylic acid for the SOA formation (Claeys *et al.*, 2009). Nevertheless, such a correlation was not found for all of the conducted experiments. Those missing correlations might be explained by additional compounds causing particle growth which are not indentified and quantified jet.

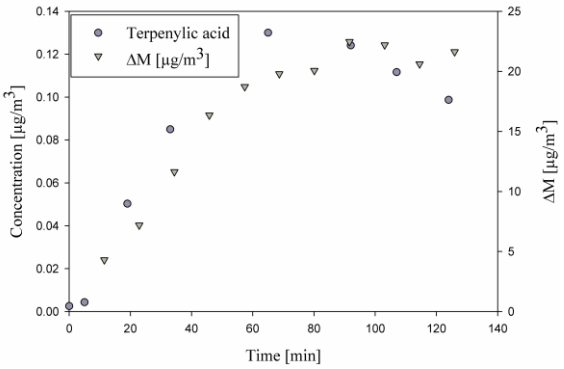

Figure 1: Relationship between the concentration profile of terpenylic acid and the particle growth during the oxidation of nopinone with OH radicals.

The decay of terpenylic acid concentration after 90 minutes of the experiments might be a result of the formation of higher molecular weight compounds (HMWCs). From the analysis it was found that a compound with *m/z* 357 is also formed which corresponds to $C_{17}H_{25}O_8$. Therefore it can be assumed that besides the central role of terpenylic acid for the particle growth it might be also an important precursor compound for the formation of HMWCs.

Dependence of α-pinene secondary organic aerosol formation on relative humidity and aerosol surface distribution

L. Pfaffenberger, P. Barmet, R. Wolf, S. M. Platt, I. El-Haddad, J. G. Slowik, J. Dommen, A. S. H. Prévôt and U. Baltensperger

Laboratory of Atmospheric Chemistry, Paul Scherrer Institute PSI, Villigen, 5232, Switzerland

Keywords: AMS, Photochemical processes, SOA (Secondary Organic Aerosols), Water soluble organic compounds

Organic aerosol (OA) represents a major fraction (20-90%) of the submicron aerosol (Jimenez et al., 2009). Potential sources and processes leading to the formation of secondary organic aerosol (SOA) are still rather poorly understood, although SOA contributes significantly to the global OA burden. To determine parameters relevant to SOA yields, in particular volatility and degree of oxygenation, the formation and aging of particles has to be investigated more thoroughly.

Several laboratory studies suggest that aqueous phase SOA formation can be almost as important as gas phase oxidation of volatile organic compounds and their subsequent partitioning to the aerosol phase (Ervens et al., 2011).

In this study, the aerosol chemical composition as a function of the vacuum aerodynamic diameter (d_{va}) was investigated using an Aerodyne aerosol mass spectrometer (AMS) equipped with a $PM_{2.5}$ lens. In the PSI smog chamber, the aerosol precursor α-pinene was irradiated in the presence of low (~30%) or high (~80%) relative humidities (RH) and various NO_x concentrations. NH_4HSO_4 was used as a hygroscopic seed, providing a large water volume at high humidity. A wide diameter range, ~50 to 2500 nm, was covered by the particle phase instruments. The aging time in the chamber was related to the atmospheric oxidation time using OH exposures derived from the decay of an OH tracer injected into the chamber (Barmet et al., 2012).

For a similar NO_X concentration, higher SOA yields were observed at higher RH compared to lower RH. Fig. 1 shows mass distributions of organics, sulfate, ammonium, and nitrate, as well as organic mass fractions f_{44} (m/z 44 / total organics, a surrogate for the degree of oxygenation) and f_{43} (m/z 43 / total organics, a surrogate for less oxygenated compounds like aldehydes, ketones and alcohols) as a function of particle diameter. The data is averaged over the experiment period when aerosol aging dominates. The wet aerosol surface distribution shown in Fig. 1 was calculated using a volume-mixed growth factor and the measured RH (72 ± 1 %). This particular experiment was conducted with 16 ppb α-pinene and 20 ppb NO_x.

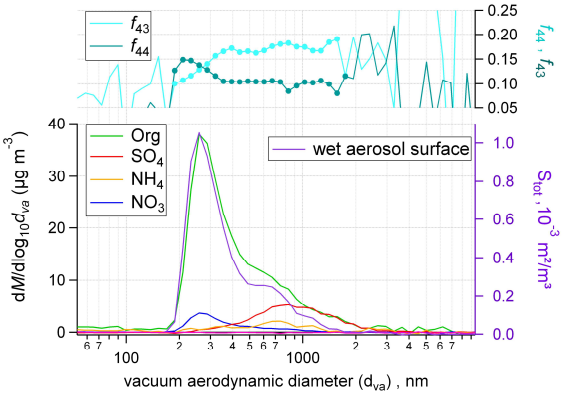

Figure 1. Averaged mass distribution of chemical species, calculated wet surface distribution and organic mass fractions f_{44} and f_{43} as a function of particle diameter. Dots (f_{44}, f_{43}) represent data when $d(org)/dlog_{10}d_{va}$ is above a threshold of $2 \mu g \cdot m^{-3}$.

The organic mass distribution follows the wet surface distribution of the aerosol, suggesting a fast, surface dependent, SOA formation process. Secondly, the chemical composition is dependent on particle size, indicated by the increase of f_{44} with diameter. This could be due to the larger available water volume, favouring aqueous phase processes that lead to more highly oxygenated products like acids.

The effect of particle size will also be assessed by analysis of single particle mass spectra acquired using a light scattering module integrated with the AMS. The combined effects of varied relative humidity and NO_x concentration on SOA yields and composition will be investigated and discussed in this study.

This work was supported by EUROCHAMP-2, a project within the EC 7th Framework Programme, as well as the Swiss National Science Foundation.

Characterization of secondary organic aerosol from ozonolysis of β-pinene

Ågot K. Watne, Eva U. Emanuelsson, Anna Lutz, Evert Ljungström and Mattias Hallquist

Department of Chemistry and Molecular Biology, University of Gothenburg, Gothenburg, Sweden
Keywords: Aerosol Chemistry, Flow Reactor, Volatility, Terpenes
Presenting author email: agot.watne@chem.gu.se

A large fraction of the atmospheric aerosol contains organics. Particulate organics can be formed in the atmosphere through oxidation of gaseous precursors to secondary organic aerosol (SOA). The processes of formation of SOA are currently not well understood. In order to predict and represent SOA influence on for instance cloud formation and climate, an accurate description of formation and properties of SOA is needed (Hallquist *et al*., 2009).

The effects of humidity, temperature and radical chemistry on the SOA formed from the ozonolysis of β-pinene were studied in Gothenburg Flow Reactor for Oxidation Studies at low Temperatures (G-FROST). G-FROST is a laminar flow reactor where SOA can be formed under well-controlled conditions (Figure 1). Through the flow reactor there is a continuous laminar flow. This creates a stable aerosol output and imposed changes to the chemistry can be monitored and analyzed.

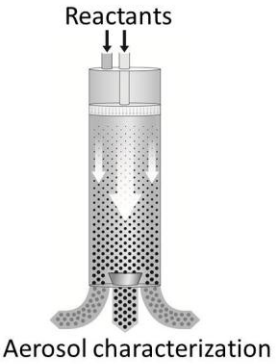

Figure 1: Schematic of G-FROST.

The relative humidity (RH) was varied in experiments conducted at 288 K and at 298 K for three different β-pinene concentrations: low, intermediate and high. In addition, the effect of using 2-butanol or cyclohexane as OH-scavenger was studied. In all experiments, the RH was changed in four steps aiming at 12, 15, 30 and 50 %. Figure 2 shows an example of an experiment.

In addition to the number and mass of SOA produced, thermal properties of the aerosol were characterized using a Volatility Tandem Differential Mobility Analyser (VTDMA). The VTDMA provides several aspects of thermal properties. An example is volume fraction remaining at 383K, VFR(383K), which is a general measure of volatility.

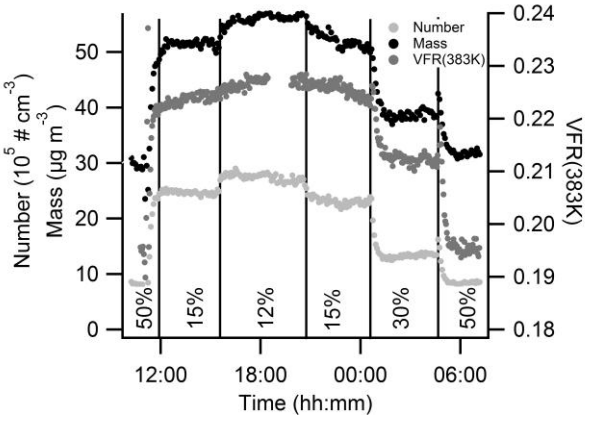

Figure 2: Change in particle number, mass concentration and VFR(383K) in with stepwise change in RH.

As can be seen in Figure 2, the SOA formed from ozonolysis of β-pinene shows a negative RH dependence. This was valid for all experiments and is the opposite RH dependence of what has been observed from the ozonolysis of α-pinene (e.g. Jonsson *et al*, 2008).

Regarding the thermal properties, several aspects were revealed. It was demonstrated that thermal properties of the SOA did change for the different conditions (e.g. temperature, RH and use of scavenger). For instance, as shown in Figure 2, the SOA got more volatile with increasing RH. This was observed as an decrease in VFR(383K) at higher RH and was valid in all experiments. These features can be linked to the changes in chemical mechanism affecting SOA number and mass (Emanuelsson *et al*,. 2013).

The results from this study suggest inclusion of new chemistry in atmospheric chemical models in order to cover relevant atmospheric changes in humidity, temperature and oxidant levels that affect SOA formation and properties.

The research presented is a contribution to the Swedish strategic research area ModElling the Regional and Global Earth system, MERGE. This work was supported by Formas (214-2010-1756) and the Swedish Research Council (80475101).

Keywords: secondary organic aerosol, anthropogenic enhancement, volatility, OH dose
Presenting author email: d.zhao@fz-juelich.de

Recent field data and model analysis show that SOA is enhanced under anthropogenic influences although the SOA material itself is mainly biogenic (de Gouw et al. 2005; Spracklen et al. 2011). Such anthropogenic enhancement may affect the global SOA loading significantly. However, its mechanism is still not clear. Direct chemical interaction of BSOA and ASOA components may contribute to anthropogenic enhancement.

In order to investigate the interaction of anthropogenic SOA(ASOA) with biogenic SOA(BSOA) we studied mixtures aromatics and monoterpenes as representatives of anthropogenic VOC and biogenic VOC in the large chamber SAPHIR in Juelich, Germany (Emanuelsson et al. 2012). SAPHIR chamber allows for studies under natural OH concentrations. Particle chemistry and properties including volatility were characterized by a High resolution Time-of-Flight aerosol mass spectrometer (TAMS), off-line filter analysis by HPLC-ESI-qTOF-MS(Kristensen and Glasius 2011), and Volatile Tandem Differential Mobility Analyzer (VTDMA, (Jonsson et al. 2007)). Gas phase OH concentration was measured by a Laser Induced Fluorescence (LIF) to quantify the OH dose to which the reaction mixtures were exposed.

We found two major drivers for the time evolution of SOA volatility: OH dose and ASOA fraction. Volatility decreases with OH dose for both BSOA and ASOA (Figure 1). ASOA has lower volatility and higher O/C since its precursor needs higher OH dose before it generate significant amount of materials to condense on the particle due to their low reactivity.
Generally, volatility of particle also decreases as ASOA fraction increase (Figure 1). However, ASOA components decrease the volatility of mixed ABSOA more efficient than expected by a simple linear combination of properties of pure ASOA and BSOA systems. Already a very small fraction of ASOA can decrease the volatility of ABSOA significantly likely initiating oligomerization(Kalberer et al. 2004), as shown in Figure 1 for case 10/6.

In contrast, mass yield, f44, O/C can be described by the linear combination of the corresponding properties of pure ABSOA and BSOA systems (Emanuelsson et al. 2012). Decreased volatility increases thermal persistence, suppresses one loss channel, evaporation by heating and dilution and therefore increases the lifetime of ABSOA compared to BSOA under same conditions. Since aromatic VOCs are mainly anthropogenic (and correlate with CO), this phenomenon may contribute to the anthropogenic enhancement. This phenomenon was further investigated in a second study in order to detect oligomerization and relate it to change of optical properties.

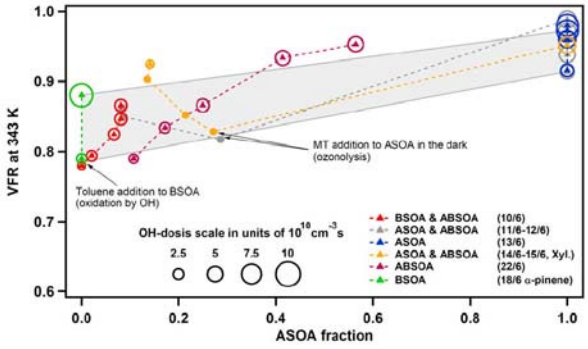

Figure 1 VFR (343K) for ABSOA experiments and BSOA experiment (18/6) as a function of the model derived ASOA fraction (triangles) with OH dose indicate by the size of the circles. The lower boundary of the shaded area is given by VFR (343K) for freshly formed aerosol at OH doses of ≈ 1-2x10^{10} cm^{-3} s for pure BSOA and of 3.6x10^{10} cm^{-3} s for pure ASOA. The upper boundary line connects pure BSOA (18/6) and pure ASOA (13/6) at about the same OH dose ≈ 9x10^{10} cm^{-3} s.

Keywords: Nucleation, QM, Kinetics, SOA.
Presenting author email: elm@chem.ku.dk

The goal of this work is to determine the effect of common aerosol precursors H_2O, NH_3 and H_2SO_4 on the OH initiated oxidation mechanism of volatile organic molecules in the atmosphere. We use methanol as a model compound due to its relatively high atmospheric abundance and long residence time. We have investigated the interaction between methanol and each of the molecules H_2O, NH_3 and H_2SO_4 to assess cluster stabilities. This has been done by calculating statistical Gibb's free energies of formation. Subsequently the effect of the aerosol precursors on the reaction rate and mechanism of hydrogen abstraction reactions by the OH radical have been calculated.

Theory

To evaluate the rate constant of the i'th hydrogen abstraction conventional transition state theory is applied:

$$k_i = \sigma_i \kappa_i(T) \frac{k_B T}{h} \frac{Q_{TS,i}}{Q_R Q_{OH}} \exp\left[-\frac{\Delta E_i^{\ddagger}}{k_B T}\right]$$

The tunnelling correction κ_i is evaluated using an asymmetrical Eckart barrier. σ_i is the symmetry factor which denotes the reaction path degeneracy. From the individual rate constants the total rate constant (k_{total}) and branching ratio (Γ_i) can be calculated.

Methodology

To systematically scan the configurational space each nucleation step was performed by adding 1000 randomly oriented nucleate molecules (H_2O, NH_3 and H_2SO_4) randomly distributed around the target methanol molecule/complex. The 1000 generated structures were geometry optimized using the semi-empirical PM6 method to yield initial guesses. The identified conformations were then optimized with M06-2X/6-311++(3df,3pd) to yield the final structures. All local minima within 3 kcal/mol of the identified "global" minima were then thermally averaged to calculate the statistical Gibb's free energy of formation. For calculating the rate constants and branching ratios BH&HLYP/aug-cc-pVTZ geometries and frequencies were used. The single point energy was corrected with a high level explicitly correlated Coupled Cluster Singles Doubles with perturbative triples CCSD(T)-F12a calculation using the VDZ-F12 basis set.

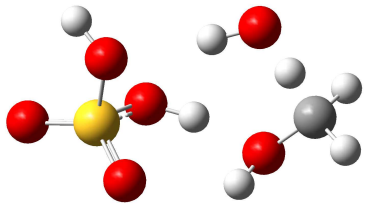

Figure 1: Transition state structure of C-H hydrogen abstraction by the OH radical from methanol in the $(CH_3OH)(H_2SO_4)$ complex.

Conclusions

The interaction between methanol and H_2O/NH_3 is found to be thermodynamically unfavourable suggesting that neither water nor ammonia catalyse the gas phase reaction of methanol with the OH radical.. We find that methanol is able to form stable complexes with H_2SO_4 which is more favourable than the corresponding hydrate. The incorporation of methanol into a pre-nucleation cluster does not hinder the subsequent addition of nucleation precursors. Due to stabilization of the transition state complex trough hydrogen bonding the complex formation is found to be able to both catalyse and change the reaction mechanism of the hydrogen abstraction reactions of methanol by the OH radical depending on collision mechanism. This intriguing result indicates that complex formation with sulfuric acid is able to alter the reaction mechanism of a simple organic compound by acting as a stabilizing scaffold and it thereby indicates an alternative new pathway for oxidation products of various organic compounds.

The oxidation of Biogenic Volatile Organic Compounds (BVOC) emitted by vegetation, such as monoterpenes ($C_{10}H_{16}$) or sesquiterpenes ($C_{15}H_{24}$) is an important source of Secondary Organic Aerosol (SOA). Because of their large global emissions and high reactivity with the major atmospheric oxidants (Atkinson and Arey, 2003) – and particularly with ozone (O_3) – they are believed to be the dominant contributors to global SOA formation (Kanakidou *et al*, 2005).

α-Pinene and limonene are two of the three most important BVOC emitted in the atmosphere (Griffin *et al*, 1999), with conifers as major sources (Geron *et al*, 2000, Pokorska *et al*, 2012). These two BVOC (especially limonene) are also emitted in indoor air by air fresheners and cleaning products such as kitchen cleaners and dishwashing detergents (Huang *et al*, 2011). It has been highlighted in previous studies that their reactions with ozone could produce SOA (Chen *et al*, 2011, Waring *et al*, 2011, Bernard *et al*, 2012) either in atmospheric or indoor environments, and could then lead to significant climate (Myhre *et al*, 2001) and health (Gaschen *et al*, 2010) effects.

In the present work, the ozonolysis reactions of limonene and α-pinene have been investigated at room temperature and atmospheric pressure using a laminar flow reactor newly developed in our laboratory (Figure 1, Duncianu *et al*, 2012), which allows the monitoring of the first steps of ozonolysis reactions (typically ~30 seconds to 5 minutes) providing complementary data to more widely performed smog chamber experiments.

The rate coefficients have been measured under pseudo first-order conditions in excess of the BVOC. The decay of ozone has been monitored with an O_3 analyser while BVOC concentrations have been determined using online sampling onto adsorbent cartridges followed by thermodesorption and subsequent analysis in a GC/FID-MS system. Specific experiments have been performed to identify and quantify both gas-phase and particulate products using a TD/GC/FID-MS system, a SMPS and a HR-ToF-AMS, respectively.

Results will be further discussed and compared to literature data.

Indoor/outdoor measurements campaigns were performed in naturally ventilated houses and offices in four European cities to investigate the relationship between indoor and outdoor particle number concentrations and aerosol modal structures. The measurements sites were located in Oslo (Norway), Prague (Czech Republic), Milan (Italy) and Athens (Greece). A number of ordinary indoor activities (cooking, smoking, candle burning, etc.) were performed during the measurements to quantify the contribution of particles emitted from indoor sources and the contribution of outdoor particles to the change of the indoor aerosol size spectra.

The size and time resolved particle concentrations in the size range 10 nm – 600 nm were measured by scanning mobility particle sizers (SMPS). The results were analysed, and the modal structure of the measured particle number size distribution data, along with the number concentration in each of the modes comprising the aerosol size distribution, were computed.

The analysis of the measurements showed that in absence of indoor sources, indoor number concentration followed the variations of the outdoor concentration. Figure 1 presents the correlation between diurnal median values of indoor and outdoor number concentrations for the measurements conducted in Prague. Indoor concentration was highly correlated to the outdoor concentration when the apartment was unoccupied, but poor correlation was observed during periods with indoor activities (e.e., cooking).

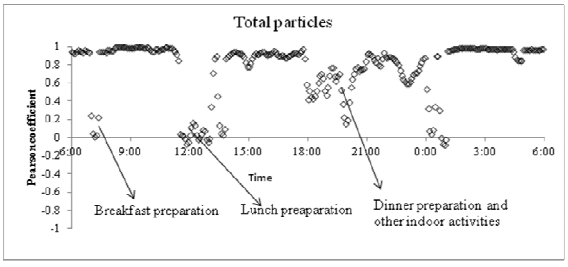

Figure 1. Correlation of indoor and outdoor diurnal median number concentrations for the measurements conducted in Prague (Czech Republic).

Emissions from indoor sources resulted in elevated indoor number concentrations and I/O ratios. Furthermore, the aerosol spectra presented different characteristics during periods with indoor activities as depicted in Table 1. The outdoor size distribution was similar to the indoor size distribution suggesting that in naturally ventilated buildings the indoor size spectra is formed according to the penetration efficiency of the outdoor particles to the indoor environment and to the emission characteristics of indoor sources.

Spatial variation of air pollutants in a multilevel office building

C. He and L. Morawska

International Laboratory for Air Quality and Health, Institute of Health and Biomedical Innovation, Queensland University of Technology (QUT), Brisbane, 4001, Australia

Keywords: indoor, aerosol, particle number, $PM_{2.5}$, CO
Presenting author email: c.he@qut.edu.au

Within-building spatial variability of indoor air quality may influence substantially the reliability of human exposure assessments based on single point samples, but have hitherto been little studied. To investigate and understand the within-building spatial variation of air pollutants, field measurements were conducted in a 7 level office building in Brisbane, Australia. The building consists of 3 sections (A side, Meddler and B side).

A portable unit consisting of a P-Trak, DustTrak and Q-Trak, was assembled on a small trolley and moved to the various locations around the building. The average particle number (PN) concentration (in the range 0.020-1.0μm), particle mass concentration ($PM_{2.5}$) and CO and CO_2 levels, as well as temperature and relative humidity, were simultaneously measured by P-Trak, DustTrak and Q-Trak Plus, at diffident locations inside and outside of the building during working hours in two typical weather conditions in Brisbane. At each sampling location, the sampling period was 5 minutes (with a logging interval of 10 seconds), and average measurements were obtained by sampling at different sub-locations within the office area including the working area, corridor, conference room and rest areas. The measurements were repeated twice at each location.

The average PN and $PM_{2.5}$ concentrations at various locations are presented in Figure 1. From Figure 1, some results can be drawn. Average particle concentration levels varied from location to location within the building, especially for PN. Indoor PN and $PM_{2.5}$ concentration levels in the underground car park, lifts and entrances were considerably higher (about 3 times for PN and 40% for $PM_{2.5}$) than those measured in the offices. Average PN concentration levels also varied from office to office within the building, in the range from 1.17×10^3 particle cm^{-3} to 6.68×10^3 particle cm^{-3}. Average indoor PN concentrations at level 7 were higher than those at other levels. This is due to there being an entrance at level 7 to the roof area of the building. It was found that the particle concentration in a printer room (24.0×10^3 particle cm^{-3} for PN and 7 μg m^{-3} for $PM_{2.5}$) was significantly higher than the average office concentration (3.7×10^3 particle cm^{-3} for PN and 5 μg m^{-3} for $PM_{2.5}$), which indicated that printers are a major indoor source of particles in this building.

A summary of the average indoor and outdoor PN, $PM_{2.5}$ and CO_2 concentration levels is given in Tables 1. From Table 1, it can be seen that both outdoor average PN and $PM_{2.5}$ concentration levels were higher (about 3 times for PN and 2 time for $PM_{2.5}$) than indoor average particle concentration levels. However, outdoor CO_2 levels were lower than indoor levels. It also can be noted that the highest $PM_{2.5}$ concentration for both indoor and outdoor was collected from the underground car park. There were also clear particle concentration differences between A side and B side for both outdoors and entrances.

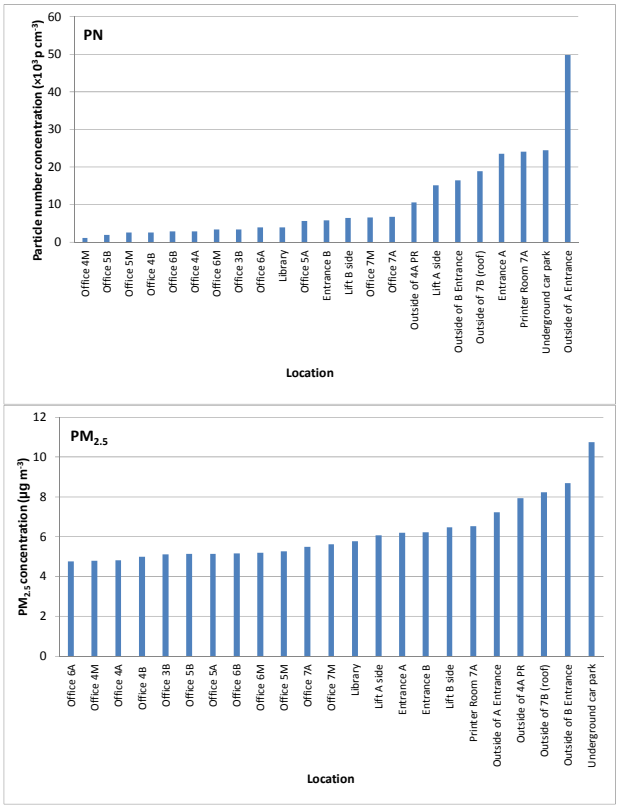

Figure 1. The average PN and $PM_{2.5}$ concentrations at various locations

Table 1. Summary of indoor and outdoor average concentration of the pollutants

	PN ($\times 10^3$ p cm^{-3})		$PM_{2.5}$ (μg m^{-3})		CO_2 (ppm)	
	In	Out	In	Out	In	Out
Average	7.74	24.0	6	8	767	496
S.D	7.84	17.6	1	1	206	115
Min	1.17	10.6	5	7	459	435
Max	24.4	49.9	11	9	1192	668
Median	3.98	17.7	5	8	795	439

CO concentration levels also varied from location to location within the building. However, CO concentration levels were clearly lower than the NEPM ambient air quality standards (8 hours: 9.0 ppm).

Effect of Anti-idling Campaign on the Outdoor and Indoor Aerosol Exposure at Schools

S.A. Grinshpun[1], M. Yermakov[1], J.Y. Kim[1], T. Reponen[1], C. Schaffer, P. Ryan[2]

Presenting author email: sergey.grinshpun@uc.edu

Exposure to traffic aerosols, including diesel exhaust particles, may be elevated at schools, partially because of the emission from cars and buses transporting students daily. Idling of vehicles in the school proximity may increase the outdoor aerosol concentration of fine particulate matter (PM2.5) as well as the concentrations of its constituents, including traffic-related elements. We hypothesize that an anti-idling campaign implemented at schools reduces the children exposure outdoors and indoors.

The objective of this study was to evaluate the impact of an anti-idling campaign on outdoor and indoor air quality at four urban schools in Cincinnati (Ohio, USA) with varying exposure to the school bus emission. Table 1 presents some of the characteristics of the selected schools. At each school, Harvard-type PM2.5 impactors (Air Diagnostics and Engineering, Inc. Harrison, ME, USA) operated in parallel – two indoors and two outdoors; in each pair, one was equipped with Teflon filter and one with quartz filter. The PM2.5 mass concentration was determined using gravimetric technique; the mass concentration of ten elements (Si, S, Ti, V, Mn, Fe, Cu, Zn, Br, Pb) was obtained using X-ray fluorescence analysis on Teflon filters. The quartz filter samples were analyzed for elemental and organic carbon (EC and OC) with thermal-optical transmittance.

Table 1. Characteristics of school A - D.

School	Average number of school buses operating	Average number of cars dropping-off students	Distance from highway (m)
A	5	18	303
B	39	77	526
C	11	27	243
D*	9	24	2,083

* A metro-bus stop is in the proximity

The outdoor concentrations of PM2.5 decreased at school B and D following the anti-idling campaign; no significant changes in PM2.5 were identified at school A and C. Some elemental constituents of PM2.5 decreased at all schools after the campaign was implemented; however, this decrease was mostly insignificant, except for school B, which had the greatest number of school buses and cars. For this school, we identified a statistically significant reduction of organic carbon as well as Si, Fe, and Zn. Furthermore, the levels of all traffic-related elements in the outdoor environment of school B measured before the anti-idling campaign exceeded the corresponding area levels (measured as a surrogate for the school B's community). The latter finding suggests that traffic emission was the dominant air pollution source at school B. In contrast to school B, the anti-idling campaign did not have a definitive effect on the outdoor elemental concentrations determined at other three schools. Most of the results seem to have been influenced by the time variability of the background aerosol, which represents a limitation of the present study.

A significant ($p<0.05$) positive association was found for the changes in outdoor and indoor elemental concentrations observed at school B (the one with the most intense local traffic). No statistically significant association was identified for any of the three other schools. The data for school B are presented in Fig. 1. Elements such as Br and Cu that fell outside the plot are marked with arrows (the outdoor concentrations of these elements did not change significantly following the anti-idling campaign). For most elements measured at school B, the decrease in outdoor concentrations followed by a corresponding decrease in indoor concentrations.

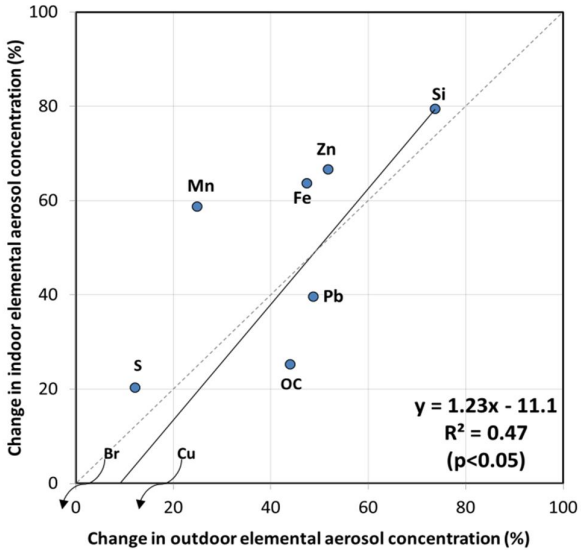

Fig. 1. Association between the changes in outdoor and indoor elemental concentrations at school B following the anti-idling campaigns. Elements detected at levels below uncertainty in at least 50% of samples were excluded.

This research was funded by the National Institute of Environmental Health Sciences, through Grant NIEHS R21ES017957. The authors appreciate this support.

Exposure assessment to air pollutants in Elderly Care Centers

M. Almeida-Silva[1], S. M. Almeida[1*], H. T. Wolterbeek[2]

[1] IST/ITN, Instituto Superior Técnico, Universidade Técnica de Lisboa, Estrada Nacional 10, 2686-953 Sacavém, Portugal;

Presenting author email: marina@ctn.ist.utl.pt

According to the United Nations the proportion of total population aged 60 years or over for the Europe is 22% for the year 2012 and prospects 34% for 2050[1]. In general, people spend about 19-20 hours indoors. These values could increase considering the older people who are institutionalized in Elder Care Centers (ECC)[2]. By these reasons and by the fact that old people are considered a susceptible group becomes increasingly important to mitigate their exposure to air pollutants. The main goal of this work was to characterize the indoor air quality in ECC in order to understand the elderly exposure to air pollutants. The current study was developed in Loures and Lisbon (Fig. 1).

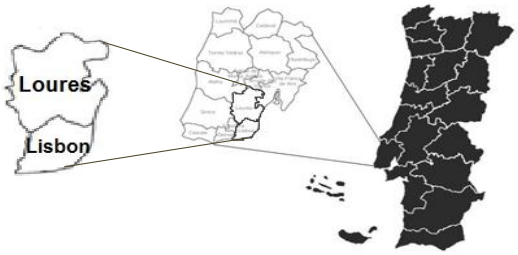

Figure 1 - Localization of the sampling sites

A time-budget survey was carried out with more than 300 elderly in order to define the time spent by the old people. This data will be used to achieve the exposure to air pollutants, according to the follow equation:

$$Exposure = \sum_{i=n}^{n} C_{z,n} \cdot t_n$$

Where *n* corresponds to the different micro-environments, *C* is the concentration of the pollutant *z* and *t* is the time spends in each micro-environment.

A set of pollutants has been selected to characterize the indoor air quality inside two micro-environments – Room (R) and Living-Room (LR) – in 4 ECC, such as air temperature, relative humidity, carbon dioxide (CO_2), carbon monoxide, particulate matter with 5 different sizes, namely $PM_{0.5}$, PM_1, $PM_{2.5}$, PM_5, PM_{10}, total volatile organic compounds. Measurements in each outdoor environment were performed simultaneously.

PM_{10} were also collected in Teflon filters and were gravimetrically assessed in a clean room (class 10,000), as well their chemical content by Instrumental Neutron Activation Analysis, in Portuguese Research Reactor.

Results showed that CO_2 and PM_{10} exceeded the Portuguese legal value (1800 and 0.15 $mg.m^{-3}$, respectively) in some periods of the day.

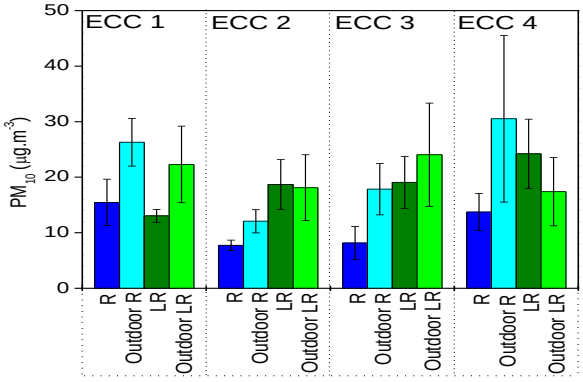

Figure 2 - Mass concentration in PM_{10} sampled for each ECC.

Fig. 2 shows the gravimetric PM_{10} concentration measured in each ECC. The outdoor levels associated with the R's were always higher, comparing with the PM_{10} concentrations determined inside the R's. In the other hand, two different ECC's presented higher values in the LR's than in the corresponding outdoors. This last evidence shows the importance of indoor sources inside of the LR's, e.g. elderly, collaborators, plants, etc.

In/Out ratio are showed in Fig. 3. Ratios for R and LR in EEC2 presented the best correlation (0.78 and 0.90, respectively) and confirm an outdoor origin of the PM_{10}.

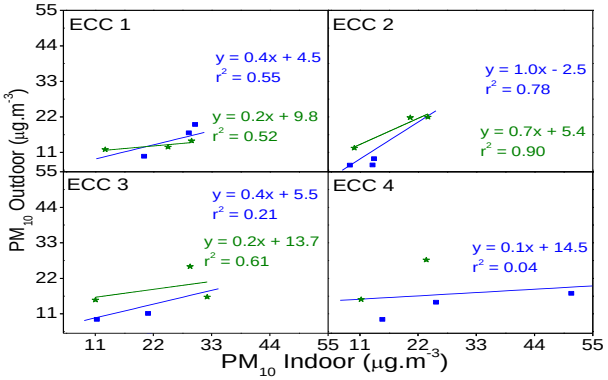

Figure 3 - Ratio In/Out per ECC for R (--) and LR (--).

An intensive aerosol research program was conducted in a university lecture hall at the Eötvös University, Faculty of Science, Budapest, Hungary to determine time-resolved aerosol mass and number concentrations, CO_2 concentration, size-resolved chemical composition of aerosol particles, and to evaluate them together with micro-meteorological variables. A computational fluid dynamics (CFD) model was developed to estimate the spatial distribution of the experimental and derived data within the hall and the transport of aerosol particles.

PM_{10} mass, particle number (N) and CO_2 concentrations, particle number size distributions and meteorological parameters were determined with high time resolution, and daily aerosol samples were collected in the $PM_{10-2.0}$ and $PM_{2.0}$ size fractions for chemical analysis in the middle of the lecture hall for one week. Median concentrations for the PM_{10} mass and N of 15.3 $\mu g\ m^{-3}$ and $3.7\times10^3\ cm^{-3}$, respectively were derived. The data are substantially smaller than the related outdoor levels or typical values for residences. There were considerable concentration differences for workdays, weekends and various lectures. Main sources of PM_{10} mass include the usage of chalk sticks for writing, wiping the blackboard, ordinary movements and actions of students and cleaning. High PM_{10} mass concentration levels up to 100 $\mu g\ m^{-3}$ were realised for short time intervals after wiping the blackboard. The mass concentrations decreased rapidly after the emission source ceased to be active. Two classes of coarse particles were identified. General indoor dust particles exhibited a residence time of approximately 35 min, while the residence time for the chalk dust particles was approximately 15 min as lower estimates. Emission source rate for wiping the blackboard was estimated to be between 8 and 14 $mg\ min^{-1}$. This represents a substantial emission rate but the source is active only up to 1 min. Most aerosol constituents have smaller indoor concentrations than their outdoor counterparts. At the same time, Ca and S showed larger indoor enrichment factors than the other constituents. This is explained by the chalk (made mainly of gypsum) usage for writing and drawing, and suspension of the chalk dust particles. The crustal enrichment factors and $PM_{2.0}/PM_{10-2.0}$ concentration ratios revealed that mechanical disintegration is the major source for many aerosol constituents. Contribution of ambient aerosol via the heating, ventilation and air conditioning (HVAC) facility was considerable for time intervals when the indoor sources of PM_{10} mass were not intensive. The HVAC facility introduces, however, the major amount of aerosol particles from the outdoors as far as their number concentration is regarded. Mean contribution of ultrafine particles to the total particle number was (69±7)%, which is smaller than for the related outdoor urban environment. This can indicate aged ultrafine aerosol. The major amounts of CO_2 arrive from the corridors through open doors by infiltration.

Spatial distribution of the PM_{10} mass concentration within the hall was derived by CFD modelling, and spatial inhomogeneities were obtained as indicated in Figure 1. A plume of particles is created along the central longitudinal band of the hall. Sitting at the outermost seats seems favourable, and the lecturers who use chalk sticks intensively are exposed to higher concentration levels than the students.

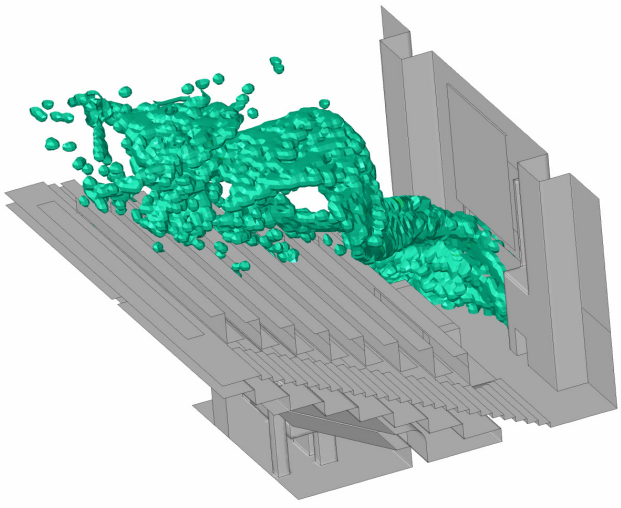

Figure 1. Modelled three-dimensional spatial distribution of PM_{10} aerosol particle after wiping the blackboard.

The effect of size, location, occupancy and microclimatic factors on air quality of university lecture rooms

M. Braniš[1] and K. Stupková[1]

[1] Charles University in Prague, Faculty of Science, Institute for Environmental Studies, Albertov 6, 128 43 Prague 2, Czech Republic

Keywords: indoor air quality, school, particulate matter, microclimate

Presenting author email: brains@natur.cuni.cz

As has been repeatedly documented in scientific literature, one of the most polluted indoor microenvironment can be found at schools. School buildings and classrooms suffer from poor air quality from two reasons: (1) Schools in cities are frequently situated in quarters or near streets with dense traffic and the infiltration of freeway particles into the school buildings represents an important source of pollutants (Janssen et al. 2001; Green et al. 2004) and (2) High levels of particulate matter in schools are frequently attributed to human activity and insufficient frequency of cleaning which is not capable in removing deposited particles (Branis et al., 2005; Fromme et al., 2007). Since these particles are only partly removed, they can be resuspended again and again. To ascertain the effect of infiltration and resuspension under various conditions (such as position of the classroom with respect to outdoor sources, its size and occupancy) we performed a year long project in three university lecture rooms situated in the centre of Prague.

Twenty-four hour mass concentrations of size-segregated aerosol were measured simultaneously in three university lecture rooms and outdoors in the central part of Prague (Czech Republic) by a five-stage A - F (<0.25µm, 0.25-0.5µm, 0.5-1.0µm, 1.0-2.5µm and 2.5-10µm) Personal Cascade Impactor Sampler (PCIS). Identical sets of instruments were deployed at the outdoor and indoor sites. Other variables such as CO_2, ventilation, temperature, relative humidity, occupancy were monitored as well. The measurements were performed during all seasons of the year during 11 three to four-day long campaigns involving working days as well as weekends and holidays.

The results documented that finer indoor size fractions (below 500nm) were significantly affected by outdoor concentrations while coarse particulate matter levels ($PM_{2.5-10}$) were predominantly dependent on the number of students in the lecture rooms. Nevertheless, some effect of human presence on the PM below 500nm was recorded as well, indicating a possible effect of the so called personal cloud (Table 1; Figure 1). The level of particulate matter concentrations corresponded to the proximity to the adjacent street (the closer the lecture room the higher the average PM concentration) and to the size of the size of the lecture room (the smallest was the space the highest PM concentrations were recorded).

In addition, concentrations of carbon dioxide frequently reached values over 1500ppm and higher. One of the common problems in all the three lecture rooms was very low relative humidity (around 30-35%). The results of the study not only confirmed previous results but also showed that measurements in one classroom per school may be insufficient because differences in position, size and occupancy may affect the concentrations of aerosol from which the estimates of exposure are made for the whole population of students in a particular school.

Table 1. The effect of occupancy on size resolved aerosol. OC - occupied; UOC - unoccupied periods; A, B, C, D, F - impactor stages; CPM ($PM_{10-1.0}$). B11, B12, B14 - lecture rooms.

Sampling of particulate matter was performed in two schools in Vienna in 2011. The first campaign started in January and lasted until April, the second from October till December, respectively. Particulate matter (PM10) was collected in parallel with a high-volume sampler (Digitel DHA80) using quartz fibre filters, a low-volume sampler (Leckel, SEQ47/50) using cellulose acetate filters and a beta particulate monitor (ESM, Eberline). In addition to the characterization of indoor air the sampling equipment was also installed outside the buildings for at least one week during both campaigns. This allowed to determine the ambient PM10concentrations in the vicinity of the two schools and to compare them with the air quality network in Vienna. This comparison showed very good agreement and allowed to take data from the air quality network as ambient concentration data for the time of the indoor sampling. Filter samples were analysed for aerosol mass, water soluble ions, carbon parameters (total carbon, elemental carbon, organic carbon, carbonates) selected anhydrosugars and other saccharides, cellulose, humic like substances and metals using protocols described in Bauer et al. (2007).

Both sampling sites were located in the western part of Vienna. The vicinity of HBLVA Rosensteingasse (RG) can be characterized as a densely populated residential area with some influence of local traffic. The other site, BG Fichtnergasse (FG), is also a residential area with a large number of single family houses and private gardens around. Average concentrations of particulate matter in the ambient were ranging from 20 µg/m³ (April at FG) to 81 µg/m³ (November at RG). Sampling times comprised most of the exceedances of the 24h-limit value of PM10 observed in Vienna during 2011.

As expected indoor particulate matter concentrations showed distinct daily and weekly cycles reflecting the activity of students and teachers moving around the building and vaccations or weekends. Superimposed to these short time fluctuations the concentrations are driven by the ambient air concentrations monitored within the air quality network in Vienna.

Chemical analyses accounted for approx. 90 % of aerosol mass using a macro-tracer model (Bauer et al. 2007) which allows to quantify the contributions of inorganic secondary aerosols, mineral dust, wood smoke, other organic material and traffic to aerosol mass. For indoor samples organic material gave the highest contribution to aerosol mass, with cellulose being the most dominant single compound measured. Furthermore pronounced differences of saccaride concentration patterns were observed by comparing indoor and ambient air samples. Thus sugar alcohols being tracers for fungal spores (Bauer et al. 2008) were only determined outside, while e.g. glucose, fructose and succrose were only determined in indoor air samples. In FG mineral dust and in RG inorganic ions were the second important contributors to aerosol mass, respectively. Traffic showed a similar and rather small contribution at both sampling sites.

For ambient air samples inorganic secondary aerosol is the most important contributor to aerosol mass, followed by mineral dust, wood smoke and other organic material.

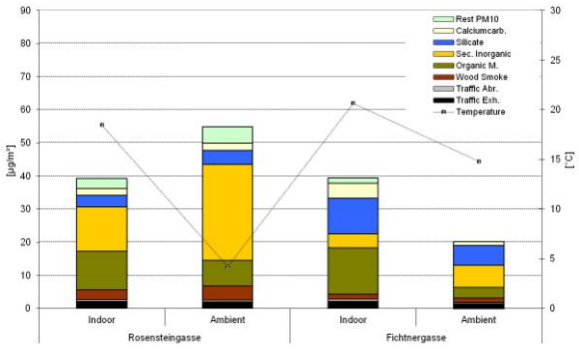

Figure 1. Source apportionment in the first campaign.

A fast-scanning DMA train for the precision quantification of nanoparticle dynamics

P.M. Winkler[1,2], J. Ortega[1], P.H. McMurry[3], J.N. Smith[1,4]

Presenting author email: paul.winkler@univie.ac.at

Nanoparticle dynamics can be measured reliably by SMPS if the size distribution is changing slowly in the course of a single scan. Once the size distribution changes significantly during one scan, the resulting distortion may heavily impact the correct interpretation of the relevant distribution parameters. The need for instruments reliably analyzing nanoparticle growth at high time resolution has been pointed out recently (Winkler et al., 2012).

In this study we report on a new experimental device dedicated to the precision measurement of freshly formed growing nanoparticles. To this end, we combine a set of five differential mobility analyzers (DMAs) into a so-called DMA train in which each DMA is set to classify a single fixed particle size. The DMA train is specifically designed to resolve growth rates exceeding the time resolution provided by conventional SMPS.

The DMA train presented here utilizes five TSI 3085 nanoDMAs together with four TSI 3025 ultrafine condensation particle counters (UCPC) and one diethylene-glycol (DEG) based CPC (Iida et al., 2009). Thereby, size information can be retrieved from large clusters around 2 nm mobility diameter and upwards. DMAs were usually operated with sheath and excess flow rates of 15 L min^{-1} and a 1.5 L min^{-1} aerosol flow. The DMA in combination with the DEG-CPC, however, was operated at 20 and 2 L min^{-1}, respectively. In order to minimize particle losses in the lines to the DMAs transport flows of 8.7 and 2.3 L min^{-1} were used for particle sizes below and above 5 nm, respectively.

The performance of the DMA train was tested under laboratory conditions using the NCAR biogenic aerosol chamber. The 10 m^3 chamber is continuously flushed with HEPA filtered dry zero air together with the precursor vapor until a steady-state monoterpene (α-pinene) concentration of ~4 ppb is reached. Particle formation is subsequently initiated by increasing ozone to about 40 ppb. Gas-phase products were monitored using a proton transfer reaction time-of-flight mass spectrometer (PTR-TOF-MS). Particle evolution was monitored with the DMA train.

Figure 1 illustrates the time evolution of different particle sizes as measured by the DMA train. The particle sizes shown were obtained from two consecutive chamber runs under identical conditions. The reproducibility of size distribution data clearly indicates stable conditions in the chamber and supports the reliable operation of the DMA train. As can be seen, all particle sizes show a steep increase in concentration from basically zero to full appearance within 7-8 minutes. Obviously, a regular SMPS with a typical 5 minute scan time would not be able to resolve the particle dynamics correctly. Also it is important to note that the results shown here are statistically significant for raw counts as low as 0.1 cm^{-3}. This is a consequence of the averaging that can be performed due to the sampling at fixed sizes.

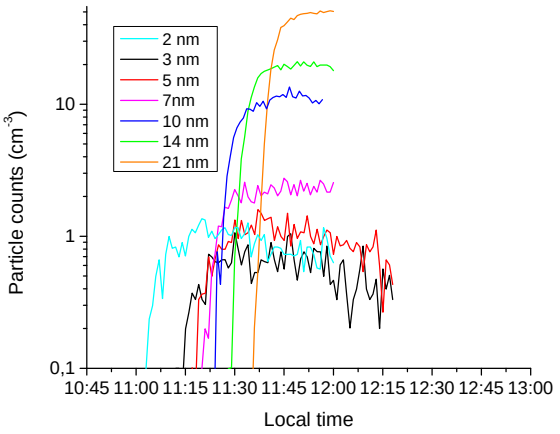

Figure 1. Raw data obtained from two consecutive formation events in the NCAR biogenic aerosol chamber under identical conditions. Chemical reaction was initiated at 10:45.

For the study of early nanoparticle growth we have designed a DMA train operating five DMAs equipped with CPCs in parallel at fixed sizes. Features of the DMA train include size distribution scan times of one second for a size range between 2 and 20 nm. Statistically significant data could be obtained for classified particle concentrations as low as 0.1 cm^{-3}. The performance test in a chamber study of α-pinene ozonolysis under close-to-ambient conditions demonstrates the superiority of this set-up over regular SMPS for the purpose of growth analysis.

Fast scanning mobility particle sizing system and classifier

J. Farnsworth, F. Quant, H-G. Horn, B. Osmondson, and R. Caldow

TSI Incorporated, Shoreview, MN, 55126, USA
Keywords: SMPS, DMA, 15900, CPC
Presenting author email: jim.farnsworth@tsi.com

Since the scanning concept was introduced by Wang and Flagan in 1990, differential mobility classification has become the measurement principle of choice for making aerosol size distribution measurements in the 1 nm to 1 µm size range. Devices such as the TSI Model 3080 Classifier, typically used as part of a Scanning Mobility Particle Sizer (SMPS) system, operate by this principle. While the technique has a reputation for reliability because it is based on basic physical principles, its primary drawback is response time: it typically takes 60 seconds or more to complete a scan.

In order to meet the need for faster measurements while leveraging the reliability of differential mobility classification, a new classifier (TSI Model 3082) is presented to enable scanning at rates down to 5-seconds (see Figure 1).

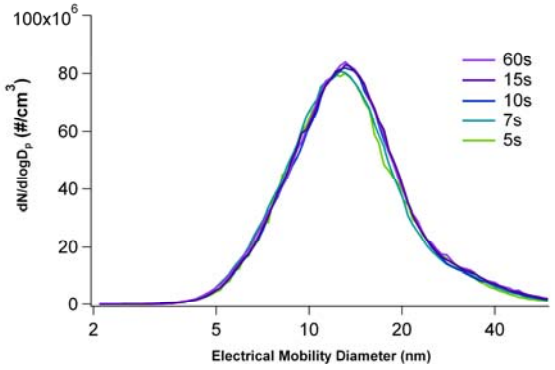

Figure 1. Polydisperse silver aerosol size distribution obtained at various scan times between 5s and 60s.

The 3082 retains the functions of the 3080 with the following additions:

1. Dual polarity DMA high voltage control with <50 ms response time for faster scanning
2. 50 Hz data sampling for higher time resolution
3. 30 L/min sheath flow capability for higher size resolution and wider size range
4. Integrated and removable x-ray bi-polar charge neutralizer (Scheckman *et al*)
5. Integrated and removable inlet impactors for aerosol flow measurement and particle pre-separation
6. Tool-free installation of DMAs and impactor set

Precise control of high voltage and sheath flow coupled with well-characterized CPC response time allows for ±1% size accuracy at 100 nm. Calibration of the device complies with ISO 15900 Standard, which was put in place to provide methodology for adequate quality control of differential mobility devices.

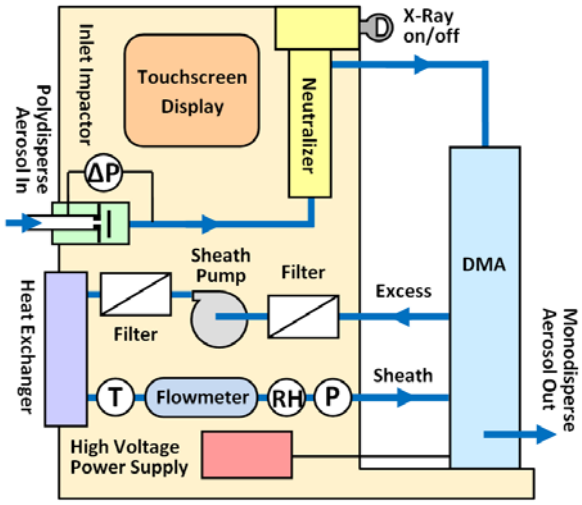

Figure 2. Flow schematic for the TSI Model 3082 Classifier.

Equivalence data comparing SMPS scans using the TSI Model 3082 Classifier versus the TSI Model 3080 Classifier are presented. These data demonstrate the agreement of both classifiers at traditional scanning rates as well as the advantages of the new model at reduced scan times.

A Drift Tube Ion Mobility Spectrometer (DT-IMS) combined with a Condensation Particle Counter for Analysis of Sub 10 nm Aerosol Particles

Derek R. Oberreit[1], Peter H. McMurry[1], & Christopher J. Hogan Jr.[1]

[1]Department of Mechanical Engineering, University of Minnesota, Minneapolis, Minnesota, 55455, USA
Keywords: Electrical Mobility Analysis, Size Distribution Measurement, Nanoparticles, Drift Tube
Presenting author email: hogan@me.umn.edu

Drift tube-ion mobility spectrometer (DT-IMS) devices allow for determination of the electrical mobilities of charged particles through measurement of the time necessary for a particle to travel a fixed distance through a tube in the presence of an electrostatic gradient. These instruments have traditionally been limited to measurements of ionized molecules and small (~1 nm) cluster ions. Previously developed devices are not able to sample charged aerosol particles from the ambient because of the high electric fields present at the beginning of the drift region. An additional limitation of existing DT-IMS devices is the low sensitivity of the Faraday Cup Electrometers at concentrations found in typical aerosols. Conversely, DT-IMS devices have the advantages of mobility invariant high resolving power (>R~20), low drift gas flow rates compared to differential mobility analyser (DMA) sheath gas flowrates and shorter measurement times as compared to most scanning differential mobility analyses. Therefore, modification of such devices, such that they can be coupled to sensitive condensation particle counters (CPCs) and used for aerosol particle electrical mobility measurement is of interest.

We have made such modifications, developing a DT-IMS applicable for 2-10 nm aerosol particle analysis, which is described in this presentation. The modifications to traditional DT-IMS devices required for application in ambient pressure aerosol measurement include a novel gateless sample introduction scheme, and the ability to couple to an aspirating CPC. The gateless sample introduction, with particle pathlines and electrical field strengths depicted in Figure 1, uses a combination of a controlled flow path and stepped voltage at the start of a measurement to effectively select a 'packet' of aerosol. Additional aerosol is not able to enter the sample region after the start of a measurement due to the presence of an electrostatic field. The coupling to a CPC requires a controlled flow that splits to provide the drift gas and the gas aspirated by the CPC at the drift tube outlet. A prototype device with these inlet and outlet modifications has been constructed and tested. Example results for charge reduction electrospray generated Cytrochrome C aerosol particles are shown in Figure 2. The prototype DT-IMS has a linear relationship between drift time and mobility, a resolving power greater than 10, and can measure 2-10 nm aerosol particle electrical mobility distributions in less than 5 seconds.

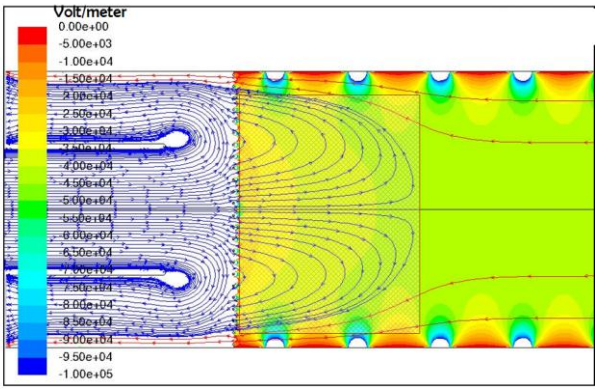

Figure 1. The pathlines (blue) of aerosol particles entering the inlet of the DT-IMS when the electric field is not applied. Color contours reveal the intensity of the electric fields when applied; these fields drive aerosol particles within the sample packet zone down drift tube (to the detector).

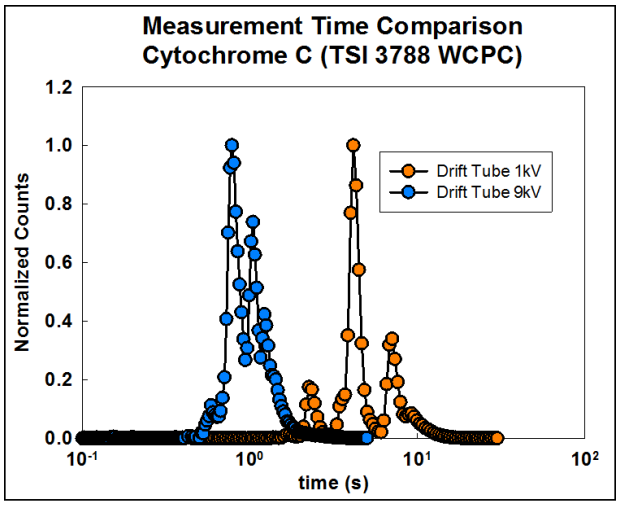

Figure 2. Normalized CPC signal intensity as a function of drift time (inversely proportional to electrical mobility) for electrosprayed Cytochrome C in the DT-IMS. The most prominent peaks in the displayed distributions correspond to the singly charged monomer ion at 3.15 nm mobility diameter, with the peak to the right corresponding to the Cytrochome C dimer (4.35 nm). Longer drift times enable greater peak separation.

A new version of the Particle Size Magnifier for detection of airborne molecular clusters and nano-particles as small as 1 nm

K. Lehtipalo[1,2], A. Franchin[1,2], J. Mikkilä[2], J. Vanhanen[2], J. Kangasluoma[1], T. Petäjä[1], and M. Kulmala[1]

[1]Department of Physics, University of Helsinki, 00560 Helsinki, FINLAND
[2]Airmodus Oy, 00560 Helsinki, FINLAND

Keywords: condensation particle counters, nucleation, nano-particles
Presenting author email: katrianne.lehtipalo@helsinki.fi

There is a growing demand on measuring airborne particles and clusters even down to the size of 1 nm. For instance, the new particle formation process is not yet completely understood on a molecular level, mainly due to the lack of suitable instrument to detect the recently formed particles. The new generation of condensation particle counters (*e.g.* Vanhanen *et al.,* 2011, Jiang *et al.,* 2011, Wimmer *et al.,* 2013) allow deriving parameters describing the new particle formation process, *e.g.* the formation and growth rates, directly from measurements also in the size range below 2 nm (Kirkby *et al.,* 2011; Kuang *et al.*, 2012; Kulmala *et al.,* 2013).

The Airmodus Particle Size Magnifier (PSM; Vanhanen *et al.,* 2011) can be used to resolve the size distribution of particles below about 3 nm. The cut-off size of the instruments was varied between 1-2.5 nm by altering the mixing ratio of saturator and aerosol flow and thus changing the supersaturation created. A schematics of the instrument is presented in Fig. 1.

The relation between the flow mixing ratio and activation diameter in the PSM has been determined in laboratory calibrations using size-selected ammonium sulphate ions. The PSM was found to activate ammonium sulphate clusters consisting of just a few molecules, and it was able to detect even single large molecules, for example tetra-alkyl ammonium halides. Clusters and particles of different composition activate at slightly different flow rate, indicating that there is a material dependency. This is further studied in Kangasluoma *et al.,* (2013).

The A09 PSM have been used to measure the size distribution of particles between 1 – 3 nm in field measurements *e.g.* at the Hyytiälä SMEAR II measurement station in southern Finland (Kulmala et al., 2013) and at the CLOUD experiments in CERN (Kirkby et al., 2011). The data was compared to neutral clusters measured with the CI-APi-TOF mass spectrometer (Jokinen *et al.,* 2012), and to ion clusters measured with the APi-TOF (Junninen *et al.,* 2011). By combining the PSM and the new mass spectrometric methods it is possible to cover the whole size range from molecules to aerosol particles.

A new version of the Particle Size Magnifier, A10, was developed during 2012-2013. It includes modifications especially in the air and liquid flow design. A special care has been taken in making the instrument stable in varying operating conditions. The A10 PSM has been tested in the laboratory, and it will be take part in atmospheric field measurement campaigns during spring 2013.

A special version of the A10 PSM will be used as a counter in the Gas Aerosol Nucleation Spectrometer built in the GANS project (http://www.gans-project.eu/, Dohányosová et al. 2013).

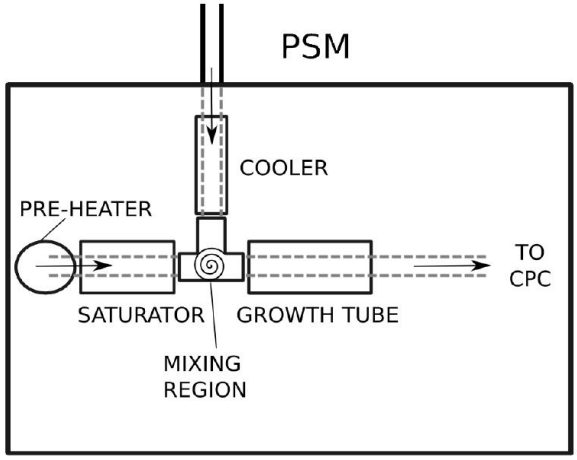

Figure 1. Schematics of the Particle Size Magnifier. Sample air is going from the inlet through a cooler before being mixed with saturated clean air in the mixing region. Particles grow to about 90 nm in the growth tube before they are directed to a counter CPC.

First results of a new Gas Aerosol Nucleation Spectrometer: GANS

P. Dohányosová, E. Montoya, E. Ramiro, S. López-Vidal

RAMEM SA., Madrid, 28027, Spain
Keywords: instrumentation, DMA, nucleation.
Presenting author email: slopez@ioner.net

Nucleation is currently a hot issue in the aerosol science field and much attention has been dedicated to the problem (e.g. special issue in the Journal of Aerosol Science and Technology in April, 2011). One of the most important difficulties for the study of aerosol nucleation is the lack of available instrumentation with good performance and enough sensitivity for size-classifying the sub-2nm nanoparticles.

GANS (http://www.gans-project.eu/) is a project whose aim is to develop a commercial mobility-based particle sizer based on a planar DMA. The new instrument covers the particle sizes where the nucleation phenomena take place and where particles and ions coexist (< 5 nm). Several important innovations can be found in GANS instrument. The first one is a multipurpose ion source suitable for inorganic and organic ions (Ultra-Violet (UV) light ion source and Atmospheric Pressure Chemical Ionization (APCI) source designed by Ramem/Ioner). As the ion source can be switched off, free ions can also be detected. The second innovation of GANS project is the development of an instrument achieving much higher resolution than the resolution obtained in conventional Ion Mobility Spectrometers (IMS). The expected resolution of new GANS instrument is 80, even though the actual state of the instrument allows a resolution around 60. GANS is available with two detectors. The first detector is an electrometer with a sensibility of femtoAmpers. The second detector, and one of the main innovations in GANS project, is the inclusion of a Particle Size Magnifier (PSM) developed by Airmodus. The PSM is a special type of Condensation Particle Counter (CPC) for ions smaller than 2nm (Lehtipalo *et al*., 2013).

In this work we present first results of GANS instrument performance. To test the instrument, an aerosol of tetraheptylammonium (THA) ions was formed from a solution of THABr with IONER® ES-3020 electrospray source. In order to optimize the Resolving Power (RP) various experimental conditions were tested. As can be observed in Figure 1, the instrument can achieve RP higher than 60.

Regarding the ion source, the inorganics will be ionized using an APCI source. The new Ramem/Ioner´s ACPI ion source was tested with ammonium sulphate under various experimental settings. The results are compared with a radioactive ion source in Figure 2. As can be seen, the APCI source can charge ammonium sulphate aerosol as efficiently as radioactive source under optimal setting.

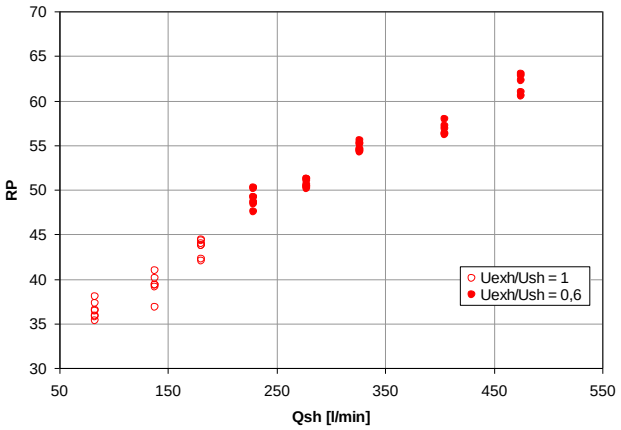

Figure 1: RP of GANS instrument for the monomer ion THA^+.

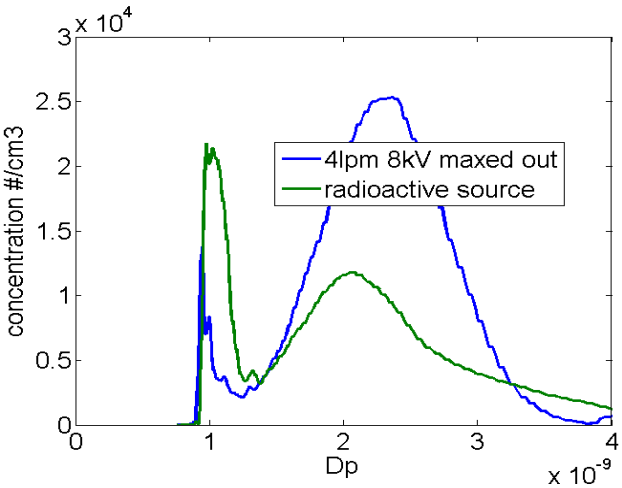

Figure 2: Comparison between Ramem/Ioner´s APCI and radioactive source for ammonium sulphate clusters.

The versatile Size Analyzing Nuclei Counter (vSANC)

T. Pinterich[1], P. M. Winkler[1], P. E. Wagner[1], M. Kulmala[2], A. Vrtala[1]

[1]Faculty of Physics, University of Vienna, Vienna, A-1090, Austria
[2]Department of Physics, University of Helsinki, Helsinki, P.O. Box 64, 00014, Finland
Keywords: Nanoparticles, nucleation studies, CPC
Presenting author email: tamara.pinterich@univie.ac.at

We present a newly developed expansion chamber condensation particle counter - the versatile Size Analyzing Nuclei Counter - suitable for studies on nanoparticles from diameters of 1-2nm upwards. The vSANC is applicable for both, laboratory as well as long-term field measurements at temperatures ranging from $-20°C$ to $+40°C$ and inlet gas pressures ranging from 0.2bar to 1.2bar.

The operation is based on heterogeneous nucleation of supersaturated vapor on aerosol particles and subsequent droplet growth, whereby well-defined uniform supersaturation inside the measuring chamber is achieved by adiabatic expansion. Thereby small particles grow to visible sizes where they can be detected by applying the multiple Constant Angle Mie Scattering method. The measuring principle was adopted from the Size Analyzing Nulcei Counter and can be found elsewhere (see Wagner *et al*, 2003). Here the droplets, growing in the expansion chamber are illuminated by a solid state laser beam ($\lambda = 488nm$). The resulting scattered light fluxes are then monitored simultaneously at 10 different scattering angles.

In order to enable an automatic establishment of a correspondence between experimental and theoretical (Mie-theory) light scattering extrema, a tailormade software was developed dividing scattering intensities for two specifically selected angles by each other. The resulting structure has strongly pronounced extrema, which make an automated data evaluation possible (Hollaender *et al*, 2002). By additionally measuring the transmitted light flux, absolute determination of particle number concentrations ranging from 50/cc to 10^7/cc is enabled without the need of external calibration. Moreover well-defined uniform conditions in the expansion chamber allow for an automated determination of droplet growth rates for precision verification of vapor supersaturation ranging from 5% up to the limit of homogeneous nucleation.

The design of the experimental setup, including expansion chamber, subpressure vessel, valves, tubing, pumps and critical orifices, enables constant and continuous aerosol flow during measurements. In addition the sampling flow through the chamber can be controlled either by means of critical orifices (active sampling mode) or externally (passive sampling mode). Particularly the latter is of advantage when performing measurements in combination with a uDMA. The redundant system layout allows the exchange of filters and dryers during experiment. Thus continuous long-term measurements are possible.

Furthermore the system pressure can be chosen independent from the ambient air pressure. The only limitation is given by the measuring range of pressure sensitive components, such as pressure gauges. Hence the input gas pressure can range from 0.2bar to 1.2bar.

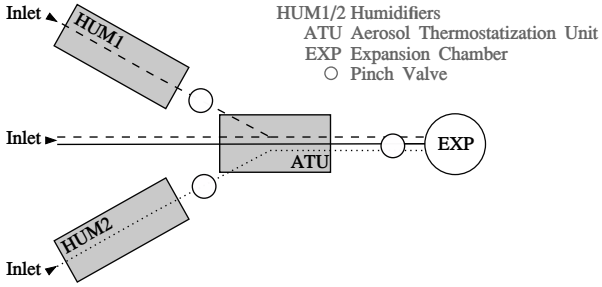

Figure 1: Schematic diagram of the aerosol inlet system. Either the aerosol is already humidified and is passed directly into the expansion chamber (solid line) or it first passes through one of the two humidifiers (dotted line) or it gets mixed with humidified air in the aerosol thermostatisation unit (dashed line).

To minimize particle losses along the sampling line the inlet system was designed as short and straight as possible using only stainless steel tubing and pinch valves with complete and true full bore, when open. The inlet system includes three alternative aerosol inlets, two humidifiers, and the aerosol thermostatization unit. Its design provides flexibility with respect to aerosol presampling conditions (see figure 1). In addition it is possible to alter two different condensing liquids, e.g. polar and non-polar, or use binary vapors.

In conclusion, the vSANC provides a powerful tool to investigate nanoparticles from diameters of 1-2nm upwards. It enables the determination of droplet growth rates and absolute number concentrations ranging from 50/cc to 10^7/cc. The vSANC was optimized to achieve high flexibility with respect to temperature, inlet gas pressure, and condensing liquid. Its mobility and the redundant system layout even enable long-term field measurements. We present first measurement results providing determinations of heterogeneous nucleation probabilities and allowing evaluations of sizes of molecular clusters.

Charging efficiency of the single-wire corona unipolar charger with radial sheath flow

V. Wattanamekhinkul[1], C.L. Chein[1] and C.J. Tsai[1]

[1]Institute of Environmental Engineering, National Chiao Tung University, Hsinchu, 30010, Taiwan
Keywords: unipolar aerosol charger, charging efficiency, nanoparticles, aerosol instrumentation.
Presenting author email: w_virat@yahoo.com

A single-wire corona unipolar charger has been developed and investigated to enhance the extrinsic charging efficiency of nanoparticles by using radial sheath air to minimize charged particle loss. Experimental charging efficiencies were obtained at a fixed aerosol flow rate of 0.5 and 1.0 L/min using monodisperse silver nanoparticles of 2.5 to 20 nm in diameter. The applied sheath air flow rates range from 0.5 to 2.0 L/min, while the applied corona voltage range from ±1.80 to ±2.70 kV respectively.

Figure 1 shows the schematic diagram of the present unipolar charger which is a modification of the nanoparticle charger with multiple discharging wires developed by Tsai et al. (2010) and the nanoparticle charger with sheath air developed by Chien et al. (2011). The outer stainless steel cylindrical casing of 30 mm in diameter is grounded. A 6 mm long grounded porous metal tube (inner diameter ID = 6.35 mm) with a Teflon tube inserted at the end from which radial sheath air is introduced, and a discharge gold wire of 50 μm in ID and 6 mm in effective length is used as the discharge electrode, on which a high DC voltage is applied from the top of the charger. The space between the gold wire and the stainless steel casing is the charging zone where aerosol charging takes place.

The aerosol flow is introduced into the charger from the top aerosol inlet through an annular slit of 0.05-mm gap formed by the stainless steel shroud and the outer casing, and filtered high-speed sheath airflow with the velocity of 0.07–0.28 m/s is introduced through the inner wall of the porous tube to avoid charged particle loss. The charged particles are accelerated to exit the charger quickly through the bottom aerosol outlet after the charging zone.

Four parameters are used for the performance evaluation of unipolar electrical aerosol chargers (Marquard et al. 2006), including intrinsic charging efficiency (η_{int}), extrinsic charging efficiency (η_{ext}), electrostatic loss (L_{el}), and diffusion loss (L^0_d).

The obtained experimental data will be used to validate with numerical results of Chien and Tsai (2012) which shows that the extrinsic charging efficiency ranges from 17.2% - 70.5% for particles ranging from 2.5 to 10 nm in diameter.

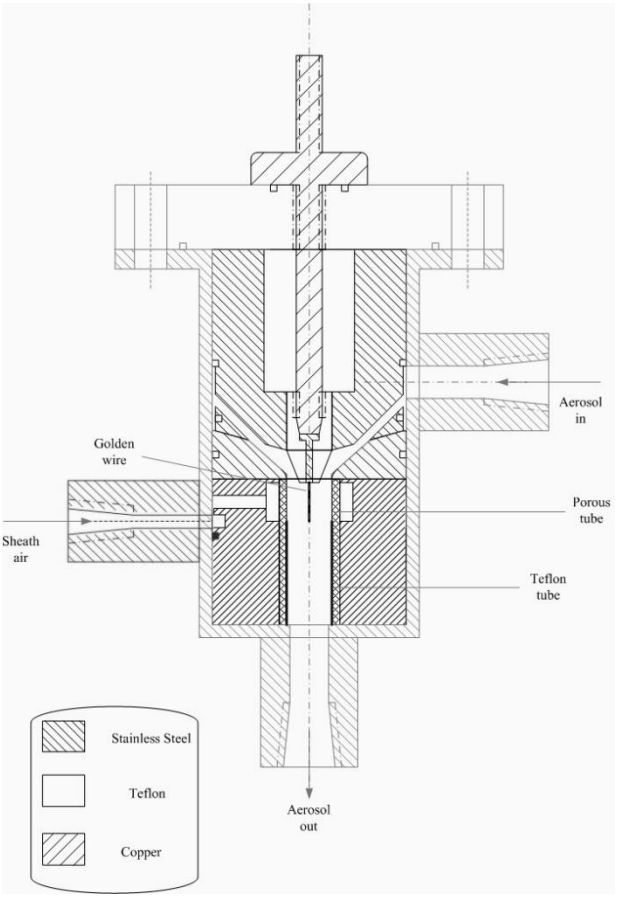

Figure 1. Schematic diagram of the present unipolar charger

There is currently much interest in light absorption by atmospheric aerosols. Recent research has shown that some types of atmospheric particles start to absorb strongly at blue and ultraviolet wavelengths, but there are few techniques to probe the aerosol optical properties at these wavelengths. Varma et al. (2009) first showed that *incoherent broadband cavity-enhanced absorption spectroscopy* (IBBCEAS) is a promising approach to measure aerosol extinction with high sensitivity. Several groups are now using IBBCEAS for studying aerosol optical properties across a continuous spectral region and at short wavelengths (Washenfelder et al., 2012; Zhao et al., 2013). Our aim in this presentation is to describe our recent work to extend IBBCEAS aerosol measurements to very short wavelengths (Chen et al., 2011; Wilson et al., 2012).

A schematic of the experimental system is shown in Fig. 1. The IBBCEAS system was coupled directly across a 4 m^3 atmospheric simulation chamber in the Centre for Research into Atmospheric Chemistry at University College Cork. The system is unusual in that it is a single channel optical cavity spectrometer with continuous spectral coverage from 320 to 405 nm. The 4 m long optical cavity partially compensated for the reduced mirror reflectivity across this broad range. A xenon short arc lamp was used as a light source across the spectral region.

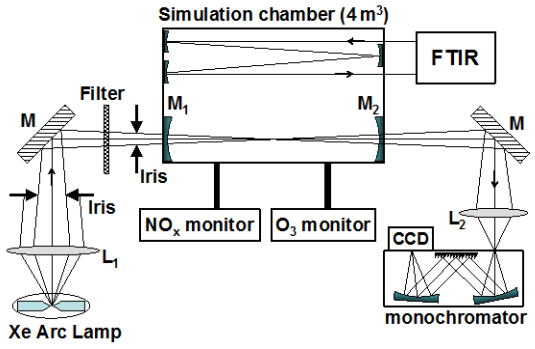

Figure 1. Layout of the atmospheric simulation chamber, IBBCEAS spectrometer, and ancillary equipment.

The stability and sensitivity of the system's extinction measurements were evaluated in a series of SOA experiments. The SOA was formed by photolysing strongly absorbing nitroaromatic compounds, which have been implicated in reducing levels of actinic radiation in large urban centres. The analysis of the total extinction spectrum is discussed, particularly how the contributions of gas phase absorption and particle extinction can be separated. We consider key elements of the experimental system and compare our approach to those of other groups. Finally, the future prospects for using IBBCEAS in field and chamber studies are assessed.

We gratefully acknowledge financial support from Science Foundation Ireland through grant 11/RFP/GEO3200.

Source apportionment-AMS and carbon based

ME-2 analysis of long-term on-line mass spectrometric data of non-refractory submicron aerosol in the city of Zurich

F. Canonaco[a], J. G. Slowik[a], U. Baltensperger[a], A.S.H. Prévôt[a]

[a]Laboratory of Atmospheric Chemistry, Paul Scherrer Institut, 5232 Villigen PSI, Switzerland
Keywords: AMS, PMF, ME2, ACSM
Presenting author email: francesco.canonaco@psi.ch

The role of aerosols in the atmosphere is of importance, because they affect climate (Forster *et al.,* 2007), human health (Peng *et al.,* 2005), ecosystems, e.g., acidification (Matson *et al.,* 2002), and visibility (Watson, 2002). Thus, the identification and quantification of formation mechanisms and sources is of high priority. However, this task is complicated due to the complexity of particle composition.

Long-term monitoring of aerosol composition provides a powerful tool for the analysis of the aforementioned effects. Long-term measurements allow capturing the seasonal variability of different aerosol constituents, which is not possible with shorter-term campaigns. Furthermore, long-range, mesoscale, and local air quality models can be improved through comparison with long-term datasets. Finally, the existence of long-term sampling records at a given site provides a framework for the interpretation of datasets from short-term intensive measurement campaigns.

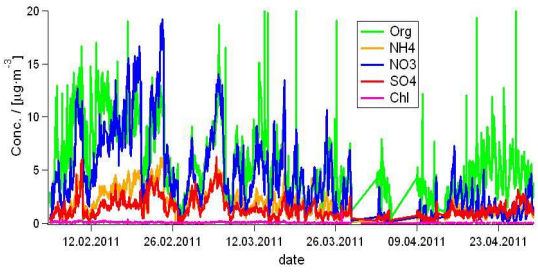

Fig. 1. Preliminary time series of the ACSM including SO_4, NO_3, NH_4, Cl and organics. For the sake of simplicity the figure contains only the winter data.

We present measurements of submicron aerosol composition from an aerosol chemical speciation monitor (ACSM, Aerodyne Research, Inc.) deployed in downtown Zurich. The ACSM yields quantitative mass spectra of the non-refractory aerosol component with an averaging period of 15 to 30 minutes. These are one of the first full-year measurements in Europe using this technique. As shown in Fig. 1, the ACSM is capable of resolving inorganic species such as NH_4, SO_4, NO_3, Cl, and the organics. The data can be further deconvolved in order to identify and apportion the sources, in particular for the complex organic fraction.

There are several possible techniques for the deconvolution of a data set. Positive matrix factorization (PMF) has been extensively exploited for this type of data. However, the multilinear engine 2 (ME2) offers advantages compared to PMF, due to the fact that the user has the possibility to introduce a priori information in form of e.g. known factor profiles into the model (Paatero, 1999).

The aim of this work is to make use of the multiple approaches available in ME2 on a large dataset, in particular on the obtained data from downtown Zurich during the full year 2011. For this purpose we implemented a user-friendly interface in the software IGOR Pro (Wavemetrics, Inc.) which shall be shared in the next future with other research groups.

We will discuss identification and source apportionment of ACSM organic data at an urban site over the full year of 2011 with the ME-2 algorithm. Different techniques, like the a-value (Lanz et al., 2008) or the pulling approach (Paatero, P. and Hopke, P.K., 2009), as highlighted in Fig.2 have been tested. Moreover, studying and comparing the outcomes of these just mentioned techniques provides useful information for estimating of the model uncertainty.

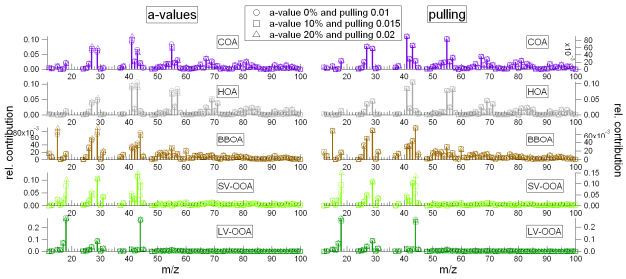

Fig. 2. Preliminary factor profiles of the source apportionment of the ACSM organic winter data. For the sake of simplicity the figure comprises only the winter data.

An Aerodyne compact Time-of-Flight Aerosol Mass Spectrometer (cToF AMS) was deployed in London as part of the Clean Air for London (ClearfLo) project. A full calendar year of data were collected, covering the two major intensive observation periods (IOPs) in the winter and summer of 2012 during which aerosols, radicals, gases and meteorological parameters were measured by a suite of state-of-the-art instrumentation. Measurements were also conducted before, during, and after the 2012 summer Olympic Games which were held in the city.

The cToF AMS was located in a permanent London Air Quality Network (LAQN) monitoring station representative of an urban background environment from 11 January 2012 until 23 January 2013 (Fig. 1). The IOP measurements also took place at this site in North Kensington. Both clean westerly conditions and more polluted conditions including transported European plumes were experienced at the site. Contrasting meteorological conditions, such as inversions and heat waves, also influenced the site throughout the year.

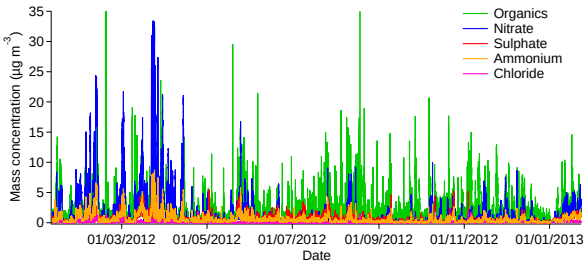

Figure 1. Time series of organic and inorganic mass concentrations measured by the cToF AMS.

Distinct diurnal profiles (Fig. 2) for the entire year of data are observed for the organic aerosols with peaks in concentration either side of midday and a large evening peak. The diurnal profile of nitrate exhibits a morning peak and afternoon trough. Seasonal trends are also evident with a change in the dominant species from nitrate to organic between winter and summer.

Preliminary positive matrix factorization (PMF) analysis identified at least five factors (Fig. 3) as potential sources for the organic aerosols in this urban environment. Primary organic aerosols include hydrocarbon-like (HOA), solid fuel (SFOA), and cooking (COA). Both type 1 and type 2 oxygenated secondary organic aerosols are identified.

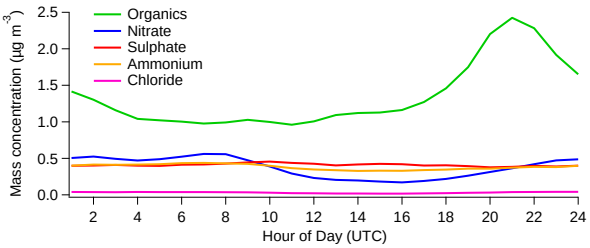

Figure 2. Median diurnal profiles of organic, nitrate, sulphate, ammonium, and chloride species.

There is a near equal contribution of primary and secondary aerosols to the total organic mass of the whole year, where primary aerosol dominate in the winter and secondary aerosols dominate in the summer.

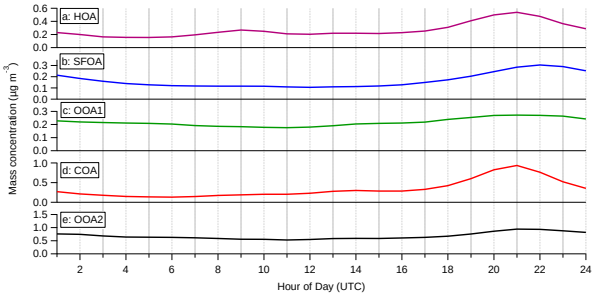

Figure 3. Median diurnal profiles of 5-factor solution from preliminary PMF analysis of organic data.

Long-term cToF AMS data, including solutions from PMF analysis will be presented, highlighting diurnal and seasonal characteristics of London urban background pollution. These data will be used to identify sources of organic aerosols and how these change with time. Furthermore the factors from PMF analysis can be used to target factors in future Aerosol Chemical Speciation Monitor (ACSM) studies at the same site.

Secondary organic aerosol (SOA), typically the dominant fraction of particulate organic mass (OA), remains poorly constrained. Its formation involves several unknown precursors, formation and evolution pathways and multiple natural and anthropogenic sources. In our work a combined gas/particle-phase source apportionment is applied to wintertime and summertime data collected in the megacity of Paris within the MEGAPOLI project to investigate SOA origin during both seasons (Crippa et al., submitted). Source apportionment was conducted by positive matrix factorization (PMF) analysis of combined mass spectra from an Aerodyne aerosol mass spectrometer (AMS) and a proton transfer reaction mass spectrometer (PTR-MS). PMF was implemented within a new source apportionment toolkit based on the multi-linear engine (ME-2) algorithm (Canonaco et al., in prep.).

The combined method improved apportionment of primary OA (POA) sources by the inclusion of gas-phase tracers. These tracers further allowed distinguishing between biogenic-influenced and continental/anthropogenic sources of SOA. We found that continental SOA was dominant during both seasons (24-50% of total OA), while contributions from photochemistry-driven SOA (9% of total OA) and marine emissions (13% of total OA) were also observed during summertime. A semi-volatile nighttime component was also identified (up to 18% of total OA during wintertime). The presence of benzene and PAN in the wintertime oxygenated continental factor suggested that this secondary fraction could be influenced by biomass smoke in aged air masses, consistent with ^{14}C data.

Apportionment of the volatile organic compounds (VOCs, see Fig.1) indicated that traffic was mostly the dominant source of the aromatic fraction. However, aged air masses (during winter) and nighttime air (during summer) were also significant sources. Cooking contributed an unexpectedly high fraction of the total aromatics, possibly due to the overlap of traffic and cooking emissions influenced by meteorology. The source apportionment of oxygenated VOCs revealed that secondary species dominated in both seasons, but especially summer. During wintertime acetic acid was also produced by wood burning emissions. Finally, biogenic emissions were produced by biomass burning during wintertime while “fresh” secondary species dominated in summer.

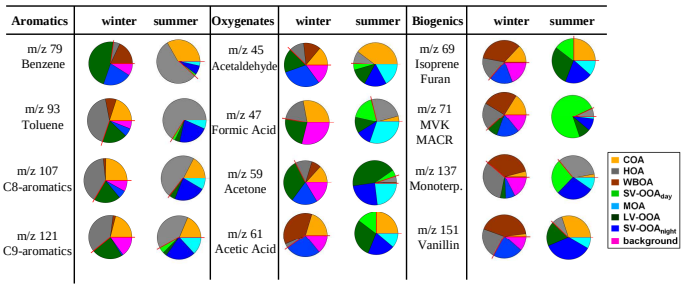

Figure 1. Source apportionment of aromatic, oxygenated and biogenic VOCs.

Keywords: $PM_{2.5}$, Particulate organic compounds (POC), PMF.
Presenting author email: raeed.qadir@helmholtz-muenchen.de

Knowledge of the temporal and spatial variation of particulate organic matter (POM) and its chemical composition are clearly needed to understand its climate and adverse human health effects. To protect both human health and the environment, it is important to combat pollutant emissions at the source and identify and implement the most effective reduction measures at local, national and international levels. Comprehensive studies are therefore necessary to evaluate the characteristics of PM at the different sources. Organic compounds of biogenic and anthropogenic origin often represent a large fraction, up to 40%, of total PM mass. The concentrations of organic compounds ranging from below $pg.m^{-3}$ to $mg.m^{-3}$[1].

A monitoring site for detailed physical and chemical characterization of ambient fine and ultrafine particles was established in Augsburg in October 2004. The station is located on the premises of the University of Applied Sciences (Fachhochschule) Augsburg (Fig.1). Daily samples of $PM_{2.5}$ were collected at the monitoring site of Fachhochschule in Augsburg city. Allowing for a thorough monitoring of particle associated organic substances and the different sources of PM pollution. The long-term monitoring data, every fifth day samples (from 2007 to 2012) are analyzed for their particulate organic compounds (POC) and carbon fraction (EC/OC) and will be considered in our investigation.

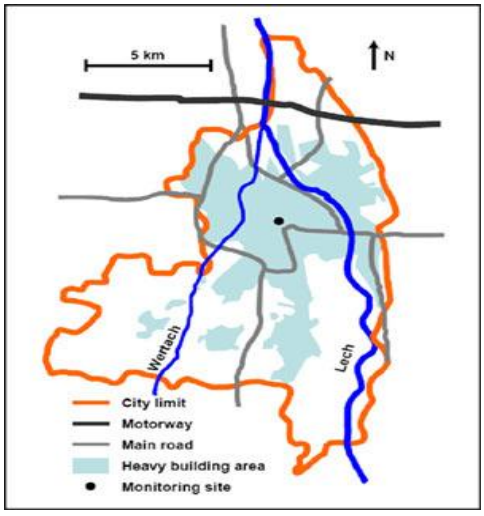

Figure1. Monitoring site in Augsburg

In-situ derivatization thermal desorption gas chromatography time of flight mass spectrometry (IDTD-GC-ToF-MS) [2] is used for the chemical characterization of POC. Elemental and organic carbon fraction (EC/OC) are analyzed by thermal-optical analysis IMPROVE-A protocol.

Results of source apportionment analysis of PM_{10} in Augsburg have been published recently. In our present study, the main sources of POC were identified using positive matrix factorization (PMF) [3]. More than 80 organic species under investigation will be used for PMF analysis, including PAH, oxidized PAH, n-alkanes, iso & anteiso alkanes, hopanes, resin acids, fatty acids, anhydrous sugars and phenolic compounds.

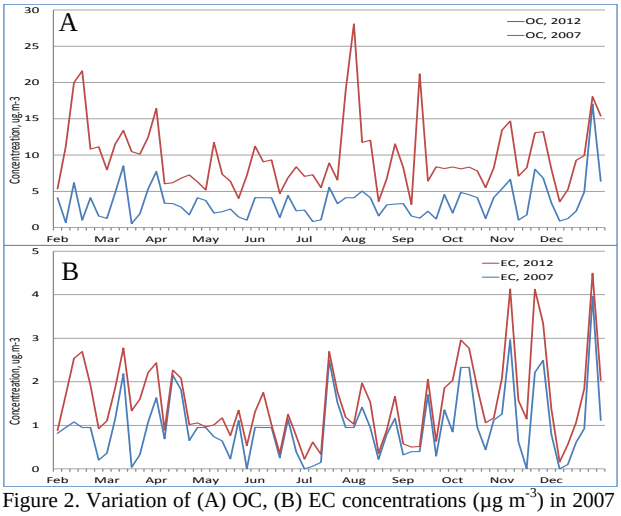

Figure 2. Variation of (A) OC, (B) EC concentrations (µg m^{-3}) in 2007 and 2012

The health effects of organic compounds in aerosols are currently investigated in the framework of the Helmholtz Virtual Institute of Complex Molecular Systems in Environmental Health, HICE (www.hice-vi.eu).

Situated on the north coast of France, Dunkirk's air quality is subject not only to the high volume of shipping traffic passing through the Dover Strait, but also to the emissions from a considerable industrial sector. The city is host to the largest steel manufacturing plant in France, an oil refinery and an industrial facility with the largest manganese ferroalloy furnace (Fe-Mn furnace) in the world.

The aim of the NANO-INDUS campaign was to characterise the transient emissions from this facility. To this end a suite of online instruments and offline techniques were located approximately 1 km to the southwest of the alloy manufacturing plant, from 15th May – 10th June 2012. An aerosol time-of-flight mass spectrometer (ATOFMS, TSI model 3800), was used to determine the chemical composition and size of individual ambient particles in the vicinity of the Fe-Mn furnace in real time.

Over 700,000 single particle mass spectra were generated and then classified using the *K*-means algorithm. Based on their mixing state, size distributions and temporality, 18 major particle types were identified including: shipping, sea salt, several elemental and organic carbon types, along with some sulfur, calcium, and various Fe-containing types emitted from nearby industrial sources.

Particles containing internally mixed potassium and chloride, typically associated with biomass burning (specifically from domestic wood combustion) were found instead to be industrial in origin. This was supported by the absence of biomass burning organic aerosol (BBOA) in the co-located Aerodyne high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS) dataset. The latter instrument was used to identify a number of sources of organic aerosol (OA) and comparison of these OA factors with the ATOFMS data has provided valuable information on the mixing state of organic aerosol in Dunkirk.

A calcium-containing particle type, usually associated with vehicular traffic emissions in urban field studies, was also found to be industrial in origin. Mass spectra for these particles were dominated by calcium (*m/z* 40, $[Ca]^+$) and carbonate (*m/z* -60, $[CO_3]^-$) and displayed a strong northeasterly wind dependence, the direction of the Fe-Mn furnace. Calcium carbonate is used as an additive in the sintering process and it is thus likely that these particles are emitted from one of the main stacks of the plant.

Fe and Mn particle types, originating from the Fe-Mn furnace were also identified. These included two Fe-containing types, one internally mixed with Na and K, the other internally mixed with Mn (Figure 1). Further Mn-containing particle types were identified and found to contain Pb and K, but not Fe. Zn-containing particles were also observed, with and without Pb. Thus, single particle mixing state was observed to be highly heterogeneous in the vicinity of the industrial facility.

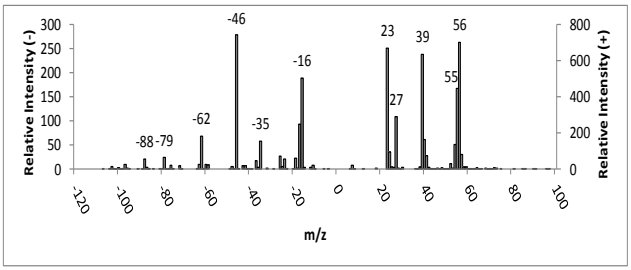

Figure 1. Average mass spectrum of Fe-Mn particles observed in the vicinity of an industrial plant in Dunkirk.

Further information on these metal-containing particles has been obtained by quantitative analysis of filter extracts using ICP-AES and ICP-MS, as well as measurements of single particles using SEM/EDX. The use of these techniques in combination with the mixing state information and high temporal resolution of the ATOFMS provides valuable insights into the sources, composition, variability and chemical processing of single particles from industrial emissions.

The NANO-INDUS project was supported by the French Environment and Energy Management Agency (ADEME) under grant N° 11-81-C0089 and by the Institut de Recherche en ENvironnement Industriel (IRENI). Jovanna Arndt was supported by the Irish Research Council.

Radiocarbon-based source apportionment of elemental carbon and organic carbon at a regional background site on Hainan Island, South China

Keywords: Source apportionment, radiocarbon (^{14}C), carbonaceous particles, elemental carbon, organic carbon
Presenting author email: yanlin.zhang@dcb.unibe.ch

Carbonaceous particles (total carbon, TC) are major fraction of fine particles and are of worldwide concern due to their important impacts on climate and human health. TC is often operationally classified into two sub-fractions: elemental carbon (EC) and organic carbon (OC) (Pöschl, 2005). Radiocarbon (^{14}C) analysis of EC and OC separately allow a quantitative and unambiguous measurement of their contemporary and fossil contributions, thereby potentially reducing a major uncertainty in the present understanding of organic aerosols emissions (Szidat *et al*. 2006).

Both fossil-fuel emissions and biomass/biofuel burning in Southeast Asia may have an important impact on regional EC and OC emissions. Here, we present a ^{14}C-based source apportionment study at a regional background site of Jianfeng (JF) on Hainan Island, South China. This is an ideal site to study air pollutions outflows from mainland China, as well as the impact of Southeast Asian biomass burning emission.

PM2.5 samples were collected about once per week from May 2005 to August 2006 using a high volume sampler (~1 m^3/min) for 24 h. All samples were measured for the EC and OC concentrations by the thermal-optical transmittance method. The EC and OC isolation for subsequent ^{14}C measurements were prepared with an optimized thermo-optical protocol (Swiss_4S) on the selective samples (Zhang *et al*. 2012).

As shown in Figure 1, both EC and OC are characterized by the lowest abundances during the wet summer season (i.e. from the Mid-May to September) and the highest levels in winter (i.e. from mid-November to February). This is most likely due to the high wash-out effect and the prevailing clean maritime air mass origins in summer on the one hand and the anthropogenic air pollutions (biomass and fossil fuel combustions) transportation from continental China with the northeast winds on the other hand.

As an example illustrated in Figure 2, the combination of the analysis of the air mass back trajectories and fire counts on the day of the highest carbonaceous particles levels during the entire study period indicate a significant contribution from open biomass burning to the carbonaceous particles. This idea is further confirmed by ^{14}C measurements, which show the non-fossil sources account for 69% and 88% to the total EC and OC, respectively. Biofuel combustion may be another important non-fossil contributor to EC and OC in Southeast China during the heating season. ^{14}C measurements of the carbon faction of interest on other samples with different air mass origins and seasons will be present as well.

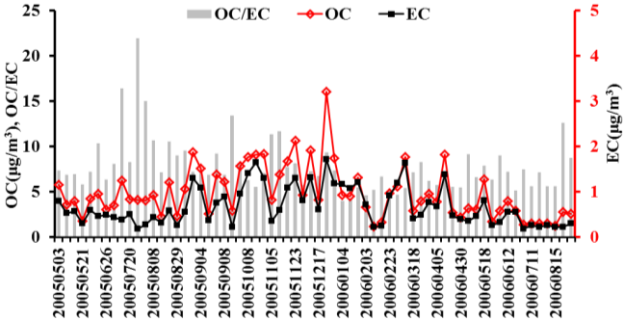

Figure 1. Temporal variations of OC, EC concentrations (μg/m^3) and the OC-EC ratios

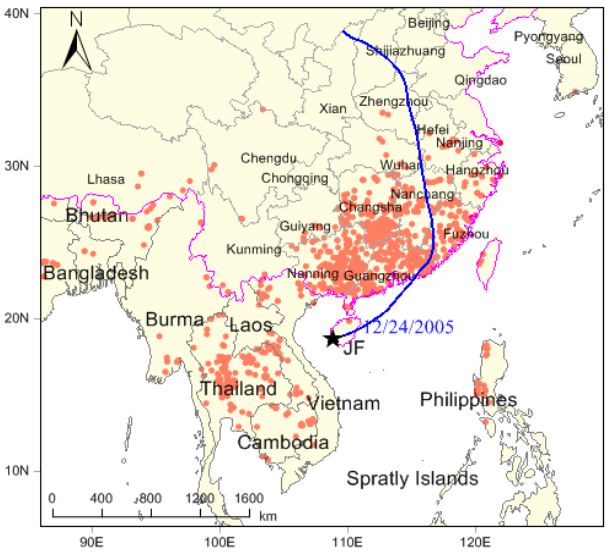

Figure 2. 5-day air mass back trajectories reaching JF and MODIS fire counts on 24 Dec 2005.

Wood-burning emissions within a continuous-flow photooxidation reactor: Soot-Particle Aerosol Mass Spectrometer characterization

J. C. Corbin[1], A. Keller[2], H. Butscher[2], B. Sierau[1], U. Lohmann[1], and A. A. Mensah[1]

Keywords: wood-burning, photooxidation, AMS, SP-AMS
Presenting author email: joel.corbin@env.ethz.ch

Wood-burning stoves, used worldwide for heating and cooking, can be an important atmospheric source of primary and secondary aerosols. Current legislation restricts only the primary aerosol emissions of such stoves, which include primary organic aerosol particles (POA), ash, and soot. Such legislation neglects the potential formation of secondary organic aerosol (SOA), which may nucleate or condense after the atmospheric oxidation of volatile organic compounds. For example, smog chamber photooxidation experiments have observed wood-burning SOA concentrations up to four times higher than the corresponding POA emissions (Grieshop et al., 2009; Heringa et al., 2011).

To characterize the SOA-formation potential of wood-burning stoves and similar emissions, Keller and Burtscher (2012) have developed a continuous-flow photooxidation reactor for monitoring potential SOA in real-time. The short residence time (seconds) of this chamber allows the time-resolved measurement of potential SOA. However, the small chamber also necessitates higher-than-ambient irradiation conditions.

Here, we present results from high-resolution Aerosol Mass Spectrometer (AMS) and Soot-Particle AMS (SP-AMS) analysis of wood-stove emissions under three different conditions: filtered and photooxidized ("SOA"), unfiltered and photooxidized ("OxPOA"), and unfiltered emissions ("POA").

Figure 1 shows the increase in aerosol oxidation after photooxidation, as measured by the AMS. The figure shows the difference of the normalized SOA and POA organic mass spectra, averaged over multiple burns. High-resolution analysis has been used to identify organic species as C_xH_y (*green*), $C_xH_yO_{z=1}$ (*purple*), or $C_xH_yO_{z>1}$ (*pink*). However, data are presented on a unit-mass scale for clarity. As shown, the relative intensity of CO_x ions was higher for SOA, whereas C_xH_y was higher for POA. The pie charts (inset) summarize all three cases, showing $C_xH_yO_z$ increasing and C_xH_y decreasing, from left to right. For POA, the contribution of hydrocarbons C_xH_y was more than double that of SOA. Also, SOA contained more $C_xH_yO_{z>1}$ relative to OxPOA. Elemental analysis indicated that the shift of H:C and O:C ratios due to oxidation was comparable to, but significantly greater than, observations in Mexico City (Heald et al., 2010).

In these experiments, refractory species (those involatile below 600 °C) were also characterized with an SP-AMS laser equipped on the same AMS. High-resolution SP-AMS analysis yielded similar results to the AMS, with the major spectral change due only to pure-carbon ions (C_x). Detailed AMS and SP-AMS results will be presented and compared.

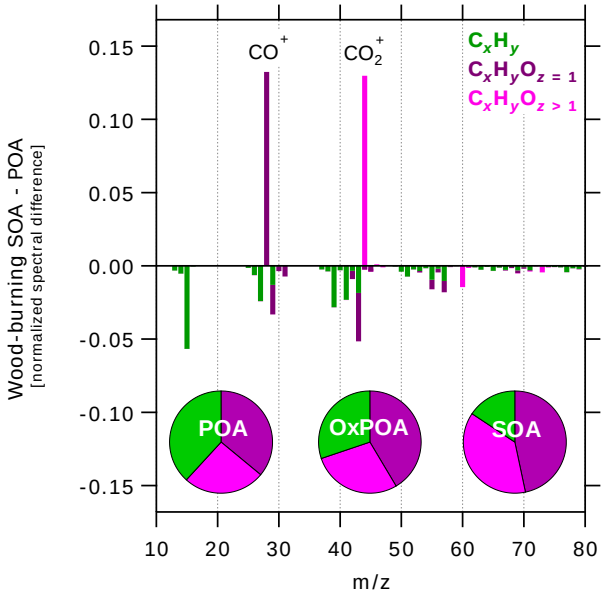

Figure 1. AMS difference mass spectrum for wood-stove SOA minus POA. Inset: pie charts of the organic composition for the three cases.

Keywords. combustion aerosols, characterization, source of emission
Presenting author email: polga@mics.msu.su

Aerosols generated by incomplete combustion of fossil fuels (FF) and biomass burning (BB) are major air pollutants. Open BB relating to wildfires contributes to almost a half of the combustion aerosol global inventory. Aerosol emissions of transport systems are currently acknowledged to be a largest source of uncertainties in understanding the impacts on the regional air quality. Ship emission is among the world's highest polluting sources per quality of fuel consumed. Combustion aerosols may serve tracers allowing a link to distinct combustion sources in apportionment studies if their key physico-chemical characteristics representative the emission sources are defined. The estimations of the source contribution to ambient particulates assume specific markers different from other combustion sources.

A complexity of multicomponent and source-specific PM emissions requires the characterization of individual particles. The classification of combustion aerosols may be done by representative particle types according to their chemical specification. This approach allows quantifying the various diesel and biomass burning sources and identifying the specific characteristic features that can serve as micromarkers emission source.

Presently, the hierarchical cluster analysis (HCA) is a data analysis technique which is used for the interpretation of electron microprobe analysis data and the determination of particle types in ambient air with a large number of pollution sources. Here, we present the development of HCA for characterization the FF and BB emissions by classification of individual particle data on characteristic groups with similar morphological and chemical composition according to the source and type of fuel used. Scanning electron microscopy (SEM) coupled with energy-dispersive X-ray spectroscopy (EDX) is used for characterization of morphology and composition of a large number of individual particles. FTIR spectroscopy and ion content measurements provide the bulk composition data for clustering expert analysis that assures that the mean composition of a cluster is close to physico-chemical identifiable type of particles. Impact of Fe content in laboratory-produced soot aerosol on its composition and structure was analysed in Bladt *et al.* (2012) to demonstrate the elaborated approach for separation individual particles into characteristic groups representing the particle types in dependence of iron content in soot.

This review presents micromarkers of source-specific combustion aerosols emitted by transport systems (road and marine diesel engines) and in open fire experiments. Microscopic and chemical characterization of Opel Astra diesel engine exhaust operated at 35 km/h speed and used diesel B0 fuel with various lube oil (low and high SAPS) and biodiesel fuel B20 with high SAPS are performed. The most abundant group (around 50%) in each exhaust is polluted soot. In diesel B0 exhaust particles, low SAPS groups of silicates, iron and aluminum oxides are found. Using high SAPS with larger ash content leads to abundance of groups of Al oxide and Al fused with Fe. The most prominent impact of high SAPS using relates with presence of well-separated groups of Nb oxides and W particles. Biodiesel exhaust particles, high SAPS contain groups of Fe and Zn oxides, and W particles. The source specific micromarker of biodiesel particles is a separate group enriched by Cl, K, and Na, the elements which are commonly recognized as biomarkers of biofuel combustion.

Exhausts from the main and auxiliary engines operated onboard of a RoRo/casetter carrier ship during TRANSFORM campaign, burning heavy and distillated fuels, respectively, are analyzed (Popovicheva *et al*., 2012). SEM/EDX observations of emitted aerosols indicate carbonaceous particles internally and externally mixed with inorganic species in the combination of spherical and irregular shapes. The composition of individual particles is varying in a wide concentration range of major elements (C, O) and impurities (S, Fe, Si, Ca, Zn, V, Ni, K, Mn) representative the origin of fuels. In distillated fuel (DF)-derived aerosols we identify groups of soot, Ca- and Fe/Si-rich particles. Calcium sulfate/oxide/carbonates and iron oxides are found to compose the group of Ca- and Fe-rich particles, respectively, while silicon oxide and silicate determine the group of Si-rich particles in heavy fuel (HF)-derived emission. Transition metals (V, Ni) containing particles specify the separate group which may serve as a specific micromarker of heavy fuel combustion.

Characterization of freshly-generated smoke particles produced in small-scale spruce open fire experiments shows the groups of soot, Ca- and Fe-rich particles while K- and Mn- rich groups identify the specific micromarkers of BB.

Thus, state-of-the-art characterization of complex multicomponent aerosols improves the quantification of contribution of various fossil fuel and biomass burning emissions to ambient particulates and the identification of a source type in the apportionment studies.

Combustion aerosol and chemical measurements

Measurement of chemisorption on metallic nanoparticles using aerosol photoemission spectroscopy

S. Onel and M. Seipenbusch
Institute for Mechanical Process Engineering and Mechanics, Karlsruhe Institute of Technology, Karlsruhe, 76131, Germany
Keywords: nanoparticles, surface chemistry, photoemission spectroscopy.
Presenting author email: santiago.onel@kit.edu

Chemisorption on metallic nanoparticles is not only a fundamental step in heterogeneous catalysis, but also builds the basis for self-assembled monolayers. We address this topic by working with gas-carried metallic nanoparticles using aerosol photoemission spectroscopy as a highly sensitive analysis tool.

Aerosol photoemission spectroscopy (APES) is a surface sensitive method, which was successfully used in the past showing a correlation between catalytic and photoelectric activity of gas-carried nickel and platinum nanoparticles (Weber et al, 2001). Changes on the particle surface modify the electronic structure, therefore leading to a variation of the photoemission parameters: work function and emission constant. As a result of this, this method shows potential for the study of adsorption on particle surfaces.

In this work we show that APES can be used for the quantitative determination of adsorbates on metallic nanoparticles. This opens up the possibility of measuring size dependent adsorption effects without metal-support interactions or mass transfer limitations due to a support. This online method can be used as well in order to monitor surface functionalization of particles in the gas phase without collecting them or having to perform any other sample preparation step.

Photoemission studies were conducted in an energy range between 5,5 and 6,5 eV, using a deuterium lamp and a monochromator for wavelength selection. The photon energy is just above the work function of metals, but considerably below the ionization energies of the gases used. Work function and emission constant were obtained using the Fowler-Nordheim equation, which describes the photoelectric yield as a function of photon energy near the photothreshold.

Au and Pt nanoparticles were produced in nitrogen 5.0 using a spark discharge generator. The generated particles were mainly aggregates with mean diameters as measured with a scanning mobility particle sizer of 16,6 nm and 18,7 nm, respectively. The primary particle size was determined using TEM being 3,4 nm and 3,8 nm, respectively. The particle number concentration used in both cases was in the order of 10^6 cm^{-3}. The aerosol flow was mixed with the reactant flows: carbon monoxide and 1-hexanethiol. Carbon monoxide 4.7 was dosed using a mass flow controller up to a concentration of 1300 ppm. 1-hexanethiol is liquid at room temperature; consequently, the dosage took place by passing a nitrogen flow through a bubbler filled with 95% 1-hexanethiol. By regulating the nitrogen flow rate and assuming the nitrogen flow is saturated, a maximum concentration of 300 ppm was used.

A positive shift of the work function was observed due to the interaction of CO with Pt. The work function shift increased with increasing CO concentration. The work function shift reached a maximum of 0,23 eV. The data points could be approximated by a Langmuir adsorption isotherm (Figure 1). This can be explained through a growing coverage of the surface with CO and shows consistency with previous results using traditional ultraviolet photoemission spectroscopy for a Pt sheet (Collins et al, 1976). No change in the work function of gold was observed when CO was added, even with higher CO concentrations.

Exposing gold nanoparticles to 1-hexanethiol led to a much larger negative shift of the work function. The effective work function decreased with higher concentration of hexanethiol and reached a saturation value 1,5 eV lower than the work function of the clean surface (5,1 eV). The dependence of the work function on concentration (coverage) was non linear. This behaviour, as well as the maximum value, is in good agreement with theoretical studies (Fragouli et al, 2007)

Validation of an online, real-time, soft photon ionisation (SPI) time of flight mass spectrometer for mainstream tobacco smoke analysis

J. Hawke[1] and M. Bente Von Frowein[2]

[1]British American Tobacco, Group R&D, Southampton, SO15 8TL, UK
[2]Photonion GmbH, Hagenower Str. 73, 19061 Schwein, Germany
Keywords: time of flight, mass spectrometry, soft photon ionisation, tobacco smoke
Presenting author email: jenni_hawke@BAT.com

Mainstream tobacco smoke is a complex and dynamic aerosol, consisting of both particulate and vapour phases. Most analytical approaches for the determination of mainstream tobacco smoke toxicant yields employ off-line per-cigarette analytical techniques that limit understanding of the processes leading to smoke formation. Therefore analytical techniques which allow for online, real time, per-puff quantifiable yield measurements offer many advantages over traditional techniques. The LM2X-TOFMS (Borgwaldt GmbH, Munich, Germany), a coupling of a linear smoking engine and time of flight mass spectrometer is an example of a real-time per-puff analysis system for the vapour phase of mainstream cigarette smoke.

The system uses an E-Lux 126 vacuum ultraviolet (VUV, 126nm) lamp as its light source for soft photon ionisation (SPI), an ionisation technique which causes almost no fragmentation of the chemical species present in the sample (photons of 9.8eV). SPI allows substances to be measured directly in complex mixtures, such as mainstream tobacco smoke whilst not ionising background gases such as O_2, N_2 and CO_2. Currently, seven constituents of mainstream smoke can be quantified (Table 1) on the system (Adam, 2006). Three of which are present on the WHO eighteen priority toxicant list (WHO, 2008).

Table 1: Quantifiable vapour phase analytes on the LM2X-TOFMS.

Class	Analyte
Alkenes	1,3-Butadiene (m/z 54)*
	Isoprene (m/z 68)
Aromatics	Benzene (m/z 78)*
	Toluene (m/z 92)
Carbonyls	Acetaldehyde (m/z 44)*
	Acetone (m/z 58)
	2-Butanone (m/z 72)

*identified as toxicants of concern by a WHO study group

Validation of the system was split into two studies based on recommendations of the International Committee on Harmonisation (ICH). Initially, robustness testing was performed to determine whether the LM2X-TOFMS was able to remain unaffected by small but deliberate changes in operational factors such as capillary length, ferrule, time of day and the day on which measurements are performed. Secondly, measurements were performed to evaluate the linear response of the system based on an individual concentration range for each analyte.

3R4F Kentucky reference cigarettes, (9.4mg ISO pack tar) were used during the first part of the study; all samples were conditioned under ISO parameters: T: 22 ± 1°C RH: 60 ± 3%, and smoked using ISO puffing parameters (35ml puff over 2s every 60s). For the linearity measurements, six certified gas mixtures of varying concentrations as well as a 'blank' were analysed in 2L gas bags over three days. Gas bag analysis was performed using sampling parameters of ten 35ml, 2s "puffs" with a frequency of 20s. Separate gas bags were used for each gas mixture to avoid contamination.

The robustness results were analysed by One-way ANOVA, it showed that no vapour phase constituent had a statistically significant difference for any of the identified changes ($p = \geq 0.05$). I-MR control charts confirm that although there is day to day variation, some of which could be attributed to cigarette variation, the overall process shows good stability and control.

To establish analyte linearity, the measured puff yield (µg/puff) for each analyte was plotted against the relevant bottle concentration range. Figure 1 shows a comparison plot of measured benzene yields vs. calculated benzene yields (assuming ideal gas law).

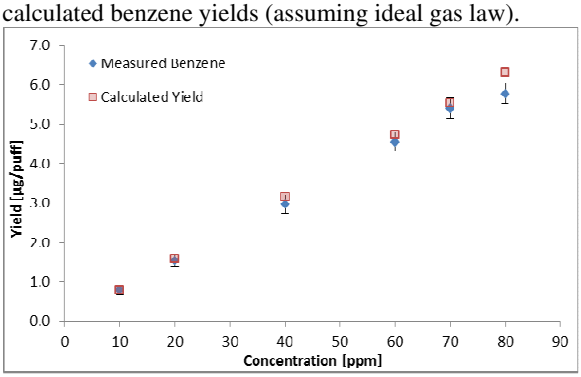

Figure 1. calculated vs. measured values for benzene.

These data will be used to determine reproducibility, repeatability and limits of detection (LOD) and quantification (LOQ).

An accurate, real-time and low-cost method to measure biomass smoke

Yungang Wang[1], Daniel L. Wilson[2], Philip K. Hopke[3], Ashok J. Gadgil[1]

[1]Lawrence Berkeley National Laboratory, Berkeley, California
[2]University of California – Berkeley, Berkeley, California

Presenting author email: phopke@clarkson.edu

Background

In the developing world, approximately 3 billion people cook their food by burning solid fuels with the majority using biomass in polluting and inefficient rudimentary stoves. This number is expected to increase in the coming decades. This use of biomass fuels represents a significant part of energy use in developing regions. The products of incomplete combustion from biomass cookstoves include methane, ozone-precursors, organic carbon and black carbon (BC), which are important greenhouse pollutants. Emissions from cookstove use also have been linked to adverse respiratory, cardiovascular, neonatal, and cancer outcomes. Exposure to cookstove emissions leads to an estimated 4 million deaths each year. Given the substantial threat to public health particularly for women and children, and the uncertainty about the climate effect resulting from cookstove use in developing countries, further study is needed to pinpoint the most beneficial strategies for reducing emissions from this source.

Problem

Mitigating emissions from biomass cookstoves depends first on identifying technologies that are proven effective in reducing emissions, and second on disseminating these technologies on a large scale. Currently, a wide range of improved stove technologies is available including Berkeley Darfur Stoves (BDS), electric stoves, advanced biomass stoves, rocket stoves, solar cooker, etc, but the potential climate and health benefits vary substantially by technology and fuel options. The ability to accurately characterize cookstove emissions in the laboratory and in the field is essential but currently very weak.

Solution

Automated on-line measurements can quantify emission reductions and exposure under actual operating conditions. Prior work has shown that organic components in biomass smoke particles absorb light at 370 nm more effectively than 880 nm in two-wavelength aethalometer (Magee Scientific, Berkeley, CA) measurements. This enhanced absorption (Delta-C = BC370nm – BC880nm) can serve as an indicator of biomass combustion emissions. A strong linear relationship between Delta-C and levoglucosan (a classic biomass combustion marker) was recently observed in Rochester, NY during the winter heating season (Wang et al., 2011). Compared to filter-based levoglucosan measurement, this aethalometer method is simpler, cheaper, more readily accessible, and has higher time resolution for indicating the contributions of biomass smoke to ambient or indoor pollution. In our study, this method will be tested using the BDS under laboratory controlled cooking conditions – water boiling tests (WBT, version 4, http://www.pciaonline.org/node/1048).

Implication

The discrepancies between laboratory and field testing have hindered previous cookstoves development efforts. Improved laboratory studies and testing protocols that can recreate field conditions are needed. This discrepancy suggests a need to undertake further validation of the Delta-C method for different biomass fuels (e.g. waste, charcoal, animal dung, twigs) over a range of burning conditions. Once validated broadly, the Delta-C method would make it easier and cheaper to accurately quantify the cookstove emission levels in the field.

Standardized tests using aethalometer Delta-C measurement performed for the variety of fuels, field conditions, and cooking practices could help determine which stoves are most successful in the field for improving fuel efficiency, emissions, and health, and shed light on the persistent discrepancy in measured emissions in the field versus in the laboratory.

Presenting author email: prati@ge.infn.it

Carbonaceous aerosol is a major component of the urban PM. It mainly consists of organic carbon (OC) and elemental carbon (EC) although a minor fraction of carbonate carbon could be also present. Elemental carbon is mainly found in the finer PM fractions (PM2.5 and PM1) and it is strongly light absorbing. When determined by optical methods, it is usually called black carbon (BC). The two quantities, EC and BC, even if both related to the refractory components of carbonaceous aerosols, do not exactly define the same PM component (Bond and Bergstrom, 2006; and references therein). Moreover, another fraction of light-absorbing carbon exists which is not black and it is generally called brown carbon (Andreae and Gelencsér, 2006).

We introduce a simple, fully automatic, multi-wavelength and non-destructive optical system, actually a Multi-Wavelength Absorbance Analyzer, MWAA, to measure off-line the light absorption in Particulate Matter (PM) collected on filters and hence to derive the black and brown carbon content in the PM (Figure 1)

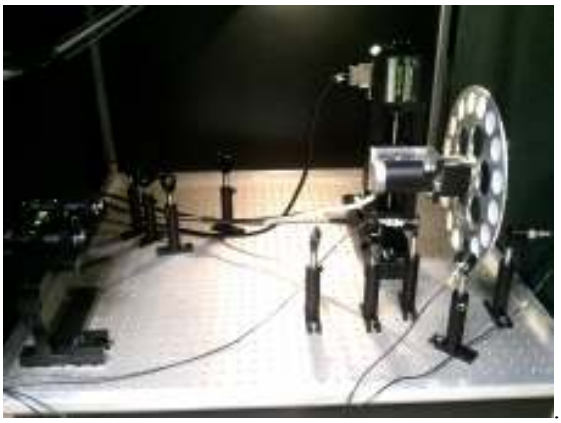

Figure 1: Set-up of the MWAA

This gives the opportunity to measure in the same sample the concentration of total PM by gravimetric analysis, black and brown carbon, metals by, for instance, X Ray Fluorescence, and finally ions by Ion Chromatography. Up to 16 samples can be analyzed in sequence and in an automatic and controlled way within a few hours. The filter absorbance measured by MWAA was successfully validated both against a MAAP, Multi Angle Absorption Photometer (Petzold and Schönlinner, 2004), and the polar photometer of the University of Milan.

The measurement of sample absorbance at three wavelengths gives the possibility to apportion different sources of carbonaceous PM, for instance fossil fuels and wood combustion. This has been done following the so called "aethalometer method" (Sandradewi et al., 2008;) but with some significant upgrades that will be discussed together the results of a field campaign presently on going in a mountain site in the Ligurian Appennines. The apportionemnt of the combustion source derived from the optical analysis, will be compared with the results of other techniques (i.e chemical characterization of biomass burning tracers and radiocarbon determination by Accelerator Mass Spectrometry).

Results of the application of the MWAA to the analysis of collecting stages of cascade impactors will be also also shown.

Filter-based measurements of aerosol optical absorption are widely used to determine Black Carbon (*BC*) concentrations in real time. Measurements at multiple wavelengths permit the separation of contributions of *BC* from different combustion sources (Sandradewi 2008). However, filter-based methods can suffer from non-linearity due to a »loading« effect as a function of increasing deposit density on the filter (Gundel 1984, Weingartner 2003, Arnott 2005, Virkkula 2007). Static algorithms to compensate for the effect fail to capture the details and potential variability of these aerosol optical properties. This impacts the accuracy of source apportionment using the data.

The dual-spot Aethalometer (Magee Scientific model AE33) provides a real-time the model introduced determination of a loading effect, based on the model introduced by Virkkula (2007): $BC_{compensated} = BC\ (1-k*ATN)$. The compensation parameter k is determined in real time for each of the operational wavelengths, and is used in the same manner as has been developed for off-line post-processing. This provides a time resolved specific spectral fingerprint that may be interpreted in terms of aerosol composition.

Optical and chemical properties of aerosols were measured with high time resolution during summer and winter EMEP campaigns in Paris (France) and Payerne (Switzerland). An Aerosol Chemical Speciation Monitor (ACSM) and an Aerodyne High Resolution Time-of-Flight Aerosol Mass Spectrometer (AMS) were used to measure quantitative chemical composition for non-refractory aerosol particles. During summer we observed complex temporal variation of k, where k(880 nm) changed from approximately 0.006 for fresh aerosols to near zero for aged aerosols as shown using Potential Source Contribution Function (PSCF) method for back trajectory analysis.

We have combined the Aethalometer and ACSM/AMS measurements, and normalized the sum of inorganic secondary and organic aerosol mass to BC. Values of this ratio are expected to be high for air parcels containing aged aerosols. The ratio correlates well with the loading compensation parameter k measured by the Aethalometer at 880 nm (Figure 1). This indicates that the compensation parameter k can be used for discrimination between local (fresh) and regional (aged) air pollution aerosols.

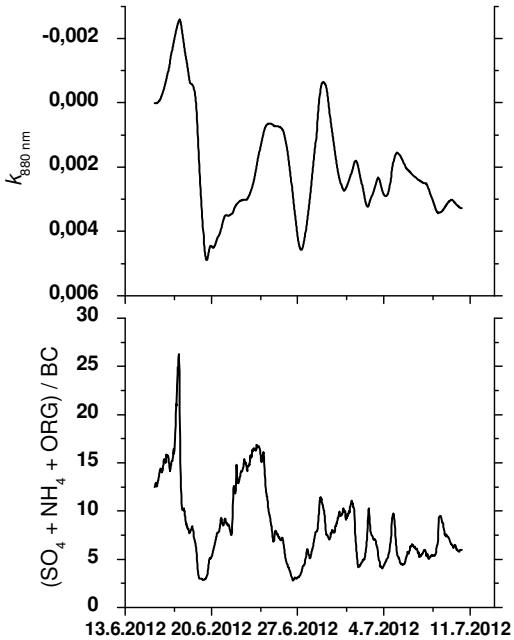

Figure 1. Time series of loading effect compensation parameter k(880 nm), compared to sum of inorganic secondary and organic aerosol mass normalized to BC, during the summer EMEP campaign at the Paris SIRTA-LSCE site.

The identification of carbonaceous fractions of particulate matter on a molecular level still provides an analytical challenge. Knowledge of organic composition is of great importance with respect to health effects or aerosol particles. The determination of sum parameters such as total organic and elementary carbon (OC and EC) following thermal desorption at different temperatures already yields valuable information. However, the method provides no insight of the molecular composition of the distinct thermal fractions. Therefore, hyphenation between a commercial thermal/optical carbon analyzer and a time-of-flight mass spectrometer equipped with photo-ionization has been developed. With this new setup, desorbed organic compounds can be analyzed prior to their oxidation to carbon dioxide by sidelining a small part of the gas flow. For this, the quartz tube between sample holder and oxidizer had to be modified. The new coupling piece extends into an aluminum box, which is heated to 230 °C to prevent condensation. The modified quartz tube is coupled inside the box to a capillary running inside a heated curing tube, which guides the molecules to the ion source of the mass spectrometer. In total a flow of 5 ml/min is led to the mass spectrometer. Ionization is carried out with two soft methods, viz. resonance enhanced multi photon ionization (REMPI), which is selective for (poly)aromatic compounds as well as single photon ionization (SPI), which allows a more universal analysis of aliphatic and aromatic species. By doing this, the molecular pattern of each organic fraction is obtained. Figure 1 depicts a scheme of the instrumental setup and an exemplary two-dimensional graph of the mass spectrometric pattern of a complete OC/EC experiment of diesel exhaust particles.

With the new instrumentation ambient aerosols as well as source particles from combustion processes have been investigated. Furthermore, particles from smog chamber experiments with α- und β-pinene and toluene as precursors were analyzed.

With the new instrumentation ambient aerosols as well as source particles from combustion processes have been investigated. Furthermore, particles from smog chamber experiments with α- und β-pinene as precursors were analyzed. Ambient samples taken in winter showed a big influence from wood combustion, whereas samples taken in summer at the same location missed wood combustion markers, but were dominated by secondary organic aerosol (SOA). Comparison with smog chamber filter samples experiments revealed typical mass to charge signals (at m/z 58 and 82, respectively) that are not observable in any other sample. These could therefore be potential marker substances for SOA. Particles from cold start emissions of gasoline cars showed larger polycyclic aromatic hydrocarbons than those from diesel cars. With diesel cars, there was also a significant influence of the biodiesel content on the product pattern. In general, at higher desorption temperatures the spectra are shifted to smaller molecules, which are formed by thermal decomposition of larger oligomeric and polymeric species, suggesting the possibility to learn more about the nature of such larger structures.

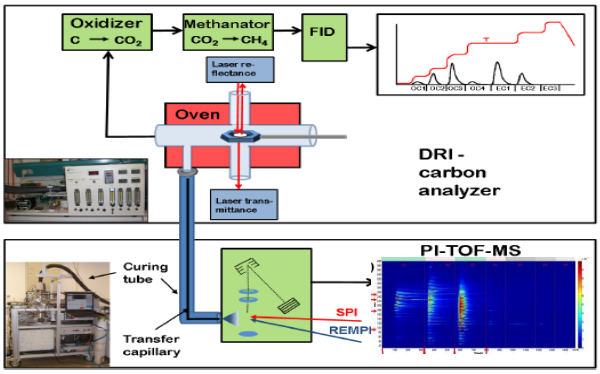

Figure 1: Experimental setup of the hyphenation between a thermal/optical carbon analyzer and photo-ionization mass spectrometry depicting a two-dimensional mass spectrometric pattern of a complete OC/EC analysis of diesel exhaust particles

Speciation at the molecular level is necessary to more fully understand the sources, sinks, transport and transformation of organic matter in the atmosphere. The thermal desorption aerosol gas chromatograph (TAG) is a mature instrument successfully deployed in five distinct field campaigns and offers a proven method for in-situ, hourly speciation of organic aerosols.

Multiple versions of this evolving instrument will be reviewed but all have in common the use of chemical separation using gas chromatography following thermal desorption. The first TAG to be deployed relied on inertial impaction to collect particulates and filter blanks to estimate vapour adsorption. Figure 1 illustrates the ability to acquire hourly time series of useful aerosol markers (primary norhopane and secondary phthalic acid) in the LA basin as part of the SOAR campaign (Williams et al., 2010). A subsequent deployment in the California Sierra Foothills (Worton et al., 2011) provided important information about the interaction of biogenic primary gases with anthropogenic pollutants that dominates secondary organic aerosol production.

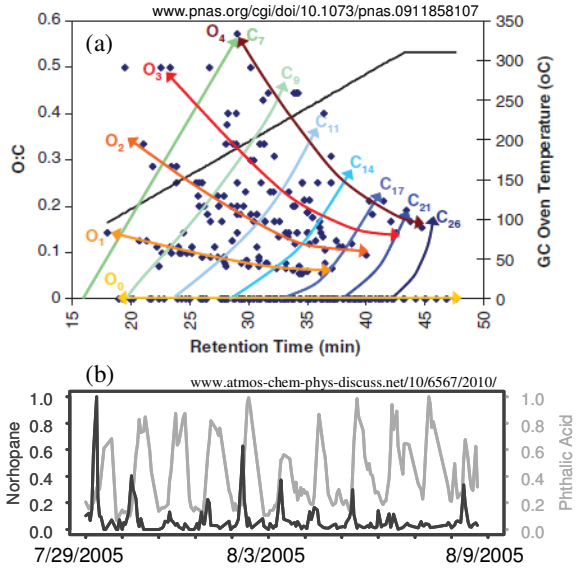

Figure 1. (a) O:C ratio, carbon and oxygen numbers vs. volatility as indicated by column retention time for ~300 compounds and (b) time series of representative source markers as measured in Riverside, CA in 2005.

To measure semi-volatile organics, which are important to secondary aerosol formation, a new version of the instrument has been developed to collect both particle and semi-volatile vapor phases (Zhao et al., 2013). Using a high efficiency carbon-based gas phase denuder and a new collection system with a reusable metal-fiber filter, alternate samples with and without the denuder provide direct partitioning measurements of organic compounds.

A parallel development has focussed on adapting the TAG instrument to function as a parallel collection system to be added to the Aerodyne Aerosol Mass Spectrometer (AMS; Canagaratna et al., 2007). This hybrid instrument (Williams et al., 2013) shares a detector to provide simultaneous size-dependent bulk and speciated organic aerosol information in one instrument. Comparing measurements from these separate instruments has proven the utility of being able to identify individual marker species corresponding to traditional AMS organic classes based on oxygen to carbon ratios such as HOA, OOA etc. (Williams et al., 2010; Worton et al., 2011).

Current efforts are directed towards expanding the range of compounds that can be analysed using in-situ derivatization of highly polar species. A dual cell version of the semi-volatile oriented instrument for initial deployment as part of a southeast US summer of 2013 field campaign seeks to ascertain the origin and fate of the large secondary organic aerosol levels present throughout the region. The paired filter cells provide simultaneous collection of denuded and undenuded aerosol streams for unique hourly measurements of derivatized SOA markers stemming from the oxidation of isoprene and other (bio-)anthropo-genic precursors.

Presenting author email: snt@iitk.ac.in

Aerosols are ubiquitous in Earth's atmosphere and their interactions with clouds via activation of cloud condensation nuclei (CCN) constitute the largest uncertainty in climate forcing. Nucleation (as a result of gas-to-particle conversion) is a predominant source of new particles in the atmosphere and thus is an important process that controls aerosol and cloud abundance.

New particle formation (NPF) occurs nearly everywhere in the Earth's atmosphere [Kulmala et al., 2004]. A variety of species may contribute to nucleation and growth processes, such as sulfuric acid (H_2SO_4) [Kuang et al., 2008], ammonia (NH_3) [Ball et al., 1999], amines [Yu et al., 2011], organic acids [Metzger et al., 2010], and ion clusters [Yu, 2010]. Previous field study by Boy et al. [2008] reported ~15% contribution of ion-assisted nucleation to NPF in the boundary layer in Hyytiälä, Finland. On the contrary, modeling approach including the association of ion–ion recombination to neutral clusters showed 100% contribution of ion–mediated nucleation (IMN) to NPF in Hyytiälä [Yu and Turco, 2008]. A recent cloud chamber study revealed that ion-assisted nucleation contribution to the boundary layer NPF is negligible but is nevertheless taking place [Kirkby et al., 2011].

We conducted measurements of particle size distributions in an Indian tropical boundary layer during March 20–May 23, 2012. Eighteen regional NPF events were observed, all of these likely occurred under the influence of transported anthropogenic plumes. We used particle growth and nucleation (PARGAN) model to calculate total particle nucleation rate (J_1) from the measured particle size distributions along with aerosol microphysics box model [Kanawade and Tripathi, 2006] incorporated with binary homogeneous nucleation (BHN) [Vehkamaki et al., 2002], ion-induced nucleation (IIN) [Modgil et al., 2005] and IMN [Yu, 2010] schemes to simulate observed NPF events. The aerosol microphysical model simulations revealed that none of these nucleation mechanisms could explain NPF solely, suggesting that two or more processes occurring simultaneously. The other nucleation mechanisms, involving species such as NH_3 or organics, may be crucial in the boundary layer NPF but these were not possible to examine. For example, NH_3 concentrations in such heavily polluted environment vary from ~3 to 42 ppbv (Singh and Kulshrestha, 2012), which exceeds the limit currently treated in the ternary homogeneous nucleation (THN) parameterization.

Our simulations further indicated that ion-induced and –mediated nucleation could be an important contributor to NPF at this location whereas BHN failed to explain NPF at all. The median contributions of IIN and IMN were about 28% and 87%, respectively . These results demonstrate the importance of ion-assisted nucleation to the tropical boundary layer NPF.

The role of sulphuric acid in the formation of atmospheric particles based on a long-term explicit modelling approach

M. Boy[1], L. Zhou[1], D. Mogensen[1], A. Sogachev[2] and S. Smolander[1]

[1]Department of Physics, University of Helsinki, Helsinki, P.O. Box 48 FI-00014, Finland

Keywords: new particle formation, long-term, boundary layer, modelling
Presenting author email: michael.boy@helsinki.fi

The role of atmospheric aerosols is perhaps the largest unknown concerning our climate and greenhouse warming. New particle formation has been observed at almost all sites, where particle size distributions have been measured (Kulmala et al., 2004). Although many field campaigns, laboratory experiments and new modelling approaches have led to increased understanding, detailed mechanisms responsible for the formation of new particles in the troposphere have still not been completely elucidated. One of the most controversial topics is the role or importance of sulphuric acid in the formation process.

In this study we present results achieved by SOSA (Boy et al., 2011). This model was developed at the University of Helsinki. The meteorology is based on a 1-D version of the model SCADIS (Sogachev et al., 2002) and the Model for Emissions of Gases and Aerosols in Nature (MEGAN) is used to simulate the emission of organic vapours from the biosphere (Guenther et al., 2006). The gas phase chemistry is solved with the Kinetic Pre-Processor (KPP) in combination with the Master Chemical Mechanism from the University of Leeds. It is a parallelized model operating on a high-performance super-cluster at the CSC - IT Centre for Science in Finland, which gives the possibility to run detailed processes in chemistry, aerosol dynamic and meteorology over long periods with reasonable model runtime.

We will present different model results for 10 years of simulations (2003-2012) and comparison with measurements. Our aim is to demonstrate the role of sulphuric acid when considering the question: What are the crucial molecules for new particle formation in the atmosphere?

One possible way to get some hints to solve this question is the use of long-term comparisons between different parameters simulated with the new model SOSA and the frequency of particle formation events (Boy et al., 2002). In this context we calculated different combinations of parameters like e.g. RP-1:

$$RP-1 = \frac{[H_2SO_4]}{CS}$$

This equation gives the concentration of sulphuric acid divided by the condensation sink of the pre-existing aerosols. Figure 1 presents the number of event days in three different classes (Boy et al., 2002) and the amount of days per month where the daytime (9-15) mean value exceed the mean value by 0, 10, 25 %, respectively.

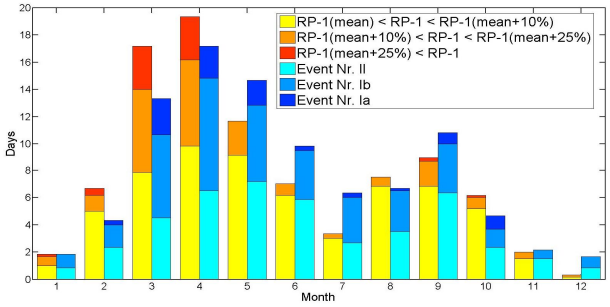

Figure 1: Monthly trend for RP-1 and observed frequency of nucleation event days

The figure shows a clear correlation in monthly distribution between sulphuric acid and nucleation event frequency. Including the monoterpenes, temperature and water vapour into the equation shifts the distribution more towards the summer months but also decrease the amount of days during the second observed event peak in autumn.

Hydration of Sulfuric Acid Clusters and the Impact of Bases

H. Henschel[1], I. K. Ortega[1], O. Kupiainen[1], T. Olenius[1], T. Kurtén[2] and H. Vehkamäki[1]

[1]Division of Atmospheric Sciences, Department of Physics, P.O. Box 64, 00014 University of Helsinki, Finland
[2]Laboratory of Physical Chemistry, Department of Chemistry, P.O. Box 64, 00014 University of Helsinki, Finland
Keywords: sulfuric acid, ammonia, water, quantum chemistry, nucleation.
Presenting author email: henning.henschel@helsinki.fi

The formation of new particles in the atmosphere is generally agreed to involve sulfuric acid and water. However, it is known that these alone can not explain the observed particle formation rates. Therefore, other substances must be invoved in the process. One substance known to enhance the formation rate is ammonia, though not either this can fully explain the observed rates.

An important goup of substances that could explain the elevated nucleation rates are amines. Especially dimethylamine has been found to be involved in particle formation events (Mäkelä, 2001).

We present here a study of the hydration of clusters formed by sulfuric acid, and sulfuric acid together with ammonia and dimethylamine, respectively.

Clusters containing up to four molecules of sulfuric acid with up to three molecules of ammonia or diemthylamine together with up to five water molecules were modelled using a RICC2/aug-cc-pVTZ//B3LYP /CBSB7 level of theory. Based on these results the realtive populations of the repsective hydrates were simulated for different relative humidities.

Clusters consisting only of sulfuric acid form in general stable hydrates with an increasing energy of hydration with increasing number of sulfuric acid molecules. Only in case of the cluster containing four molecules of sulfuric acid one hydrate was found to be considerably more stable than would be expected from the trend in energies. Consequently this hydrate is also predominantly populated over a wide range of relative humidities.

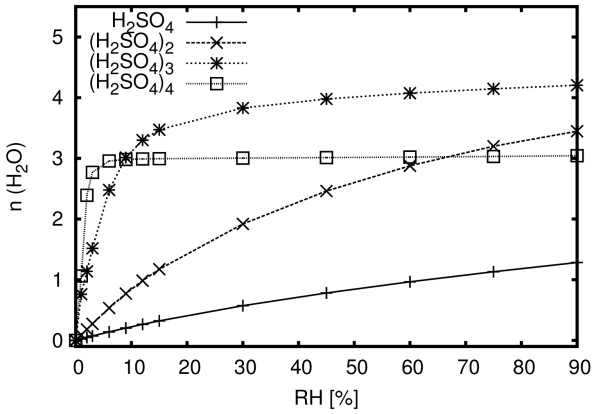

Figure 1. Hydration profiles for sulfuric acid clusters.

The resulting average hydration of clusters containing no base can be found in Fig. 1.
For systems containing both sulfuric acid and ammonia in general smaller hydration energies were found as compared to the base free system. Also, these systems do not exhibit broad distribution of hydration energies as the systems containing only acid, and show average hydration umbers between approximately 1.5 and 2.5 for relative humidity approaching 100 %.

Clusters containing both sulfuric acid and dimethylamine show an even lower affinity for water. For all clusters studied, the energy for at least one hydration step has been found to be positive. In case of the cluster consisting of two molecules of sulfuric acid and dimethylamine, all hydration energies were positive. Consequently, the average hydration of the dimethylamine-containing clusters is lower than for the other systems (cf. Fig. 2).

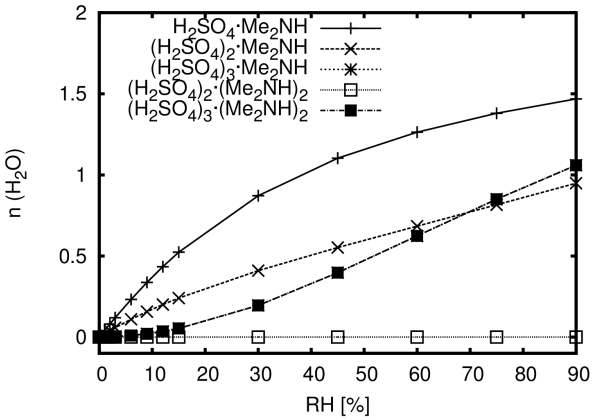

Figure 2. Hydration profiles for clusters containing sulfuric acid and dimethylamine.

At the same time, the profiles of the average hydrations of these clusters are not as uniform as for the other systems studied.

The observed differences in the hydration profiles will clearly have consequences on new-particle formation. Due to the differences in stability of certain hydrates, pathways towards particle formation can both become more and less likely, potentially altering the importance of different factors for the overall process significantly.

Simulations of SOA formation from alpha-pinene ozonolysis and photo-oxidation in chamber experiments

G. Capes[1], D. Lowe[1], G. McFiggans[1]

[1]Centre For Atmospheric Science, University of Manchester, Manchester, M13 9PL, U.K.
Keywords: SOA, chamber, MCM, alpha-pinene.
Presenting author email: gerard.capes@manchester.ac.uk

Model description

We present here simulations of secondary organic aerosol formation from ozonolysis and photo-oxidation of alpha-pinene in a smog chamber. Simulations were performed using the MANIC model (Lowe et al., 2009), which uses gaseous VOC photochemistry from the MCM (Jenkin et al., 1997; Saunders et al., 2003) coupled to aerosol microphysics through mass transfer driven by Raoult's Law using predicted vapour pressures. The aerosol size distribution and size-resolved composition are represented by 16 size bins, which can use either moving-centre or moving-grid numerical schemes to follow particle growth.

Results

Two nucleation (i.e. unseeded) test cases will be presented:

1. ozonolysis of 100 ppb alpha-pinene by 135 ppb ozone, in the absence of NOx. This experiment was performed in the EUPHORE chamber, and is taken from Jenkin et al. (2004). Measurements of ozone, alpha-pinene and aerosol mass are compared with model output.

2. photo-oxidation of 55 ppb alpha-pinene, with initial concentrations 15 ppb NO2, 3 ppb NO and no ozone. This experiment was performed in the University of Manchester aerosol chamber, and measurements of NO, NO2, O3 and aerosol concentration are compared with the simulated quantities.

In both test cases, simulated aerosol mass concentrations reproduced measured aerosol mass concentrations to within a factor of 5, without the need to tune vapour pressures. Aerosol nucleation rate was tuned to the measured number concentration, and wall loss rates were also derived from the measured aerosol number distributions (Verheggen et al., 2006).

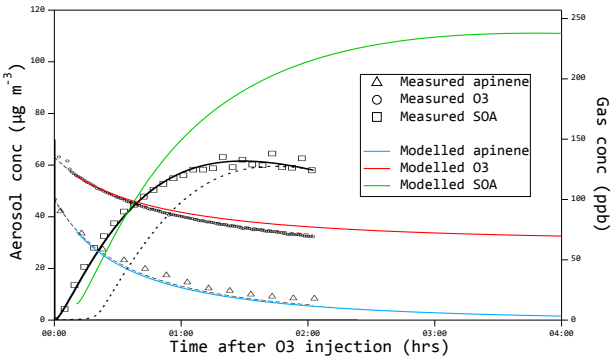

Figure 1: Preliminary results from the ozonolysis simulation. SOA mass is over-predicted by a factor of two.

Effects of electric vehicles on air quality in street canyons

T. Schöllnhammer[1], F. Lommes[2], T. Schulz[3], H. Hebbinghaus[3], and S. Wurzler[3]

[1]Department of Civil and Environmental Engineering, Ruhr University Bochum, Bochum, Germany

[3]North Rhine Westphalia State Agency for Nature, Environment, and Consumer Protection, Recklinghausen, Germany
Keywords: electric vehicles, air quality, street canyon.
Presenting author email: sabine.wurzler@lanuv.nrw.de

Road traffic is one of the main causes of poor air quality in European cities. Electric vehicles (EV) are often presented as solution for air quality problems in cities. In addition they are claimed to be a climate friendly means of transport owing to their non-existent exhaust emissions. The German government has formulated the ambitious goal to increase the amount of electric vehicles in Germany to 1 million in 2020 and 6 million in 2030. The aim of this paper is to investigate how much of this claim is true. While traffic is a major source of air pollutants in street canyons, it is often forgotten that electricity production nowadays is a significant source of air pollutants on the regional scale.

Focus of the present study is the air quality in street canyons, to be more precise the PM10 and NO_2 concentrations. We concentrate our investigation on road traffic, taking the fleet composition into account. We have investigated the following questions:

- Is the goal of the German government effective with regard to an improvement of the air quality?
- What share of electric vehicles would be needed to
a) significantly reduce the annual immission load (5 µg/m³ for NO_2 and 3 µg/m³ for PM10)?
b) comply with the EC limit values?
- Which vehicle type is most promising with regard to an efficient immission reduction? E.g., passenger cars? Busses? Heavy duty vehicles?
- What is the impact of the reduced traffic emissions on the regional background concentration of PM10 and NO_2?
- How much electricity is consumed by the vehicles? What is the resulting effect on power plant emissions?

We present results for two street canyons in Germany with moderate EC air quality limit value exceedances: Gladbecker Street in Essen, and Friedrich-Ebert-Street in Mönchengladbach. The air quality analyses were carried out using the canyon plume box model Immis^{Luft} for the contribution of local traffic, combined with field observations of air quality and model results of the chemical transport model EURAD (Memmesheimer et al., 2004). The change in power plant emissions was estimated based on the emission inventory of LANUV NRW. The energy consumption by the vehicles was estimated based on values from the recent literature, such as product information (Schöllnhammer, 2012).

As already mentioned the German government wants to increase the amount of electric vehicles in Germany. An example of the effects of this program on the air quality is shown in Table 1 for the annual average PM10 concentration. Reference year is 2009. We have assumed that the replacement of vehicles with combustion engines by electric vehicles would happen instantaneously. The proportion of electric vehicles in our street canyon was assumed to be the same as for the vehicle fleet in Germany. The findings are rather daunting for PM10, the results for NO_2 are somewhat better. The good news for these scenarios is that the effect of the increased electricity production on the regional air quality is leveled out by the emission reduction by the vehicle fleet on the regional scale.

Table 1: PM10 annual average concentration in µg/m³ in Friedrich-Ebert-Street for different scenarios: no electric vehicles (None), 1 or 6 million electric vehicles (EV) of the different vehicle types in Germany. HDV = heavy duty vehicles; LDV = light duty vehicles.

PM10 annual average concentration in µg/m³					
EV	None	Cars	HDV	Busses	LDV
1 mio.	29,6	29,6	29,5	29,4	29,6
6 mio.	29,6	29,4	29,5	29,4	29,6

One general finding of our study is that electric vehicles can reduce the NO_2 burden but are not the right measure to significantly influence the PM10 concentration in a street canyon. Only a minor share of the PM10 emissions is caused by vehicle exhaust. The lions share is produced by friction and abrasion processes. Those are present anyhow no matter of the engine type.

What amount of electric vehicles would be necessary to find a major impact on air quality will be addressed further in the presentation. The tradeoff between local emissions by the vehicles and the more regional emissions by the power plants will be critically discussed.

Remapping of aerosol emissions in a modal models as a source of error

T. Korhola[1], H. Kokkola[2], H. Korhonen[2], A.-I. Partanen[2], A. Laaksonen[1,3], S. Romakkaniemi[1]

[1] Department of Applied Physics, University of Eastern Finland, Finland

Presenting author email: tapani.korhola@uef.fi

Prescribed datasets for natural and anthropogenic aerosol emissions are widely used in global climate modelling. These inventories include i.a. recommendations for size distributions for emitted aerosol particles often given as parameters for log-normal modes. Most aerosol models use log-normal modes to describe the aerosol distributions. In these global models, the maximum mode diameter is often restricted due to technical reasons. These restrictions cause artificial minima in the model's aerosol size distribution at certain fixed sizes.

We have noticed that if the recommended mode diameters (Dentener *et al* 2006) in emission inventories are close to these artificial minimums, the model then remaps the emitted particles between two adjacent modes and never uses the actual emission distribution that is described in the inventories. In this work, we study how this affects the cloud droplet number concentration (CDNC) and aerosol-cloud interaction (ACI) parameter.

The simulations were done by using a box model, which allows the use of both free and restricted modes and a better control over physical, technical and statistical phenomena compared to a global model. The CDNC was calculated by using the Fountoukis and Nenes (2005) parametrization. The ACI was defined by

$$\mathrm{ACI} = \frac{d\log(\mathrm{CDNC})}{d\log \mathrm{N}}, \qquad (1)$$

where N is the total number concentration of the emitted (inventory based) aerosol. The ACI parameter fundamentally describes the sensitivity of droplet formation to aerosol distribution.

To study the effects of the mode size restrictions and the following remapping on the CDNC and ACI, we calculated both parameters with the unaltered emission size distribution recommended by the inventories and with the emissions that were forced under the global model restrictions. We did the same simulations with and without background aerosol.

The CDNC and ACI were evaluated as a function of N and vertical velocity of the cloud forming air parcel. Finally, we calculated the relative difference of these parameters between the unaltered and remapped emission.

The mode remapping effectively reallocates the mass and number concentration that exceeds the set upper diameter limit of a given mode (Binkowski and Roselle 2003). This reallocation decreases the mode average diameter and creates a new larger mode, or increases the number concentrations of pre-existing larger mode (Figure 1).

Our results show clearly that the mode remapping causes underestimation of both the CDNC (Figure 2) and ACI. The underestimation of the CDNC is most evident in the case with no background aerosol, where the relative difference is more more than 50 %. With the background aerosol, it is still more than 30 %. The underestimation due to remapping is because the critical diameter is smaller than the average diameter of the emission mode, but bigger than the smallest particles in the mode resulting from mode remapping. When the mode is remapped, significant number of the particles that would activate, are moved to a mode that is mostly below the critical diameter. For the same reason, as mentioned above, the ACI parameter shows stronger correlation between the unaltered emission and CDNC compared to the remapped emission. The underestimation of ACI by remapped emissions is up to 40 % with background and up to 20 % without background aerosol.

Depending on the emission inventories and aerosol models used, the widespread method of aerosol reallocation and mode remapping can cause a clear underestimation of cloud droplet number concentration and aerosol-cloud interaction parameter.

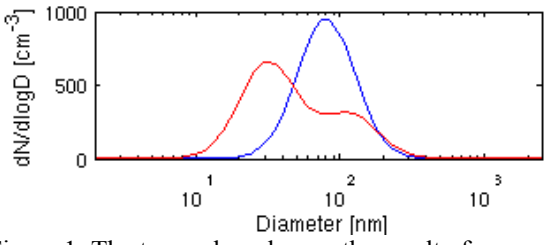

Figure 1: The two red modes are the result of remapped blue mode.

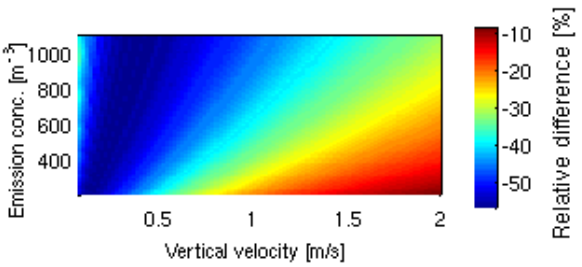

Figure 2: The relative difference between unaltered and remapped emission modes without background aerosol.

Impact of biogenic emissions on $PM_{2.5}$ concentration over Europe

E. Tagaris, R.E.P. Sotiropoulou, N. Gounaris, S. Andronopoulos and D. Vlachogiannis

Environmental Research Laboratory, NCSR Demokritos, Aghia Paraskevi Attikis, 15310 Athens, Greece
Keywords: biogenic emissions, particulate matter, Europe
Presenting author email: tagaris@ipta.demokritos.gr

Natural and biogenic emissions are contributing to atmospheric pollution in addition to anthropogenic emissions. Over 90% of the total Volatile Organic Compounds (VOCs) entering the atmosphere are biogenic (Greenberg et al., 1999), having an important role in regulating the atmospheric composition. The impact of both anthropogenic and biogenic emissions on air quality is very important, as only the anthropogenic part can be influenced by abatement measures. Curci et al. (2009) estimated that biogenic VOC emissions increased on average summer daily ozone maxima over Europe by 5% (2.5 ppbv) using the CHIMERE chemistry-transport model. Sartelet et al. (2012) using the Polyphemus air quality modeling platform estimated that ozone decreased by 10-11% on average over Europe (locally up to 35%) while secondary organic aerosols decreased by 72-88% when removing biogenic emissions. The objective of this study is to estimate the effect of biogenic emissions on $PM_{2.5}$ concentration and chemical composition over Europe.

Meteorological fields are derived using the Penn State/NCAR Mesoscale Model (MM5) (Grell et al., 1994).

Emissions are processed by the Sparse Matrix Operator Kernel Emissions (SMOKE v2.6) Modeling System (http://www.smoke-model.org). The TNO gridded anthropogenic emissions inventory for the year 2006 over Europe in a 0.1 × 0.1 degrees resolution (ftp://neptunus.tno.nl) is used. The Biogenic Emission Inventory System, version 3 (BEIS3) is used for processing biogenic source emissions (http://www.epa.gov/asmdnerl/biogen.html) using the USGS gridded land use data in 1 Km resolution (http://edc2.usgs.gov/glcc/glcc.php).

The Community Multiscale Air Quality (CMAQ v 4.7) Modeling System with the Carbon Bond mechanism (CB05) (http://www.camx.com/publ/pdfs/CB05_Final_Report_120805.pdf) is used for the regional air quality modeling (177 × 217 grid cells of 35 km × 35 km, with 14 vertical layers) (Byun et al., 2006).

$PM_{2.5}$ concentrations are simulated with and without biogenic emissions for July, 2006. The effect of the addition of biogenic emissions to anthropogenic ones is computed to reduce the average monthly mean $PM_{2.5}$ concentration over European land by 2% with both positive and negative responses regionally (Fig. 1). The addition of biogenic emissions increases the average monthly mean organic carbon concentration by 14% (Fig. 2) and decreases the monthly mean inorganic component concentrations (SO_4: -6%, NO_3: -4%, and NH_4: -6% on average) due to the reduction in oxidant levels (OH: -30% on average). However, regional changes in inorganic concentrations with both positive and negative responses are simulated.

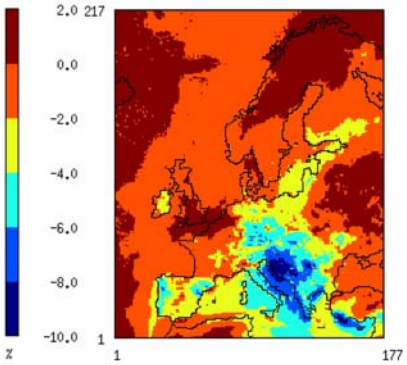

Fig. 1: Average change in $PM_{2.5}$ concentration (%) for July 2006 when biogenic emissions are added to anthropogenic emissions

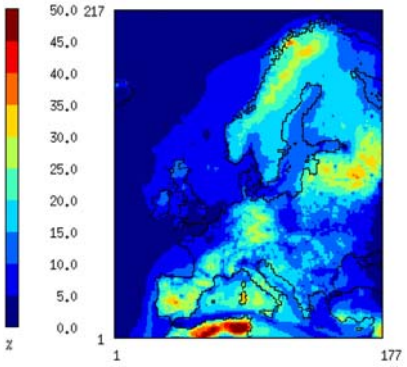

Fig. 2: Average change in OC concentration (%) for July 2006 when biogenic emissions are added to anthropogenic emissions

Session: Combustion Aerosols,
Characterization methods of combustion aerosols

Automatized determination of the primary particles size of soot aggregates by TEM image analysis

A. Bescond[1], J. Yon[1], C. Rozé[1] and F. X. Ouf[2]

[1]UMR 6614 CORIA, Avenue de l'université, 76801 Saint-Etienne du Rouvray, France
[2]Institut de Radioprotection et de Sureté Nucléaire (IRSN), 91192 Gif-sur-Yvette Cedex, France
Keywords: soot, morphology, TEM, EDM.
Email: alexandre.bescond@coria.fr

The needs for reference methods to analyse the physico-chemical properties of combustion aerosol have been of rising concern of the scientific community over the last three decades. The morphological characterization of soot aggregate is possible by analysing images obtained by Transmission Electron Microscopy (TEM). Indeed, it is shown that maximum projected length is related to the gyration radius size parameter. The 3D number of primary spheres in the aggregate can also be determined from the measurement of the particle projected area. Finally, these parameters are linked by a power law that permits to determine the soot fractal dimension (Brasil, et al., 1999; Köylü, et al., 1995). These measurements can be achieved automatically over a set of numerous TEM images in order to determine statistically the fractal dimension. However, the size of the primary particles is also needed and the classical method for determine it from TEM pictures is manual, time consuming and tedious.

Recently, an automatized method based on the Hough transform has been proposed in order to determine the primary particle size (Bradski and Kaehler, 2008). Here, we present another approach based on the Euclidian Distance Mapping (EDM) method which is robust, rapid and easy to implement. Indeed, EDM is often used to characterize the morphology of complexes objects as human cells (Ballerini and Franzen, 2001) or atomizing liquid flows (Grout, et al., 2007). In addition to its ability to determine the size of primary spherules, this method is promising to inform us of the fractal dimension of the particles.

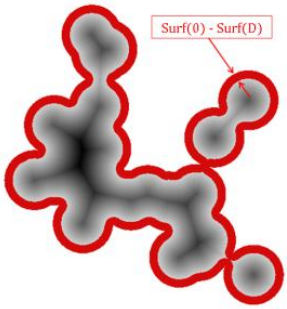

Figure 1. Illustration of the EDM method

The EDM analysis permits to determine, for each position in the image, the smallest distance to the border of the particle. This distance is represented in gray levels in figure 1. The more the Euclidian distance is, the more the gray level is dark. From this EDM map, we define a surface $S(D)$ corresponding to the part of the aggregate whose distance to the border is less than D, a scaling parameter. This surface is illustrated in red in figure 1. A dimensionless function ranging from 0 to 1 is finally defined:

$$S(D) = 1 - Surf(D)/Surf(0)$$

This function is established over a set of images of virtual aggregates generated by a DLCA (Diffusion Limited Cluster Aggregation) code (Meakin, 1999). The interest of this numerical investigation is to control the primary particle size (mode and standard deviation).

The Figure 2 presents the $S(D)$ functions determined for aggregates made of different sizes of primary particles. For each case, 200 aggregates whose number of primary spheres ranges from 10 to 60 are considered. In case of monodisperse primary particles, the representation of $S(D)$ as a function of D is shown to indicate that primary particle size can be determined easily from EDM analysis.

Based on different sets of DLCA aggregates, the way to determine simultaneously the primary spheres mean diameter and standard deviation is discussed.

After all, the EDM method is applied to TEM pictures coming from thermophoretic sampling of real soot aggregates of ethylene diffusion flame and CAST5201© generator.

Electrical Conductivity Measurements in Combination with Raman Microspectroscopy and Temperature Programmed Oxidation for Analysis of Microstructure and Reactivity of Soot

B. Grob[1], F. Knoller[1], N. P. Ivleva[1], R. Niessner[1]

[1]Chair for Analytical Chemistry, Technical University of Munich, Munich, 81377, Germany
Keywords: electrical conductivity, Raman microscopy, temperature programmed oxidation, soot reactivity, real-time detection
Presenting author email: benedikt.grob@mytum.de

Soot particles emitted by diesel engines are a well known problem especially in urban areas due to their influence on the human health but they can have a significant influence on the climate as well. Therefore the emission regulations for light and heavy duty vehicles prescribe a strict limit of diesel soot particle emission. This can only be accomplished by diesel particle filters (DPF). To control the back pressure of this filters a continuous or periodically gasification of the deposited particles is necessary. The efficiency of this regeneration step is mainly affected by the oxidation behaviour of the soot, which is directly connected to its microstructure.

To optimize the engine in the way that they produce highly reactive soot, tools are required to analyse soot samples regarding their oxidation behaviour. Currently, the temperature controlled oxidation of soot samples is used as a common method for engine optimization. But as we could show in early publications Raman microspectroscopy as well as the electrical conductivity measurement are a promissing tool for soot microstructure characterization (Schmid 2011 & Grob 2012) Especially the conductometric measurement method is very attractive, because it is a simple, rapid and cheap tool compared to the other techniques. So far we could show in basic experiments the possibilities and the limitations of this method (Grob 2012).

Our approach is now to develop a device which makes it possible to investigate the influence of the microstructure and the oxidation behaviour of soot on the electrical conductivity combined with the monitoring of the processes by the Raman microspectroscopy (RM) and the temperature programmed oxidation in one setup. Therefore we developed a flowcell (Fig. 1) which can be heated up to 1273 K and can be placed under the Raman microscope, due to a good isolation and a effective cooling of the cell frame. Through a quartz glass window it is possible to observe the soot layer on the conductometric sensor (Fig. 2) inside the cell. On the outlet of the cell a FTIR can be plugged as a gas detector of the controlled oxidation. The soot particles are collected by a thermophoretic particle precipitator on the conductometric sensor surface, which consists of a oxidized silicon substrate with interdigitated AlSiCu electrodes on it.

The setup allows us to change the graphitization of a soot sample under controlled atmosphere. By cooling down the sample under protective gas atmosphere in the same device a contamination or further oxidation of the sample can be prohibited. In the second step the measurement of the electrical conductivty of the sample follows and can be correlated with the fingerprint spectra of the RM provided through the window of the cell.

So far the conductometric sensor principle is only used for on board particle detection to monitor the DPF in light duty vehicles. We hope that we are able to extend the use of the principle by this experminental setup for soot microstructure and reactivity analysis.

The soot particle aerosol mass spectrometer (SP-AMS) instrument, recently developed by Aerodyne Research, Inc., combines the ability to measure the mass and chemical composition of size-resolved particulate matter, including refractory black carbon components (Onasch et al. 2012). This instrument was developed to address the issue that refractory black carbon-containing particles formed in incomplete combustion processes are strong light-absorbers with significant climate forcing impacts and potential health effects. The complex nature of these particles makes their characterization (microphysical, chemical and optical) challenging. The SP-AMS technique represents a new method for characterizing and quantifying the chemical and physical properties of particulate refractory black carbon. Using the SP-AMS, we have participated in a growing number of laboratory studies and field campaigns to characterize refractory black carbon-containing particles from a range of sources and over a range of atmospheric aging. We will present selected highlights from these studies.

The SP-AMS is equipped with an intracavity Nd:YAG CW laser vaporizer (1064 nm). Only light absorbing particles, such as refractory black carbon containing particles, will vaporize in the laser beam. Both the nonrefractory and refractory components are vaporized. Particulate vapors are ionized by electron ionization (70 eV) and detected with high resolution time-of-flight mass spectrometry. The SP-AMS can be operated with or without a resistively heated (600^{o}C) tungsten vaporizer; with both vaporizers, the SP-AMS measures all refractory and non-refractory particles.

Laboratory results have focused on characterizing the chemical and physical properties of laboratory-based flame soot and manufactured refractory black carbon particles as a function of coating with organic compounds and sulfuric acid and thermal denuding (Eben S. Cross et al. 2010). These studies have provided the foundation for using the SP-AMS instrument to constrain measurements of the optical properties of ambient soot particles, specifically relating to the absorption enhancement due to atmospheric aging.

In addition, we are characterizing the carbon ion distributions generated by different refractory black carbon particle types. These mass spectral signatures may provide unique information on different types of refractory black carbon sources. Figure 1 shows five carbon ion mass spectra for laboratory and field measured rBC particle types and illustrates a trend towards larger carbon clusters.

The field measurements conducted include biomass burning (FLAME3), flare emissions (Fortner et al. 2012) internal combustion engine sources (Massoli et al. 2012; Cross et al. 2012; NYC, MIT Engine Lab, and Caldecott Tunnel), and urban environments (Cappa et al. 2012; CalNex 2010 and ClearfLo 2012). Mass spectral features and size distribution results for several field deployments will be presented with emphasis on source characterization and the characterization of the chemical and physical changes that rBC particles undergo as a function of atmospheric aging.

Keywords: combustion aerosol, on-line mass spectrometry, aromatic compounds, ship diesel-/wood-combustion

Polycyclic aromatic hydrocarbons (PAH) and benzene derivatives represent important compound classes, present in combustion aerosols. On the one hand, PAH and their derivatives are known to be of high health relevance (chronic and acute lung and cardiovascular diseases). On the other hand, the signatures of the aromatic molecules in combustion aerosols characterize the combustion process and allows conclusion on the molecular formation mechanisms of soot and other pyrolysis and combustion by-products. Photoionisation mass spectrometry is an ideal approach for on-line-detection of the molecular signature of combustion aerosols. When the laser based resonance-enhanced multiphoton ionization method (REMPI) and a time-of-flight mass analyser (TOFMS) are used, unsurpassed sensitivities (ppb/ppt) and time resolutions (sub-second) are achieved for detection of aromatic molecular species. In Fig. 1A an on-line measured REMPI-TOFMS mass spectrum of wood combustion aerosol is depicted. The

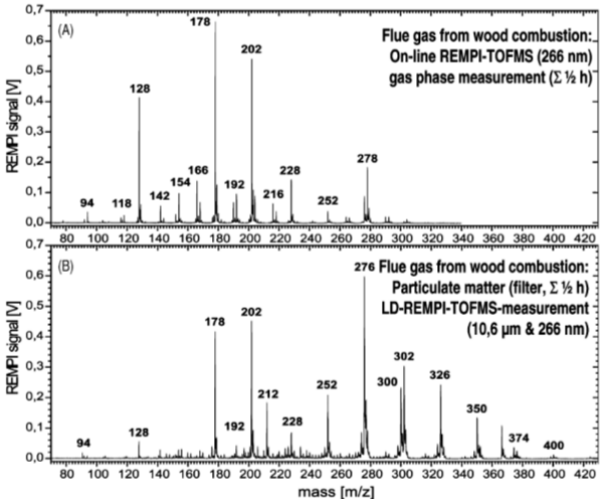

*Figure 1) REMPI mass spectra of **wood combustion aerosol** A) Signal of the aromatic compounds in the **gas phase** of a wood combustion experiments: more volatile aromatics are detected B) Laser desorption-REMPI mass spectrum of the aromatic compounds from the **particulate phase** (collected simultaneously to measurement of A): larger PAH are observed*

selectivity of the REMPI ionisation for aromatic compounds allows a straight-forward assignation of the observed mass peaks in the mass spectrum (e.g. for Fig. 1A: 94 m/z-phenol, 118 m/z-indane, 128 m/z-naphthalene, 166 m/z-fluorene, 178 m/z-phenanthrene, 202 m/z-pyrene, 228 m/z-chrysene, 252 m/z-5-ring PAH including Benz[a]pyrene, 278 m/z 6-ring-PAH). By

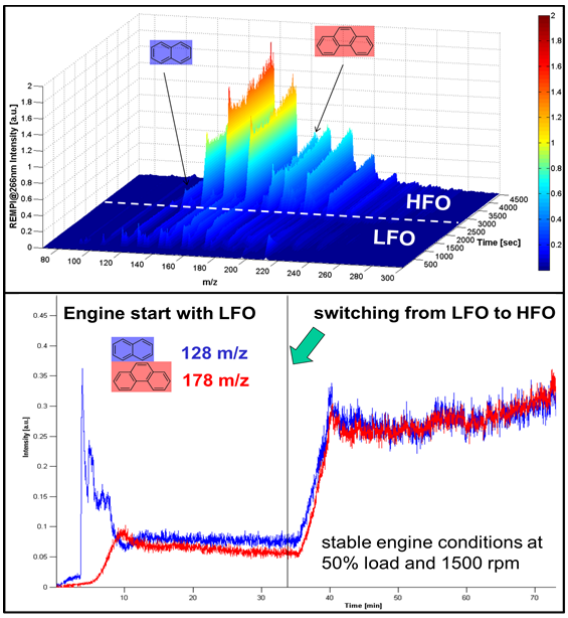

*Figure 2 On-line measurement of the gas-phase aromatics (PAH and alkylated-PAH) in combustion aerosol from a **ship diesel engine** operated with distillate fuel (light fuel oil, LFO) and residual fuel (heavy fuel oil, HFO) top) 3D-representation of the changes in aromatic REMPI mass spectral signature over time during a switch from "clean"LFO -fuel to"dirty" HFO-fuel. The lower part of the figure depicts the time-intensity curves for 2 selected PAH, naphthalene and phenanthrene.,*

using laser desorption (LD, e.g. direct from PM on filter) also the particle-bound aromatics can be rapidly analysed (Fig. 1B). It is obvious from Fig. 1 that the larger PAH are predominately particle bound.
During the HICE campaign at a ship diesel engine test bench, REMPI-TOFMS was used to follow the switch from LFO to HFO fuel in real time (Fig. 2). During the engine-start period, the large ship diesel engines are operated with LFO. The HFO fuel (melting point ~ 60 °C) is only introduced when the engine is at operational temperature. Fig. 2 shows clearly, that the emission of aromatic compounds, including the toxic polyaromatics, is increased significantly after the transition to HFO. The PM from ship diesel and wood combustion aerosol was furthermore investigated by a new coupling of an EC/OC-thermal analyser to a REMPI-TOFMS system, showing the aromatic signature of different thermal steps in the thermo-optical EC/OC measurement.

Keywords: absorption, black carbon, brown carbon, optical properties
Presenting author email: claudia.linke@kit.edu

In urban environments carbonaceous aerosols have serious impact on air quality and therfore on human health. Moreover due to their strong absorption properties in the visible spectral region they directly contribute to radiative forcing on regional and global scales.

In spite of various analytical and/or optical methods the accurate determination of atmospheric burdens by carbonaceous aerosol is still challenging (Cavalli et al., 2010, Lack et al., 2008).

In a combined laboratory and field study we characterised the spectral light absorption properties of soot with a single cavity multi wavelength photoacoustic spectrometer. During laboratory experiments we studied artificially generated combustion soot (mini-CAST) of increasing organic content. Therefore the burning conditions were stepwise changed towards more and more incomplete combustion (Schnaiter et al., 2006). From these experiments we can show that different burning conditions correlate to different wavelength dependencies of the measured absorption coefficients. Moreover, absorption cross sections were independently calculated from off-line filter measurements analysed by Sunset EC/OC.

Table 1. Absorption cross sections (ACS) of CAST soot for different burning conditions and for a wavelength of 532nm

CAST soot C/O ratio	ACS from PAS and EC (m2/g)	ACS from PAS and TC (m2/g)
0.29 (35%EC,65%OC)	14.5 ±1.6	5.4 ±0.4
0.4 (10%EC,90%OC)	18.6 ±4.2	1.6 ±0.1

For the first time we operated the multi-wavelength photoacoustic spectrometer during an urban field campaign (AIDA mobil urban) in autumn 2012 at Durlacher Tor in Karlsruhe, Germany. At that time, the measurement site was characterised by intense road works (construction of subway tube) and high traffic volume. In combination with concurrently determined refractory black carbon mass concentrations from a single particle soot photometer (SP-2), we derived absorption cross sections for the three photoacoustic wavelengths.

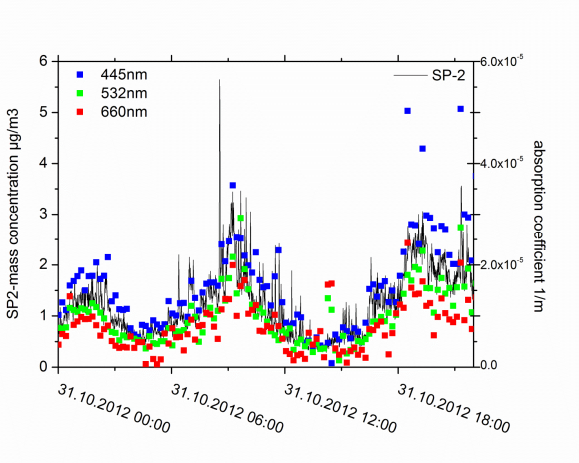

Figure 1. Diurnal variations of incandescence derived refractory BC mass concentration (SP-2) and photoacoustic absorption coefficients in the blue, green and red wavelength range during the field campaign at Durlacher Tor, Karlsruhe, Germany, in autumn 2012

It is widely accepted that combustion derived particulate matter (PM) is related to adverse health effects in humans. However, it is still unclear, what is the mechanism behind these effects, and which properties of the PM (size, shape, chemical composition, surface properties) besides of mass concentration are relevant (Mills et al. 2009). Therefore, detailed analyses of the PM properties are needed.

Density is a fundamental property of particles, and by one definition, links the particle mass m_p and mobility diameter in relation of

$$\rho_{ef} = \frac{m_p}{\frac{\pi}{6} d_{el}^3}$$

Density is also the link between electrical mobility diameter d_{el} and aerodynamic diameter d_{ae}, which enables measurements with impactors and classifiers to be compared. However, errors in determination of particle size arise as particles deviate from ideal spheres with standard density. One of the key properties in particle sizing is the fractal dimension D_f,

$$\rho_{ef} = D' d_{el}^{D_f - 3},$$

where D' = constant and D_f = mass related fractal dimension (Park *et al.*, 2003). Combustion derived soot agglomerates, readily found in atmospheric samples, are a typical example of non-standard, fractal particles that are shown to have significant role in particle mediated health issues.

In this study, we compared experimental results as follows: the effective densities ρ_{ef} of particles in various size fractions (<1 µm) from i) different biomass grate combustion situations (Torvela et al. 2011), ii) biomass gasification combustion experiments (Nuutinen et al. 2010) and iii) synthesis of TiO_2 nanoparticle (Backman et al. 2009). An APM-SMPS method was applied to determine effective densities of particles.

In Fig. 1 the measured effective densities are shown as function of d_{el}. According to the equation above, the slope of these graphs is related to the fractal dimensions of those particles.

The effective density was found to be connected with the source of the particles and with combustion conditions. In biomass combustion a relatively small change in the combustion conditions (air staging and fuel feeding) caused significant differences to ρ_{ef}, even for particles of approximately same mobility diameter. This was due to differences in both chemical composition and morphological properties of the particles, observed by single particle analyses by TEM.

The fractal dimension was not constant for the smallest particles in Fig 1 (slope of the graph). However, larger particles seem to have a clear fractal structure (close to constant D_f).

As a conclusion, no single value can be used for effective density of biomass combustion particles. Rather, effective density should be determined for each particle type separately.

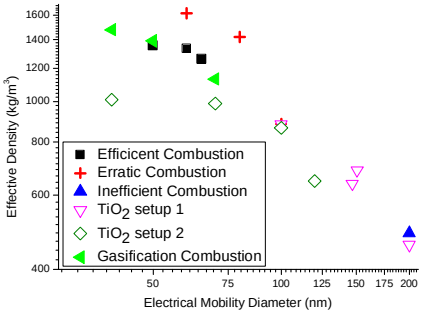

Figure 1. Effective density of particles from biomass combustion (Efficient: low CO-emission, Erratic: elevated CO and Inefficient: high CO), gasification combustion and TiO_2 particles in log-log graph.

Residential biomass combustion is known to be a significant source of particulate matter (PM) in regions where it is in common use. Sampling of fine particles from residential combustion appliances is of great significance because of a need to create standards for particulate emission measurements. Small-scale biomass combustion sources often emit fine particles that contain substantial amounts of organic compounds that condense at relatively low temperatures. Sampling procedures, such as temperature control and dilution ratio (DR), are known to affect sampled particles, especially as concerns their organic constituent (Lipsky et al. 2006). The aim of this study was to identify the effect of DR on fine particles, and to study the use of porous tube diluter in this type of measurements.

Batch combustion appliance with simple combustion technology, a sauna stove, was used in the experiments. Sampling of flue gases was done with a setup of porous tube and ejector diluters (Tissari et al. 2007). Three different DRs, 15, 40 and 115, were used. DRs were controlled with simultaneous CO_2 concentration measurements in the flue gas and in the diluted sample gas. Two similar dilution and sampling systems were operated during each measurement at different DRs. This ensured that the samples were comparable even if the combustion process varied slightly between each individual experiment, which is often present in batch-combustion process.

Overall, only a minor effect of DR on sampled PM mass was observed in the experiments. As expected, the smallest DR seemed to lead to the highest PM mass. While the total PM mass remained rather constant, a large variation as a function of DR was observed in measured particulate form PAH content, in the studied combustion conditions. The total particulate PAH at DR 15 was 1.8-fold to 2.9-fold compared to DRs 40 and 115, respectively (Fig. 1). The PAH/PM_1 ratio decreased from 9.4% to 5.8% and 2.5%, while DR increased from 15 to 40 and 115. The effect of DR was the largest for light PAH compounds. Heavy PAH species have most likely condensed prior to sampling. The fact that their measured concentrations scaled very well with DRs indicated that the porous tube diluter worked in a reliable way.

Computational fluid dynamics (CFD) modelling was used to obtain a better understanding of flows and losses inside the porous tube diluter. The studies identified the tip of the porous tube nozzle as the critical region for condensable organic vapour and fine particle losses. Right at the tip, the porous flow does not provide protection. Overall, only minor sampling losses are predicted for typical small-scale biomass combustion conditions. Model considerations of dynamics involved in gas-to-particle conversions indicate that the residence times in the diluter are sufficient for equilibrium, provided that no chemical reactions are involved. This is the case for PAH compounds that are the same in the gaseous and condensed forms. Indeed, vapour pressures seem to provide sufficient explanation of the observed trends in PAH contents.

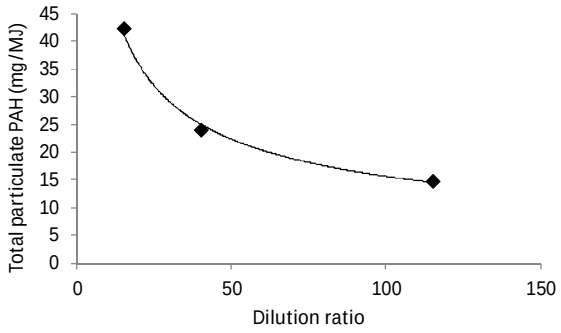

Figure 1. The effect of dilution ratio on total particulate PAH.

The porous tube diluter worked in a consistent and reliable way in the measurements. The experiments indicate that, even in cases where total PM emissions only show weak DR dependence, particulate properties may still be significantly affected by DR. This is especially true of health effect studies. The samples have large variation in their PAH contents, and consequently, possibly in their health effects as well.

Road surface dust load is dependent on road surface macro texture

G. Blomqvist, M. Gustafsson and T. Lundberg

VTI – Swedish National Road and Transport Research Institute, Linköping, SE-58195, Sweden
Keywords: road, dust, texture, abatement.
Presenting author email: goran.blomqvist@vti.se

Emission of road dust into the air is negatively dependent on the road surface macro texture (Blomqvist *et al*, 2011; China and James, 2012). That statement is, however, based on controlled experiments where equal amounts of dry dust were applied on clean road surfaces.

This abstract concludes that the actual dust load in city streets are positively related to the road surface macro texture and also strongly related to the season (Figure 1). The amount of vehicle induced emission of the road dust suspended into the air will, however, not only be dependent on the dust load amount on the road surface, but also to its emission availability, which to a very large degree depends on the road surface wetness. The large seasonal variation of the dust load is to large extent due to the studded tire wear of road surfaces, and winter sanding material spread on roads and sidewalks.

The road dust was sampled with the VTI Wet Dust Sampler (Jonsson *et al* 2012) on four test sites, representing different city streets, at eight different occasions from October 2011 to January 2013. The road surface macro texture (Table 1) was measured at each sampling site by the sand patch method (CEN-standard EN 13036-1). The macro texture was also measured along the entire road lengths of the sampled streets using the VTI Laser Road Surface Tester, RST.

Table 1. Road lengths and texture at sampling sites.

Testsites (Street name)	Road length (km)	Road surface macro texture (mean texture depth) (mm)	
		Wheel track	Between tracks
Hornsgatan	2.4	1.5	2.0
Folkungagatan	0.6	1.7	1.0
Sveavägen	1.6	1.3	1.1
Norrlandsgatan	0.3	1.2	0.9

The mode and standard deviation of the road surface macro texture histograms differ largely between and within the four studied city streets (Figure 2). This points out that the geographic variation of the road surface texture and, hence, the amount of road dust load can be very large.

Together with the fact that the road dust load also shows a large seasonal variation, this knowledge could be used from an abatement strategy point of view as it gives information regarding the questions of *when* and *where* abatement activities such as street cleaning should take place. That will, however, require knowledge of the road surface texture along the city road network.

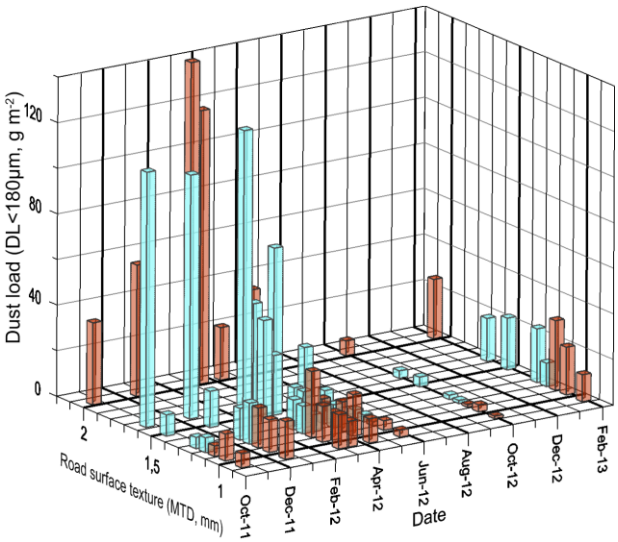

Figure 1. Road surface dust load as related to road surface macro texture and time of year. Red = between wheel tracks, Blue = in wheel tracks. Data partly from Gustafsson *et al* (2012).

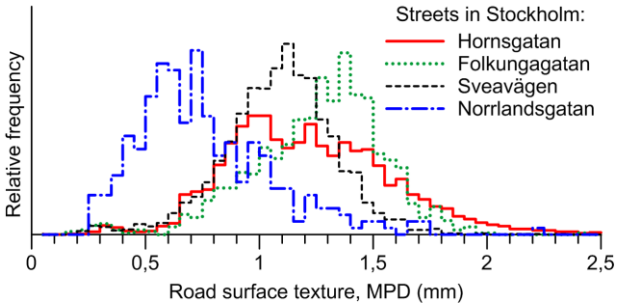

Figure 2. Histogram of road surface macro texture (mean profile depth) in the left wheel track in four city streets.

Evaluating the use of dust suppressant to control local PM_{10} concentrations

G. W. Fuller, B. Barratt, D. Carslaw, D. Green, A.H. Tremper

MRC HPA Centre for Environment and Health, King's College London, London, SE1 9NH, UK
Presenting author email: gary.fuller@kcl.ac.uk

Introduction

Around Europe cities are struggling to meet EU Limit Values for PM_{10} requiring ever more creative measures to control concentrations in PM_{10} hotspots. Trials have found that street sweeping alone is not effective. The combination of street sweeping and washing has led to decreased PM_{10} in some locations with decreases of 7-10% at the kerbside in Barcelona (Amato et al 2009) but other studies have found no effects. Similarly dust suppressants have had impressive results in some studies such as those in Sweden where Norman and Johansson (2006) found a reduction of 35% in ambient air PM_{10} levels and 29– 43% decreases were found in Klagenfurt, Austria (Hafner, 2007) but other studies have reported no benefits at all (Amato et al 2010).

The application of calcium magnesium acetate (CMA) dust suppressant was tested over two years at nine locations in London ranging from a busy urban centre street canyon to suburban streets around industrial areas; each location having its own distinct geographical and emissions characteristics, allowing an assessment of the impact of CMA in differing situations and at varying application rates.

Methods

Changes in ambient PM_{10} as a result of CMA application were tested using different assessment methods each with their own controls:

a) NO_X tracer methods which sought changes in NO_X:PM_{10} emissions ratios from CMA applications reasoning that CMA would affect PM_{10} but not tailpipe NO_X.

b) Meteorological statistical modelling to remove as much of the interfering behaviour of meteorology, giving a much better chance of observing the effect of an intervention or emissions change.

c) PM_{10} mass closure from measured PM chemical components.

d) Detailed analysis of PM_{10} measurements looking at diurnal variations in PM10 from road sources on days with CMA and days with no CMA.

Results

Three roads showed no decrease in PM_{10} concentrations. This may be explained by low concentrations of PM_{10} from sources that may be susceptible to control by CMA; the mean contribution of mineral PM to total PM_{10} mass concentration was 5%, tyre wear 6% and brake wear 14%. These are typical of most roads in London.

Decreases in local PM_{10} were found in an underpass but only during high CMA dosing. CMA led to a decrease of ~ 12% in annual mean PM_{10} at one road near a construction site and the local increment in PM_{10} concentrations decreased by between 18 and 41% when CMA was used on industrial sites and surrounding residential roads.

Conclusions

Although CMA is not an effective method to decrease PM_{10} on typical London roads it may have a role to play in controlling local PM_{10} on roads around industrial and construction sites. Local PM_{10} at locations with greater than expected NOX:Primary PM_{10} emissions ratios (those above the regression line in Figure 1) would be most amenable to control by CMA.

Assessment methods developed for this programme can be useful to assess other air quality management interventions.

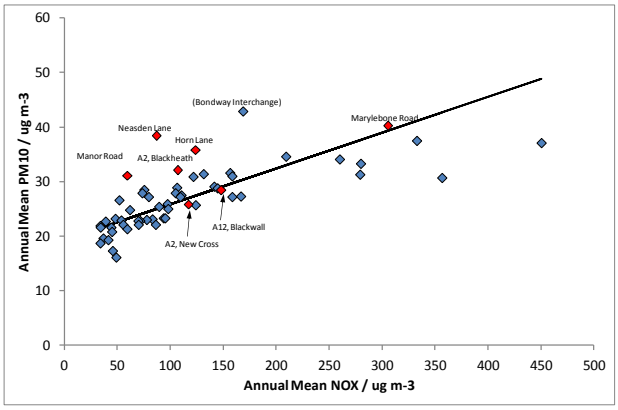

Figure 1 Annual mean PM_{10} vs NO_X; the regression line indicating a typical NO_X:Primary PM_{10} emissions ratio. Red diamonds = CMA study locations.

CHEMKAR PM_{10}
A year-long chemical characterization of PM_{10} in Flanders (Belgium) in 4 major cities and 3 types of locations

J. Vercauteren[1], D. Roet[1], C. Matheeussen[1], E. Roekens[1], R. Vermeylen[2], W. Maenhaut[2] and M. Claeys[2]

[1] Flemish Environment Agency (VMM), Kronenburgstraat 45, 2000 Antwerpen, Belgium
[2]University of Antwerp (UA), Dept. of Pharmaceutical Sciences, Universiteitsplein 1, 2610 Antwerpen, Belgium

Keywords: PM_{10}, chemical characterization, elemental carbon, streetcanyon

Presenting author email: d.roet@vmm.be

From July 2011 until July 2012 the Flemish Environment Agency (VMM) carried out its fourth "*Chemkar PM_{10}*" campaign as part of the European Life+ ATMOSYS project. This was a large scale chemical characterization project of PM_{10} in Flanders (Belgium) in four major cities (Antwerp, Ghent, Bruges and Ostend; see also *Figure 1*). In each city measurements were done at 3 types of locations: a streetcanyon, an urban background and a regional road. The focus of the current project was to compare the results on both a city and location type level. Such comparison allows us to assess the contribution to PM_{10} that can be attributed to local contributions like a streetcanyon. Besides the total PM_{10} mass, ions, metals also elemental- and organic carbon (EC/OC) and levoglucosan (wood burning tracer) were analysed.

Experimental setup:

During one full year PM_{10} was sampled simultaneously on every 4th day at each location type in each city totaling **about 1000 samples** (including field blanks).

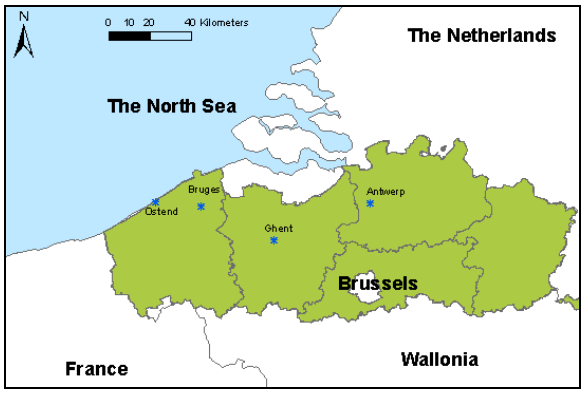

Figure 1: Location of the project cities

Sampling was done for 24h with one Leckel SEQ 47/50 low volume sampler at 2.3 m^3/h on 47mm Pallflex® Tissuquartz™ 2500 QAT-UP filters. After sampling the PM_{10} mass concentration was determined by dual weighing of the filters according to the European reference method EN14907. Next, the filters were punched for chemical analysis and stored at -18°C until analysis. One punch (1.5 cm^2) was used for the determination of **elemental and organic carbon** (thermal/optical transmittance) with the NIOSH protocol. Another punch (1.5 cm^2) was used for determination of **levoglucosan** by means of GC/MS after derivatisation with *N*,*O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) containing 1% trimethylchlorosilane (TMCS).

Results:

On average, concentrations in the **street canyons** were 7.5 µg/m^3 higher than at the urban background sites. This local contribution was mainly due to the resuspension of mineral dust (+ 3 µg/m^3), organic matter (+2 µg/m^3) and elemental carbon (+ 1 µg/m^3). *Figure 2* shows more detailed results for the streetcanyons in each city.

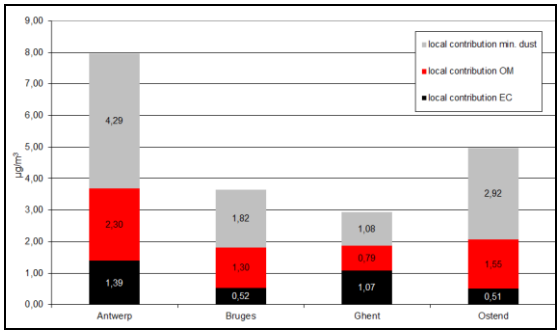

Figure 2: Local contributions to PM_{10} in streetcanyons in different cities.

More results and extended analysis will be presented at the conference.

Non-exhaust PMx emissions from road traffic

M. Maasikmets[1, 2], E. Teinemaa[1], T. Arumäe[1], V. Kimmel[2]

[1]Estonian Environmental Research Centre (EERC), Marja 4d, 10617 Tallinn, Estonia; [2]Estonian University of Life Science (EULC), Institute of Agricultural and Environmental Sciences, Kreutzwaldi 5, 51014 Tartu, Estonia
Keywords: non-exhaust emissions, studded tyres, PMx
Presenting author email: marek.maasikmets@klab.ee

Non-exhaust vehicle emissions are formed from wear particles of vehicle components such as brakes, clutches, chassis and tires. Although the non-exhaust particles are relatively minor contributors to the overall ambient air particulate load, reliable exposure estimates are few. (Panko et al. 2013). Suspended road dust will remain a problem because of an increasing number of vehicles in urban and rural areas. Only few real-world measurements of road dust resuspension have been performed to date. There is still a knowledge gap regarding the dominant mechanisms leading to road dust emissions, although resuspension of surface particle loading obviously plays an important role. (Pirjola et al. 2010). In practice, quantification of road dust emissions is complicated because of the many different factors that might need to be controlled —vehicle type and speed, tire type, pavement type and conditions, the use of road salt and sand (Hussein et al. 2008).

In current study the mobile measurement system was used to quantify the relative importance of road PMx emission and suspension of accumulated dust versus direct pavement wear, tire type (studded, non-studded and summer), pavement type, and vehicle speed. The mobile sampling cart was built, which enables simultaneously measure PMx concentrations directly behind the both rear tyres and the background air from the front of the vehicle. Simultaneously road and tire temperature were measured with infrared thermometer system. The tire pressure and ambient conditions were measured before and after each driving test. Measurements were performed during March-September on selected roads with different pavements and traffic conditions in Estonia. Particle number concentration and size distribution from 30 nm to 10 µm with 1-sec time resolution were measured by ELPI (Electrical low pressure impactor, Dekati Ltd.), behind the tires with the sampling rate of 2 x 29.25 l/min. The minimum detection level at 1 stage for the mass concentration is 0.01 µg/m^3 and for the number concentration 142 1/cm^3. The upper concentration limit at 13 stage for the mass concentration is 8269 mg/m^3 and for the number concentration 2.7E+04 1/cm^3. Simultaneous particle measurements were carried out using TSI optical particle counter OPC Model 3330 and DustTrak DRX. PM samples on impactor plates were also analysed by SEM (scanning electron microscopy, Zeiss EVO MA15 with Inca EDS) technique for chemical composition and morphology.

Results

The initial data show clear relationship between the vehicle speed and total PM emitted. Humidity of the road surface had strong implication on the PMx emission. Pavement composition has significant impact to the road wear and therefore PMx emission.

Studded tyres are generating more coarse PM emission compared to the non-studded winter and summer tyres.

There was a clear indication that the smallest particles with diameter less than 200 nm originate from the tires and not from the pavement. During the ride the tyre temperature is increasing, which leads to emissions of loosely bound reinforcing filler material and evaporation of semi-volatile softening oils. Particles larger than 300 nm consist mostly carbon reinforcement filler from the stone material in the pavement.

Presenting author email: nina.schleicher@kit.edu

Air quality remains one of the major challenges for the megacity Beijing. Mercury is known as a global pollutant, which is highly mobile in the environment and toxic to humans as well as to wildlife at extremely low levels (Carpy, 1997). However, unlike other heavy metals, only few studies investigated total particulate Hg (HgT_P) concentrations in atmospheric particles in Asian megacities. Sources for HgT_P are abundant in a city like Beijing. Coal combustion for industrial and residential use as well as coal-fired power plants constitutes a major source. Other potential sources are non-ferrous metal smelting, cement production, Hg mining, biofuel and biomass combustion, or waste incineration (Fu *et al.* 2012).

Within this study, weekly $PM_{2.5}$ (particles ≤ 2.5 µm, separately for day- and night-time) and total suspended particles (TSP) were investigated continuously for the whole year 2006 at one central sampling site in Beijing. Additionally, three months (Jan, Feb, Mar) within this period were selected for comparing HgT_P concentrations at four different sampling sites within the city. This approach aimed at (i) assessing the major HgT_P sources in Beijing and (ii) investigating the spatio-temporal variations in detail.

Furthermore, the period of the Olympic Summer Games in August 2008 with its strictly enforced mitigation measures (including traffic reductions and industry closures) provided the unique opportunity to investigate the efficiency of these comprehensive actions taken to reduce air pollution. The data set presented here includes TSP samples of each August from 2006 to 2010 in order to gain knowledge about HgT_P concentrations before, during, and after the Olympic Games period.

All samples were collected actively on quartz fibre filters (Mini-VS, 200 L/h, for $PM_{2.5}$ and TSP sampler, 1 m^3/h for TSP, Leckel, Germany). Mass concentrations were determined gravimetrically. Total particulate Hg was analyzed from circular filter punches by cold vapor atomic absorption spectrometry after calcination in an O_2 stream and amalgamation on an Au trap using a Direct Mercury Analyzer (DMA-80, Milestone, Italy).

Results show strong seasonal differences in HgT_P concentrations (Fig. 1). Lowest HgT_P concentrations occurred during summer months, while winter concentrations were up to 15-times higher. Both, meteorological conditions and seasonal sources were responsible for these high variations over the annual course. Usually, day-time HgT_P concentrations were higher compared to those during night. However, during the summer months (Jun, Jul, Aug, and also Sep), night-time concentrations were higher (Fig. 1).

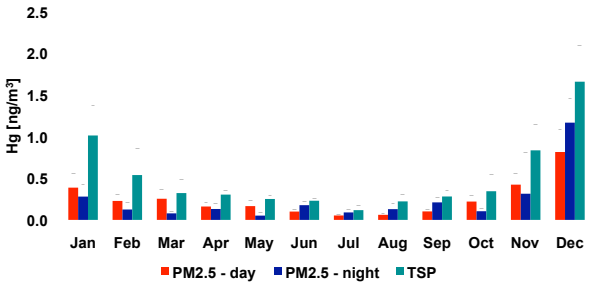

Figure 1. Average monthly HgT_P concentrations in ng/m^3 for $PM_{2.5}$ and TSP samples in 2006.

In Aug-08, the mitigation measures reduced not only overall mass and metal concentrations in Beijing (Schleicher *et al.* 2012) but also HgT_P (Fig. 2). On average, HgT_P in Aug-08 was reduced by about 60% compared to the previous two years. However, after the Olympic Games, HgT_P increased again to pre-Olympic levels. Generally, HgT_P concentrations in Beijing are comparably high and sustainable urban planning needs to include comprehensive reduction measures for Hg.

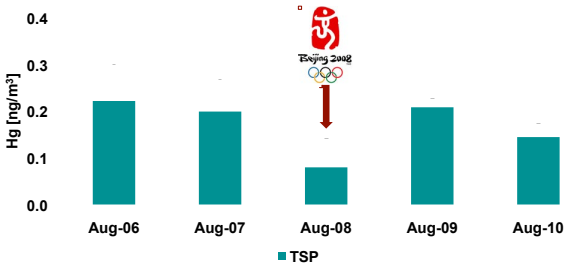

Figure 2. Average HgT_P concentrations in ng/m^3 for each August from 2006 to 2010.

Presenting author email: roberta.vecchi@unimi.it

In April/May 2012, aerosol filter measurements were carried out in and around the coastal town of Port Talbot in South Wales which has an approximate population of 35,000 and is located on the M4 corridor (51 34' N and 3°46' W). The town sites one of the UK steel manufacturing plants owned by Tata and is the main source affecting air quality in the area (AQEG, 2010). The site covers approximately 28 km^2, comprises of ~50km of roads, 100 km of railway, and 25,000 vehicle movements per day. The production capacity is around 5m tonnes per year with the main processes in the steelworks being iron-making (sintering, blast furnace and raw materials), steel-making (basic oxygen steel-making (BOS) and coking) and rolling mills (hot and cold mills) (Moreno et al., 2004; Dall'Osto et al., 2008).

Instruments were deployed at four sites around the perimeter of the steel works (one at a coastal site (Little Warren LW) and the remain in 3 inland sites placed along the length of the works (Fire Station FS, Prince Street PS and Dyffryn School DS) in the study area for a four-week campaign (16th April to 16th May, 2012) (see Figure 1). With a view to measuring elements and water soluble ions within the fine and coarse fraction, our main site was located at FS where we deployed: a micro-orifice uniform deposit impactor (MOUDI) (3 day samples); a Partisol Dichotomous sampler (daily sample); a Streaker sampler (hourly samples); an Aerosol time-of-flight Mass Spectrometry (ATOFMS); a GRIMM particle size spectrometer and an Aethalometer.

Figure 1. Overview of the sampling sites used in Port Talbot.

Gaseous and meteorological data measured during the period of sampling were also collected from the Automatic Urban and Rural Network (AURN) located next to the FS site. This main site was in itself complemented by 3 other sampling sites where we deployed another 3 Partisol samples (24 hr sampling rate). At our coastal site, we ran a second Streaker sampler, which when paired with the FS Streaker, collected data to measures the increment in PM caused by the steel works.

An example the results with huge peaks of Fe and Mn detected in one of the sites nearby the steel works is reported in Figure 2.

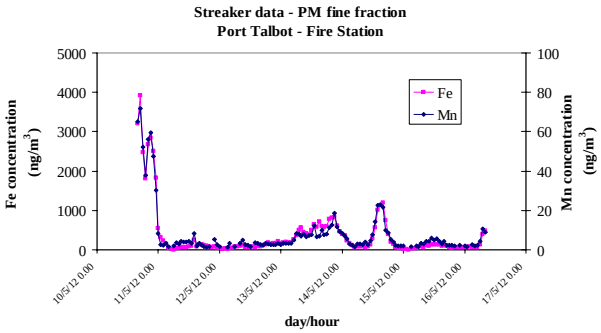

Figure 2. Fe and Mn hourly concentration (in ng/m^3) detetcted in Port Talbot (FS site).

Given this large data set of elements, ions and chemical species, our aim was to assess the impact of the steel works on the local area and in particular understand the nature of PM episodes detected by ongoing continuous PM measurements within the area which were suspected to be generated by fugitive dusts.

Blue sky over the Ruhr – a review of the effectiveness of more than 50 years of air quality measures in Germany

S. Wurzler, H. Hebbinghaus, P. Bruckmann, J. Friesel, U. Pfeffer

North Rhine Westphalian State Agency for Nature, Environment and Consumer Protection, Recklinghausen, Germany
Keywords: air quality
Presenting author email: sabine.wurzler@lanuv.nrw.de

In January and February 2013, the poor air quality in many major cities in parts of Asia, such as Peking and Delhi, made headlines worldwide. The high concentrations of air pollutants and the accompanying pictures and effects look very familiar to those, who lived in the area Rhine Ruhr during the fifties and sixties. Notable was, e. g., the smog episode in December 1962, leading to an increase of mortality by 30 %. This drastically increased number of deaths owing to poor air quality made very apparent that something had to be done.

Already the year 1961 marked a turning point in German air quality planning, because of a notable speech of the subsequent chancellor, Willy Brandt, who demanded a change in politics concerning air quality with the catch phrase of blue sky over the Ruhr area. This was the first time that someone so prominently focussed on the combination of air quality, health effects and social justice, turning smoking stacks into something more than just a sign for economic success.

While this single talk did not mean an immediate change in politics and public awareness, it was a popular vision from which future activities could build. These activities included monitoring air quality as well as measures for emission reduction. The awareness of air quality as a challenging problem has grown in the public since then. Now, the blue sky is again visible over the Ruhr area, at least on sunny days. The European Commission has declared the year 2013 as the year of air quality. When comparing today's air quality in Europe to the situation in the past and to the present situation in Asia, this might seem a bit exaggerated at the first glance. But is this true? Are all problems already solved? Therefore, we review the past, present and possible future activities in Germany and Europe and their results for air quality. It can be seen, that the work on clean air includes some success stories. As an example, figure 1 shows the SO_2 concentration in the area Rhine Ruhr from 1964 till 2011. The TSP and PM10 trend from 1968 to 2011 can be seen in figure 2. These figures well illustrate the success stories of air quality measures – as well as some less favourable measures. It can be seen that the general trend shows a clear decrease in SO_2, PM10, and TSP concentrations. Measures like dust separation in industrial facilities, substituting solid fuels in space heating as well as the structural change in the Ruhr area all led to a reduction of SO_2, PM10, and TSP, while the policy of high stacks only led to a change in distribution, causing acidification and eutrophication in ecosystems. Particularly the desulphurisation of power plants since 1977 enhanced the decrease and it can be stated that today the concentrations of SO_2 in Germany are no longer problematic with respect to human health.

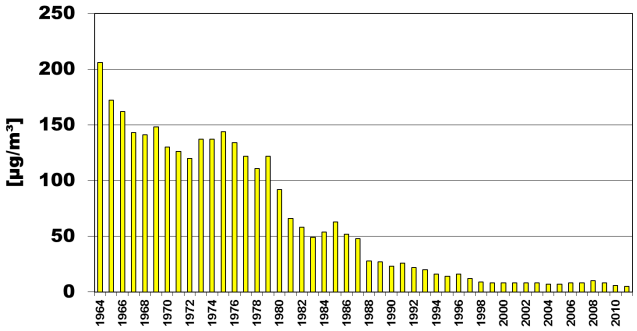

Fig. 1: Trend of annual average SO_2 concentrations in µg/m³ in the area Rhine Ruhr from 1964 to 2011. The highest concentrations correspond to values above 200 µg/m³, the lowest are below 10 µg/m³

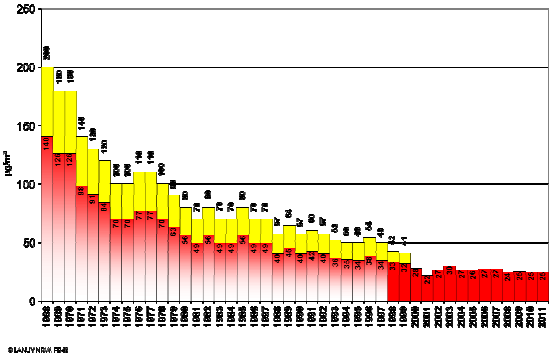

Fig. 2: Trend of annual average total suspended particle (TSP, yellow bars) and PM10 (red bars) concentrations in µg/m³ in the area Rhine Ruhr from 1968 to 2011. The highest concentrations correspond to values above 200 µg/m³, the lowest are below 50 µg/m³

But despite all advances, there are still problems to face. E. g., the high amount of road traffic is a main source for high NO_2 concentrations in cities. The number of PM10 exceedance days is still occasionally too high. Another challenge is the preservation of nature protection areas that can be adversely affected by high depositions of nitrogen, acid, or heavy metals.

Our presentation will give an overview of the last 50 years' challenges, success stories and memorable events as well as a reflection on current and future challenges in the area of air quality planning.

Session: Aerosol-based Nanotechnology
Applications of engineered nanoparticles

Nanostructural engineering of Pt/C catalyst via spray-drying for electrocatalyst applications

R. Balgis[1], G.M. Anilkumar[2], S. Sago[2], T. Ogi[1] and K. Okuyama[1]

[1]Department of Chemical Engineering, Hiroshima University, Higashi-Hiroshima, Hiroshima, 739-8527, Japan
[2]Research and Development Centre, Noritake, Co., Ltd., Miyoshi, Aichi, 470-0293, Japan
Keywords: spray-drying, electrocatalyst, mass activity.
Presenting author email: ratna-balgis@hiroshima-u.ac.jp

The great advantages of proton exchange membrane fuel cell (PEMFC) drive us to develop industrially friendly processing techniques and technologies for the production of its components such as a fuel cell catalyst. Platinum nanoparticles supported on carbon (Pt/C) are the most widely used catalyst material. Many researchers have demonstrated intense effort in the development of Pt/C catalysts. They were concerned with not only reducing Pt consumption, but also with keeping the catalytic performance at a reasonable level by means of structural engineering of the catalyst support materials to provide a high surface area. However, the common methods have been relatively time consuming (Balgis *et* al, 2012 and Balgis *et* al, 2013). In this work, we report development of a facile in-situ synthesis route to control the morphology and atomic content of Pt/C catalyst using spray-drying technique. The prepared catalyst showed high performance catalytic activity with excellent durability. The present method, described herein, is simple and cost-effective with a short processing time, which presents high opportunity for large-scale commercialization.

A precursor containing polystyrene latex (PSL, 300 nm), carbon black (40 nm), H_2PtCl_6 solution, and Polyvinyl alcohol (PVA, Mw = 500, at a mass ratio of 16:1) was spray-dried at 180°C with an air flow of 11.1 l/min as shown in Figure 1. Ammonia solution, $(NH_3)_{aq}$, was added into the precursor to intrude Nitrogen atom to the catalyst support (carbon). As-sprayed composite particles were calcined at 700°C for 30 min, under a nitrogen atmosphere in order to decompose PSL particles, to allow for a reduction process and for the crystal growth of platinum, accomplish N-doping process, and to obtain spherical microflower architecture. Electrocatalytic activity was performed using cyclic voltammetry (CV) and rotating disc electrode (RDE) measurement.

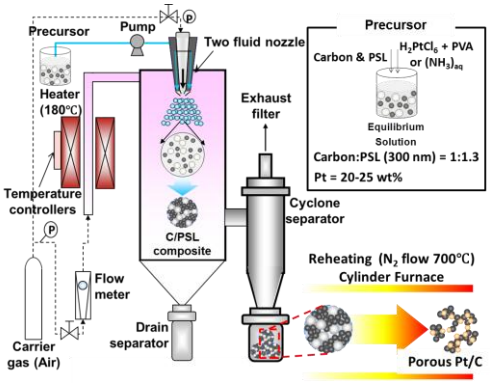

Figure 1. Schematic diagram of the experimental setup.

The prepared Pt/C catalysts have a unique porous structure that appears as a flower bunch in micrometer scale, namely spherical microflower catalyst (Pt/C_{SMF}) and Pt/C_N for sample with N-doping, as shown in Figure 2(a) and (b), respectively. Pt nanoparticles were very well dispersed on both catalysts, without any sintering, even after exposed at high temperature. The average particle size of Pt was 3.34 and 4.01 nm for Pt/C_{SMF} and Pt/C_N, respectively. The XRD pattern of both catalysts (data not shown) was indicating face-centered cubic crystal structure, which means complete reduction of H_2PtCl_6 was achieved.

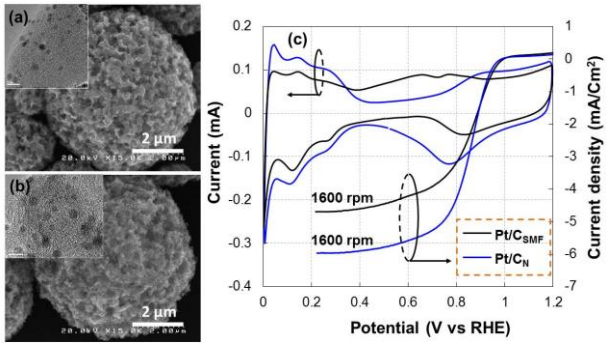

Figure 2. SEM and TEM image of: (a) Pt/C_{SMF} and (b) Pt/C_N; and (c) polarization curve of CV and ORR at 1600 rpm of Pt/C_{SMF} and Pt/C_N

The electrochemical characteristics of the prepared catalysts are presented by CV and ORR polarization curve shown in Figure 2(c). The electrochemical surface area (ECSA), mass activity (MA), and specific activity (SA) values of the catalysts summarized in Table 1. This work demonstrates an ample opportunity for the large-scale commercialization of a high-performance Pt/C catalyst with an exotic architecture.

Table 1. Catalyst characterization results.

Sample	Pt loading (wt%)	ECSA (m^2/g_{Pt})	MA (mA/mg_{Pt})	SA ($\mu A/cm^2_{Pt}$)
Pt/C_{SMF}	20.1	63.70	132.26	207.62
Pt/C_N	25.1	68.00	564.00	834.00

Keywords: breath, gas sensor, acetone, blood glucose.
Presenting author email: righettoni@ptl.mavt.ethz.ch

Breath analysis has become increasingly significant for its potential in clinical diagnoses (Manolis, 1983). It is also one of the least invasive procedures for monitoring diseases and particularly attractive for patients who have to control body parameters such as glycemia for diabetics. Among all volatile organic compounds and gases in the human breath, acetone is one of the most abundant. Its breath concentration increases in patients with uncontrolled diabetes (Cao and Duan, 2006) and during normal overnight sleep of healthy persons (King et al., 2012).

Several methods (e.g. GC-MS, PTR-MS) can be used for measurements of breath composition (Risby and Solga, 2006). They provide detailed characterization of breath composition but are usually bulky. So there is considerable interest in the development of hand-held devices for reliable monitoring of specific breath markers. For this, chemo-resistive gas sensors based on semiconductor nanoparticles are attractive for breath analysis (Righettoni et al., 2010) offering low fabrication costs, high sensitivity and high miniaturization potential (Tricoli et al., 2010). Portable gas sensors made of Si:WO_3 nanoparticles were already applied to continuous monitoring of the breath acetone from healthy subjects during rest or physical activity and these measurements were in agreement (>98%) to simultaneous PTR-MS analysis (Righettoni et al., 2012).

Here, a portable acetone sensor consisting of flame made Si-doped WO_3 nanostructured films (Righettoni et al., 2010) was used to analyze the end tidal fraction of the breath collected in Tedlar bags from eight volunteers after overnight fasting and after lunch. These samples were analyzed simultaneously by proton transfer reaction, time-of-flight, mass spectrometry (PTR-TOF-MS). Furthermore, blood glucose levels were measured for each person after breath sampling to investigate possible correlations with specific breath markers and sensor response. Figure 1 shows the PTR-TOF-MS signals of acetone (red broken line) and ethanol (blue dotted line) compared to the Si:WO_3 sensor signal (black line) of the exhaled breath of three different subjects or persons after overnight fasting. Subjects S1 and S3 showed similar acetone signals in agreement with their corresponding sensor responses. Subject 2, in contrast, showed a higher acetone signal by PTR-TOF-MS that is captured nicely by the sensor response. Additionally, the strong difference in breath ethanol content between S1 and S3 hardly affected the sensor response, confirming the high selectivity against ethanol of these sensors. These results showed a reliable sensor response to different breath acetone concentrations from different subjects independent of ethanol and other breath gas concentrations. Similar agreement was obtained for most of the subjects in the afternoon. Statistical analysis showed indeed strong correlations in the morning (after overnight fasting) between blood glucose and breath acetone (0.98), sensor response (0.96) that became, however, weaker after lunch. These results are promising for future breath-based glucose testing for further development of portable devices based on chemo-resistive gas sensors in clinical applications.

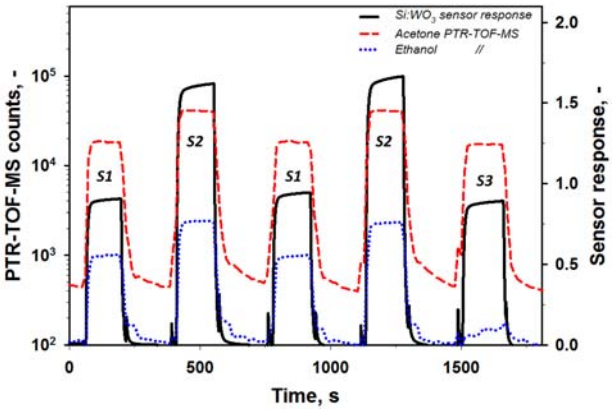

Figure 1. Exhaled breath concentrations of acetone (red broken line) and ethanol (blue dotted line) measured by PTR-TOF-MS for three different persons along with the portable sensor response (black line).

Aerosol synthesis of porous Particles for structured layers as catalyst support for Fischer–Tropsch reaction

Lintao Zeng and Alfred P. Weber

Institute of Particle Technology, TU Clausthal, Leibnizstrasse 19, 38678, Clausthal-Zellerfeld, Germany
Keywords: spray drying, porous silica particles, catalyst support, Fischer–Tropsch synthesis
Presenting author email: zeng@mvt.tu-clausthal.de

Using materials with well-defined porous structures as catalyst support provide new possibilities for tuning the catalytic properties (particularly the selectivity) for the Fischer-Tropsch (FTS) synthesis [Zhang 2010]. Saib et al found that the pore size of the support has a strong effect on the activity and selectivity of the catalyst [Saib 2002].Therefore, for FTS, it is desirable to develop a new method to prepare a catalyst support with controllable pore size distribution.

In this paper, we present a novel aerosol approach towards the preparation of well-defined trimodal porous layered structure as catalyst support for Fischer–Tropsch synthesis, which consists of two layers of porous SiO_2-building blocks and one layer of spherical glass particles (Fig. 1).

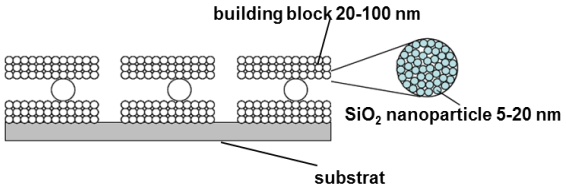

Fig. 1 Schematic representation of porous structured layers of building blocks

Firstly, porous silica particles were synthesized by spray drying process. The synthesis setup consists of an aerosol generator, a tube furnace and a filtration station. Templates (Polyvinylpyrrolidone, PVP) containing silica aerosols were generated by an atomizer operated with compressed air. The droplets were tempered in a tube furnace at 400-500°C. The dry particles were collected on a filter in a filtration station which was heated to 100°C during the synthesis.

The collected particles were heat treated at 500°C for 6 h to remove PVP. After calcination the products were characterized by SEM, TEM and nitrogen sorption.

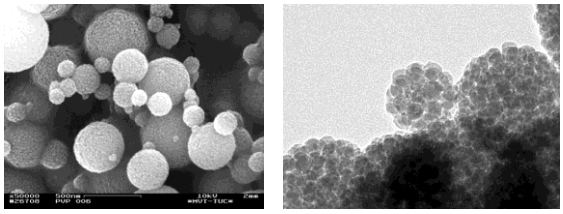

Fig. 2 SEM (left) and TEM (right) micrographs of porous particles

Through surface filtration or impaction of the aerosol, two layers of building blocks were deposited and reinforced by pressure and thermal treatment. The two single layers were then bound by partially melted glass particles.

In this contribution the aerosol synthesis of the different building blocks will be outlined together with the results of the porosity characterization. It will be shown that pore size and the porosity can be tailored by controlling the amount of polymer template and the type of colloids. In addition, the thermal stability of the porous particles will be presented.

This work was supported by the Deutsche Forschungs Gemeinschaft (DFG) under grant DFG-We 2331/13-1.

Optical heating of nanorods in a laser tweezers

P.B. Roder[1], B.E. Smith[1], P.J. Pauzauskie[1] and E.J. Davis[2]

[1]Department of Materials Science and Engineering, University of Washington, Seattle, WA 98195-2120, USA
[2]Department of Chemical Engineering, University of Washington, Seattle, WA, 98195-1750, USA
Keywords: Electromagnetic heating, optical tweezers, nanorods
Presenting author email: davis@cheme.washington.edu

The capture of nanoparticles with the optical tweezers makes it possible to perform a variety of measurements of physical and chemical properties, but the high irradiances usually encountered can lead to excessive heating of the particles. In a previous paper we (Roder et al., 2012) analyzed the heating of nanowires illuminated at right angles to the wire axis using Mie theory to determine the heat source function. Here we extend the analysis to finite length nanorods illuminated end-on in a laser trap. The theoretical predictions of the rod temperature are compared with optical tweezer studies which involve measurement of the Brownian motion of trapped particles using the methods of Peterman et al. (2001) and Marago et al. (2008) to determine the particle temperature.

The temperature distribution in a circular nanorod satisfies the energy equation given by

$$\frac{\partial T}{\partial t} = \alpha \nabla^2_{r,\theta,z} T + S(r,\theta,z) , \qquad (1)$$

in which α is the thermal diffusivity of the rod, and $S(r,\theta,z)$ is the volumetric rate of heat generation, which must be determined from the internal electric field, that is,

$$S(r,\theta,z) = \frac{1}{2\rho C}\sigma(\mathbf{E}\cdot\mathbf{E}^*) , \qquad (2)$$

where ρ is the particle density, C is its specific heat per unit mass, σ is its electrical conductivity, which is a function of the complex refractive index of the particle. The electric vector **E** and its complex conjugate **E*** depend on the optical characteristics of the irradiation. It is assumed that the heat source is not a function of time, and for the special case of infinitely long cylinders it is not a function of the axial position, z.

Equation (1) has been solved for boundary conditions and initial conditions appropriate for a rod (or wire) trapped in a stagnant fluid for three cases of possible applications: (i) illumination at right angles to the cylinder axis, the case examined by Roder et al. (2012), (ii) illumination of the lower end of a highly absorbing rod by a plane wave, and (iii) the more general case of a rod illuminated by a plane wave propagating in the z-direction.

Examples of the dimensionless source function and temperature distribution for case (i) are shown in Figures 1a and 1b, respectively, for a strongly absorbing carbonaceous rod. In this case Mie theory was used to compute the internal electric field, and the dimensionless source function is seen to have a complex structure of peaks and valleys. The dimensionless temperature distribution, $(T-T_\infty)/T_\infty$, is seen to be highly non-uniform.

Computations for nanoparticles show that even though the heat source function can be very non-uniform, the temperature can be uniform due to internal conduction, eliminating the possibility of photophoresis. For a carbonaceous rod with the temperature distribution shown in Figure 1b photophoresis can be expected.

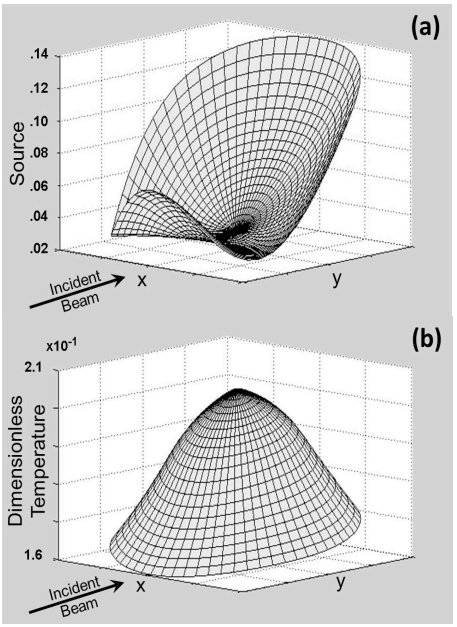

Figure 1. The dimensionless source function (a) and dimensionless temperature distribution (b) for a carbon rod with a radius of 100 nm in air irradiated at 1,000 W/cm^2 at a wavelength of 488 nm .

For case (ii), which applies to strong absorbers such a carbonaceous particles, we have applied the Fresnel equations to obtain an approximation for the internal field, and used that in the general solution of the energy equation to determine the temperature distribution. Very high temperatures are predicted for the high irradiances usually used for laser traps. For case (iii), which is a much more difficult problem, we have used numerical methods to determine the internal electric field, and then inserted the results in the general solution of Eq. (1).

Correlation between Catalytic Activity and Production of Reactive Oxygen Species for Airborne Engineered Palladium Nanoparticles

N. Neubauer[1], J. Palomaeki[2], H. Alenius[2] and G. Kasper[1]

[1]Karlsruhe Institute of Technology (KIT), Institute for Mechanical Process Engineering and Mechanics, Karlsruhe, 76131, Germany

Keywords: catalytic activity, reactive oxygen species, palladium nanoparticles
Presenting author email: nicole.neubauer@kit.edu

Catalyts are widely used in industry, and the catalytic functionality of nanoparticles is a major scientific topic for engineered nanomaterials. However, their influence on human health and biological systems is currently not understood because studies linking the catalytic activity with biological effects are largely unavailable. Therefore, we were investigating correlations between catalytic and biological activity for airborne palladium aerosols as a basis for better understanding of biological effect pathways.

Methods
The catalytic activity of palladium nanoparticles was investigated by the Catalytic Activity Aerosol Monitor (CAAM) which allows the detection of catalytically active nanoparticles (e.g. palladium) with a high sensitivity (Neubauer et al., 2013). As the ability to produce reactive oxygen species (ROS) is believed to be one of the key factors of nanotoxicology (Nel et al., 2006), the generation of ROS was measured by using the DCF method (Le Bel et al., 1992) both in a cell-free environment and with THP-1 cells (human monocytic leukaemia cells).

Experimental
Palladium aerosols produced by spark discharge were thermally conditioned in a tube furnace to generate differently sized palladium primary particles. These aerosols were characterized by an electrical mobility spectrometer for number concentrations and agglomerate size distributions. The mass concentration of the aerosols was determined from filter samples by inductively coupled plasma optical emission spectroscopy (ICP-OES). The geometric diameters of the primary particles were investigated by electron microscopy (TEM).

Detection of the catalytic activity by the CAAM is based on sampling defined volumes of the palladium aerosols onto filters, and then immediately initiating a substance specific chemical reaction on the filter – in this case the hydrogenation of ethene. For this purpose pre-mixed gaseous reaction educts are added to the deposit. The composition of the gaseous reaction products was measured by an IR sensor. Their concentration provides a measure for the catalytic activity of the palladium particles.

For the ROS measurements, the aerosols were transferred into suspension using a phosphate buffered saline. The production of ROS was then determined from these suspensions of differently sized palladium particles via the DCF method. A fluorescence spectrophotometer was used to detect DCF which was formed via the oxidation of non-fluorescent DCFH by ROS. TEM pictures of the suspended palladium were also taken to investigate potential changes in particle size or morphology.

Results
TEM analysis of the palladium aerosols directly after the production gave median primary particle sizes between 3 and 30 nm, depending on preparation. It was also determined that the primary particles did not change their size while the catalytic activity measurements took place, or during their transfer into the liquid.

The measurements with the CAAM showed a pronounced dependence of the activity on the primary palladium particle size, with a sharp maximum at 6 nm. The ROS production also showed a strong size dependence with a maximum in the same size range as the catalytic activity.

Conclusion
The catalytic activity of palladium nanoparticles as determined by a gas-phase reaction correlates strongly with their ability to produce ROS in suspension. This coincidence points to a link between the biological and catalytic activities of palladium nanoparticles. It also demonstrates the usefulness of the CAAM for quasi-real time detection of airborne catalysts.

Substance release kinetics of spherical and non-spherical hybrid nanoparticles generated by aerosol-photopolymerization

E. Akgün[1], M. Vranceanu[2], B. Sachweh[2], J. Hubbuch[1], M. Wörner[1]

[1]Process Engineering in Life Sciences, Karlsruhe Institute of Technology, Karlsruhe, 76131, Germany

Keywords: controlled release, hybrid nanoparticles, photopolymerization, nanocaps
Presenting author email: ertan.akguen@kit.edu

Release of the absorbed or encapsulated material from polymeric environments in a controlled manner has extensive and emerging applications as, for example, self-healing coatings (Suryanarayana *et al*, 2010) and controlled release platforms in the pharmaceutical and medical fields (Pinto Reis *et al*, 2006). The main advantages of such nano – and microscale particles are storing and protecting the inner material from the environment and performing controlled and sustained release (Suryanarayana *et al*, 2010).

Romero-Cano and Vincent (2002) compared the controlled release kinetics from poly(lactic acid) nanoparticles with different morphologies. All of the morphologies were spherical, but the active ingredient to be released was at different locations within the spheres. In this contribution, we compare the release kinetics of spherical and non-spherical (nanocaps) nanoparticles.

In our previous contributions, aerosol-photopolymerization has already been shown to be suitable for the generation of differently structured polymeric and hybrid nanoparticles. Figure 1 illustrates such polymer particles not hybridized yet. This contribution deals with loading of the produced spherical nanoparticles and nanocaps with specific substances such as caffeine and comparing their release kinetics from nanopolymers with different structures. A power of this method is the possibility of loading the nanoparticles *in situ*. Apart from this, photoinitiation serves for fast initiation rates, contributing to increased overall polymerization rates. Fast kinetics is favoured due to the sub-minute average aerosol residence time in the process. Photoinitiation permits an operation at ambient temperature, minimizing monomer droplet evaporation before polymerization. The aerosol-based process results in a continuous hybrid particle generation process. In addition, the incorporation of surfactants, required for many liquid phase processes, may be avoided, leading to highly pure particulate products.

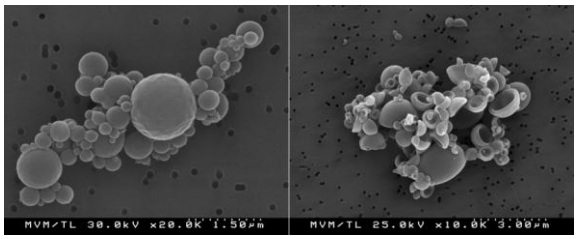

Figure 1. Spherical and non-spherical polymer nanoparticles generated by aerosol-photopolymerization.

The structure of the produced hybrid nanoparticles loaded with a specific substance was characterized by scanning electron microscopy. Transmission electron microscopy was also performed for further investigations on the hybrid character of particles before and after substance release.

The released amounts of caffeine from spherical nanopolymers and nanocaps were measured by HPLC. Figure 2 illustrates an exemplary comparison of the two particle types for low caffeine loadings of polymer particles.

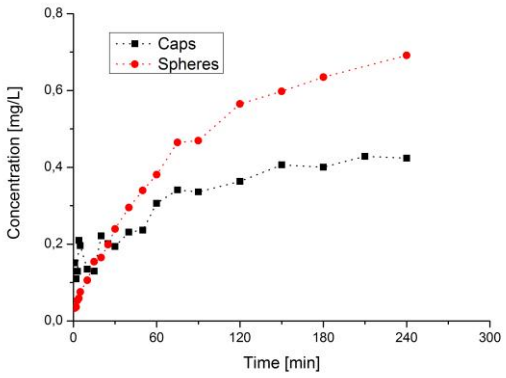

Figure 2. Caffeine release profiles from nanocaps and nanospheres produced by aerosol-photopolymerization.

Release profiles of higher concentrated hybrid particles and other material combinations will be illustrated as well.

Keywords: $LiFePO_4$, CVS, phase composition.
Presenting author email: tommi.karhunen@uef.fi

The structure of global energy supply is changing rapidly towards sustainable energy solutions. However, all forms of sustainable and intermittent energy production (e.g. wind power, photovoltaics) and sustainable transportation (e.g. hybrid and full electric vehicles) require excellent energy storage systems in order to increase their effectiveness (Hall and Bain, 2008).

Li-ion secondary cells are one of the most advanced battery energy storage systems currently available due to their high energy density (Du Pasquier *et al*, 2003). One of the main obstacles in their wide scale adoption, however, is the high cost of such batteries.

This obstacle can be overcome, firstly, by increasing the operational life time of the batteries. $LiFePO_4$ is a very promising electrode material for achieving this. In proper combination with an conductive additive it can be used to make Li-ion batteries that can undergo at least 1000 charge/discharge cycles without significant degradation in performance (Song *et al*, 2011). Furthermore, $LiFePO_4$ and its precursors are environmentally friendly.

Secondly, the cost of the precursor materials can be reduced by utilising alternative sources, such as industrial by-products. At least iron and phosphorus are available in the industrial waste streams. Utilising these streams will also reduce the environmental impact of the production.

Lastly, the synthesis process itself can be optimised. Gas-phase processes are highly material and energy efficient routes for synthesis of nanoparticles with controlled composition and particle size. With the proper selection of the process environment the waste streams can also be easily utilised in these processes.

In this paper we present a gas-phase method for the synthesis of LiFePO4 nanoparticles utilising industrial waste stream of FeSO4·7H2O. The precursors were dissolved in water and atomized using an ultrasonic nebuliser. The produced droplets were then carried to the heated zone of the reactor. Experiments were carried out at temperatures between 200 and 1000 °C in atmospheres with varying reduction potentials. The aerosol exiting the heated zone was rapidly cooled with a large volume of dilution gas (air or N2) at ambient temperature.

With increasing temperature the particles became more solid with increasing fraction of $LiFePO_4$ (Figure 1). Increasing the reducing potential of the synthesis atmosphere increases the ratio of the Pnma-to-Cmcm polymorphs of $LiFePO_4$ (Figure 2). The effects of temperature, precursor composition and process atmosphere on the product composition will be presented.

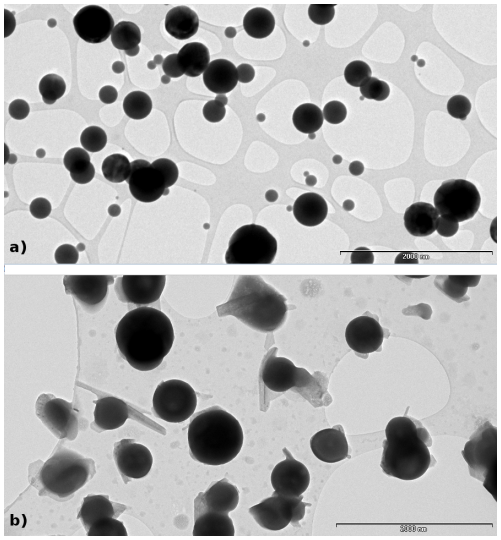

Figure 1: TEM images of $LiFePO_4$ samples synthesised at (a) 800 °C and (b) 600 °C.

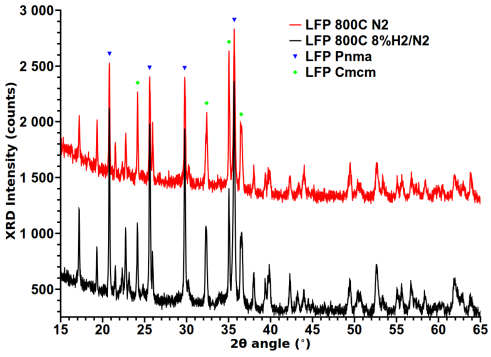

Figure 2: XRD diffractiograms of $LiFePO_4$ samples synthesised in N2 (red) and 8%H2/N2 (black).

Special Session: Aerosol Chemistry
Radical chemistry and aerosol formation

Partially oxidized radicals – crucial intermediates during atmospheric aerosol formation

J. Ahrens, P. T. M. Carlsson, C. Keunecke, M.-C. Maas, J. L. Wolf and T. Zeuch

Institut für Physikalische Chemie, Universität Göttingen, Göttingen, 37077, Germany

Keywords: radical chemistry, aerosol formation, sulfur dioxide, Criegee intermediates.
Presenting author email: tzeuch1@gwdg.de

The dynamics of reactive mixtures under conditions being typical for important environmental issues and technical applications are driven by chemical kinetics being related to the elementary reaction steps of a zoo of stable and transient species. This complexity limits our current understanding of important phenomena like the atmospheric formation of secondary organic aerosol.

Reactions of partially oxidized, transient species like alkoxy and peroxy radicals or Criegee intermediates (CIs) represent key mechanistic branch points in hydrocarbon degradation schemes. However, for some crucial reaction steps like the atmospheric oxidation of SO_2 by CIs the rate coefficient was not accessible until recently (see Welz et al., 2012). Such knowledge gaps are critical since incorrect data for sensitive elementary steps can drastically mislead predictions of atmospheric models with regard to aerosol formation.

In recent years we applied and combined different experimental and modeling techniques for dealing with the complexity being inherent to atmospheric and combustion chemistry. This overall examination approach helped us to derive e.g. a compact and consistent kinetic model with fully validated peroxy radical chemistry (Zeuch et al., 2008). For the study of atmospherically relevant reactions we apply a specially designed reactor experiment featuring fast initial reactant mixing and aerosol characterization at the end of main reactive processes (Carlsson et al., 2012). The final product analysis at the end of β-pinene ozonolysis in the presence and absence of SO_2 revealed the high influence of SO_2 on mechanistic branching in the chemistry of CIs (Figure 1) and aerosol formation (Figure 2).

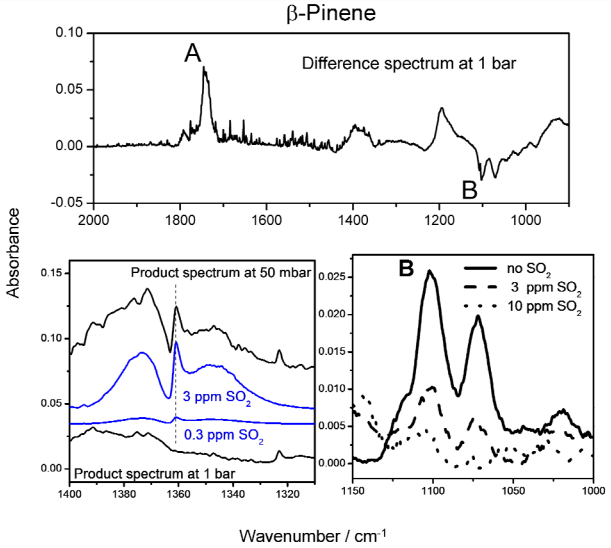

Figure 1. IR spectra of final products from β-pinene ozonolysis at 1 bar and 50 mbar. The difference spectrum in the upper panel shows the suppression of secondary ozonide formation (feature B) and highly increased nopinone formation (A). The lower panels show the consumption of SO_2 at high pressure and the suppression of secondary ozonide formation by SO_2.

The combined use of time resolved infrared spectroscopy and kinetic modeling gives reliable constraints for the rate coefficient of SO_2 + CI from biogenic terpenes under ambient conditions. In (cis and trans) 2-butene ozonolysis experiments the measured particle numbers in the presence of SO_2 show a slope of ~2 in a double logarithmic plot against predicted sulfuric acid concentrations in support of atmospheric and smog chamber observations (Carlsson et al., 2012), which represent much different reactive environments.

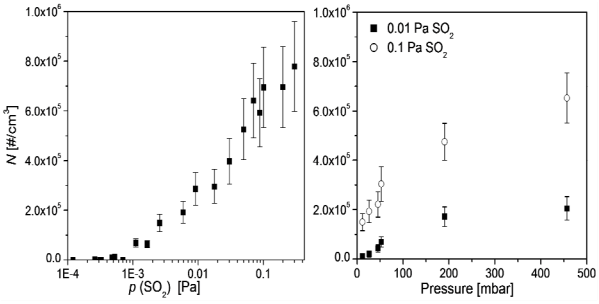

Figure 2. Aerosol formation during 2-butene ozonolysis as a function of SO_2 concentration and pressure.

Formation of organosulfates from the sulfate radical induced oxidation of methacrolein and methyl vinyl ketone

J. Schindelka[1], Y. Iinuma[1], D. Hoffmann and H. Herrmann[1]

[1] Leibniz Institute for Tropospheric Research (TROPOS), Leipzig, D-04318, Germany

Keywords: Isoprene, Sulfate radical, SOA
Presenting author email: schindelka@tropos.de

Recent studies show that organosulfates are an important fraction of ambient secondary organic aerosol (SOA). The contribution to the organic mass was estimated to be up to 30% in ambient aerosols and up to 20% for isoprene-derived organosulfates (Froyd et al., 2010, Surratt et al., 2008). The isoprene-derived organosulfate with *m/z* 215 ($C_5H_{11}O_7S^-$) is often reported to be the most abundant single organosulfate compound. Its formation is explained by the acid catalyzed sulfation of isoprene epoxydiol (IEPOX) that is suggested to form from the OH oxidation of isoprene under NO_x-free conditions(Paulot et al., 2009, Iinuma et al., 2007).

C_2 to C_4 organosulfates are found in ambient and laboratory generated SOA that can be related to isoprene oxidation products (Froyd et al., 2010, Surratt et al., 2007, Gómez-González et al., 2008). These compounds have been suggested to form from the sulfate radical induced oxidation of semi-volatile isoprene oxidation products in the particle phase (Galloway et al., 2009, Perri et al., 2010, Nozière et al., 2010). Here, the formation of organosulfates originating directly from methacrolein (MACR) or methyl vinyl ketone (MVK) with *m/z* of 199 and 183, are of interest because their existence was shown in studies of ambient aerosols (Froyd et al., 2010, Gómez-González et al., 2008). A sulfate radical reaction with unsaturated compounds is as fast as other organosulfate formation mechanisms and is even competitive to the reaction with hydroxyl radicals (Nozière et al., 2010, Buxton et al., 2000). Supporting the theory of the contribution of a radical mechanism in the formation, a very recent study reports a dependency of the fraction of organosulfates in particle mass on the season and photochemical activity (Tolocka and Turpin, 2012). This might indicate the involvement of solution phase radical chemistry.

In the present study, experiments on the sulfate radical induced oxidation of methacrolein and methyl vinyl ketone were performed in bulk aqueous phase as well as in an aerosol chamber, to investigate their relevance in aqueous phase SOA formation. Samples from aqueous phase experiments and extracts from filters collected after chamber experiments were analysed with UPLC/(-)ESI-IMS-QTOFMS.

All the samples showed the abundance of highly oxidized organosulfates with *m/z* values corresponding to the species found in ambient particle samples (see Table 1). Chamber experiments showed a distinct increase in particle mass for experiments with sulfate radical precursor ($K_2S_2O_8$) in the seed particles (see Figure 1).

Table 1. Selected organosulfate species of MACR and MVK with elemental composition.

Reactant	m/z [M-H]	Formula
MVK/ MACR	153	$C_3H_5O_5S$
	183	$C_4H_7O_6S$
	199	$C_4H_7O_7S$

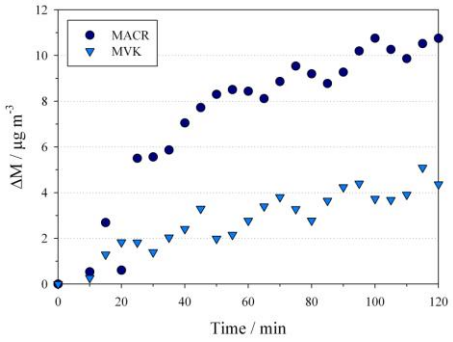

Figure 1. Time series of particle mass increase (ΔM) for MACR and MVK with $K_2S_2O_8/H_2SO_4$ as seed particles.

This study shows that sulfate radical reactions in the aqueous phase can partly explain the formation of these organosulfates from methacrolein and methyl vinyl ketone.

Ozonolysis of shikimic acid particles caught in the act

S. Steimer[1,2], A.J. Huisman[3], U.K. Krieger[2], T. Peter[2], M. Lampimäki[1], G. Gržinić[1], E. Coz[4], B. Watts[5], J. Raabe[5] and M. Ammann[1]

It has been shown that organic compounds may become solid or semi-solid under atmospheric conditions (Virtanen et al., 2010). It is therefore important to understand how the physical state of aerosol components might affect chemical ageing and thus their environmental impact (Shiraiwa et al., 2011). Shikimic acid is a plant metabolite, which has been found to be present in biomass burning aerosol (Medeiros et al., 2008), and which has convenient physical properties at low relative humidity for the purpose of the present experiment. Here, we studied the chemical aging of individual submicron shikimic acid particles on a substrate as a function of size and humidity in situ using scanning transmission X-ray microscopy (STXM) and near edge X-ray absorption fine structure spectroscopy (NEXAFS).

Shikimic acid particles were generated by ultrasonic nebulisation of solution, dried with a diffusion drier, size-selected by a differential mobility analyzer (DMA) and then impacted on a silicon nitride membrane. A temperature controlled environmental micro reactor (Huthwelker et al., 2010; Zelenay et al., 2011) was used to adjust relative humidity during the experiment (13%-83% RH) and facilitate in situ exposure to ozone. All STXM and NEXAFS experiments were conducted at the Pollux beamline at the Swiss Light Source.

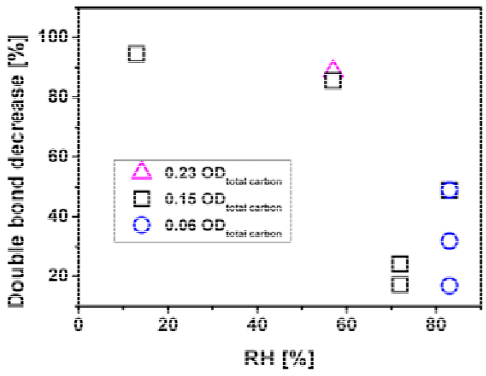

Figure 1. Humidity dependence of oxidation after 211 min exposure to 2.5 ppm ozone. Different symbols mark particles of different total carbon optical density, which is a measure of particle thickness.

Upon oxidation, the carbon K-edge spectra for shikimic acid particles show a clear decrease of the optical density (OD) at 284.5 eV, where resonant absorption occurs due the carbon-carbon double bond of shikimic acid. Figure 1 demonstrates the increasing degree of oxidation with increasing humidity. It is likely due to water acting as a plasticizer for shikimic acid, which leads to a decrease in viscosity and thus increase in diffusivity of reactants. Detailed analysis shows that no gradient is observed within the particles. Combined with the size dependence of the oxidation shown in figure 2, this points to either a shallow gradient or a surface limited process.

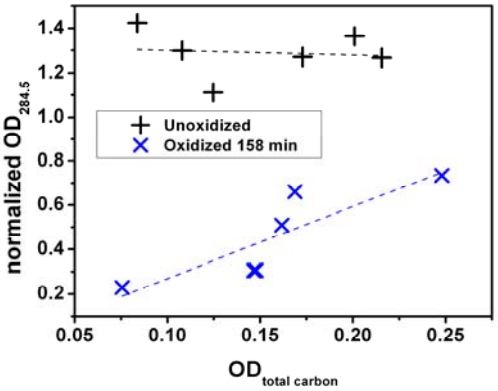

Figure 2. Double bond peak height at 72% before (black +) and after (blue ×) oxidation with 2.5 ppm ozone as a function of particle size, expressed as optical density of total carbon (310-320 eV).

Presenting author email: michal.farnik@jh-inst.cas.cz

A unique versatile molecular beam CLUB (CLUstr Beam) apparatus has recently been exploited for various studies of atmospherically relevant aerosol particles in vacuum. These studies will be briefly reviewed demonstrating the significant potential which the implementation of the molecular beam techniques has for the aerosol studies.

In molecular beams clusters are prepared by expansion of suitable gases into the vacuum through supersonic nozzles. Depending on the expansion conditions the clusters of various sizes can be generated ranging from a few molecules to small aerosol particles with sizes in the nanometer range composed of hundreds molecules. Our CLUB apparatus enables various experiments with these particles: (1) doping them with different molecules; (2) investigating photodissociation and photochemistry in/on the clusters by the fragment velocity imaging method; (3) studying the composition, dynamics and reactions by a unique reflectron time-of-flight mass spectrometer.

Several experiments will illustrate the variety of information about the small aerosol particles gained with the CLUB apparatus. First, we will exemplify the pickup cross sections of small ice nanoparticles for uptake of various atmospheric molecules (Lengyel, Kočišek *et al*, 2012). The cross sections were measured by precise velocity measurements of particles after their passage through a pickup cell filled with the particular gas. The cluster velocity change in dependence on the pickup pressure allows the pickup cross section determination. The experimental results are in good agreement with molecular dynamics simulations. They show that the actual cross section for the pickup is significantly larger than the geometrical cross section. This effect should be considered in the atmospheric models and nucleation theories.

Photochemistry of ice nanoparticles doped by hydrogen halide molecules HX (X= Cl, Br, I) is highly relevant to the stratospheric ozone depletion process. We have studied $HX{\cdot}(H_2O)_n$, n= 10^2-10^3, clusters under the influence of UV laser radiation at 193 nm and 243 nm. A series of experiments and theoretical calculations (Poterya, 2007) (Poterya, 2011) (Ončák, 2011) revealed that the HX molecule is acidically dissociated on the ice particle and a neutral hydronium radical H_3O is generated upon the UV excitation. This radical also represents a cluster model for solvated electron.

Most recently we have also investigated the photodissociation of CF_2Cl_2 molecule in clusters revealing the detailed dynamics of the molecular dissociation, and Cl-fragment caging and escape from the clusters.

Finally, we have studied mixed nitric acid/water ice nanoparticles in two different mass spectrometric experiments (Lengyel, Pysanenko *et al*, 2012). The comparison between the electron ionization and photoionization after Na-pickup showed that HNO_3 molecules act as very effective condensation nuclei, and no pure water clusters were generated even from vapors with 100 fold excess of water molecules. Besides, we have demonstrated that the Na doping can be used for detection of species reacting with Na or solvated electron in the aerosols.

In general, all these results are relevant for the ozone depletion process in the stratosphere.

Photoionization and infrared excitation of clusters with radical sites: Probing size and structure of neutral, sodium doped water clusters

[1]C. C. Pradzynski, [2]U. Buck, [1]R. M. Forck, [1]F. Zurheide, and [1]T. Zeuch

Keywords: sodium doping, neutral clusters, water crystallization, photoionization, infrared spectroscopy
Presenting author email: cpradzy@gwdg.de

An interesting application of the sodium doping technique is the size selection of neutral clusters or aerosol particles (Bobbert et al. 2002, Yoder et al. 2011). The most general method to prepare size selected clusters is a crossed beam scattering experiment, where the mass dependency of cluster deflection by the second beam is exploited. However, this approach is experimentally demanding and restricted to cluster sizes up to around 12 molecules (Pradzynski et al., 2012). Tagging neutral clusters with a sodium atom has emerged in the last decade as a general and experimentally much less complicated method for neutral particle sizing in laboratory experiments.

A key idea of this technique is the formation of a solvated electron when the alkali metal (usually sodium, but lithium and caesium atoms work very similar) interacts with the cluster after pick-up. The site where the metal atom is attached features a single or multi radical type chemical environment, which is crucial for the photoionzation of the cluster. This effect is quite general and works with many hydrogen bonded complexes (secondary organic aerosol are highly hydrogen bonded aggregates) and even rare gas clusters. This first stage of the method has the character of chemical pre-ionization. The sodium atom is ionized at the particle surface which decreases the binding energy of the Na 3s electron such that photoionization with tuneable, commercially available lasers becomes possible. When photoionized at the threshold only the most sodium centered clusters become visible. In this case the zwitterionic type potential of the neutral and the cationic potential of the photoionized clusters are quite similar near the energy minimum. This property explains the formation of cold cations without fragmentation because in the cation only low energy modes are populated. The method has a hybrid character. It combines the softness of chemical ionization with the universal applicability of single photon ionization, which is also a rather soft method, even for clusters. The chemical pre-ionization component can be modulated by IR excitation, which provides an additional dimension – the generation of size resolved infrared spectra of the clusters (see Figures 1 and 2).

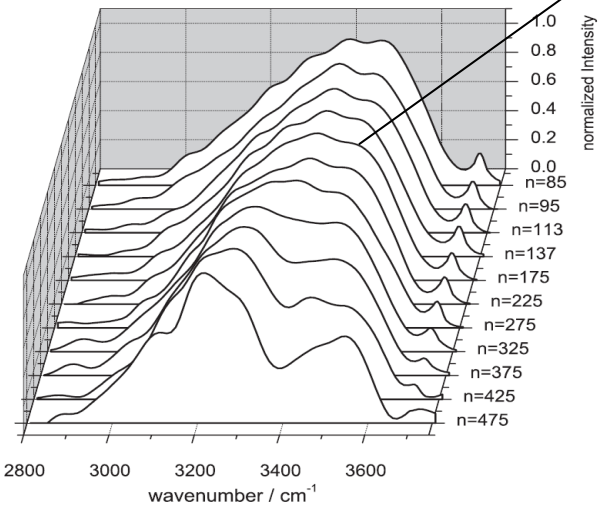

Figure 1. Evolution of crystalline core of water clusters with increasing cluster size (Pradzynski et al., 2012).

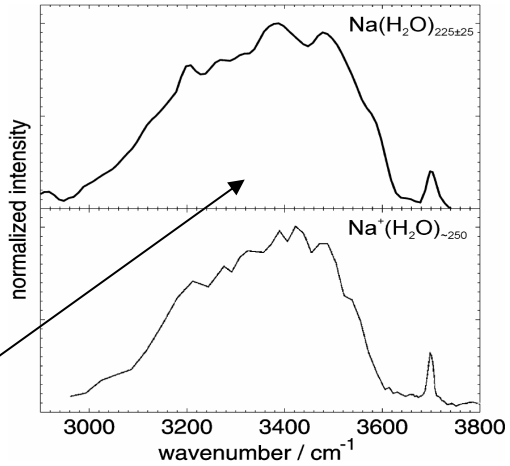

Figure 2. Comparison of infrared spectrum of $Na(H_2O)_{225\pm25}$ with $Na^+(H_20)_{\sim250}$ clusters (O´Brien and Williams, 2012).

In recent years we applied and refined the sodium doping technique and tested some new applications. In a recent work we could experimentally observe for the first time in the cluster size range between 250 to 500 molecules the transition between amorphous and crystalline ice on the basis of precisely size selectively determined infrared spectra in the OH stretching region, see Pradzynski et al., 2012.

The oxidation of alpha-pinene and limonene in a flow tube, investigated using the CI-APi-TOF

M.P. Rissanen[1], M. Sipilä[1], M. Ehn[1], N. Sarnela[1], T. Jokinen[1], J. Kangasluoma[1], T. Petäjä[1], H. Junninen[1], D. Worsnop[1,2] and M. Kulmala[1]

The oxidation of alpha-pinene and limonene were studied in a Pyrex flow tube reactor using nitrogen (N_2) or synthetic air (N_2 and O_2) as the bath gas. The products of the reactions investigated were detected using a novel CI-APi-Tof (Chemical Ionization Atmospheric Pressure interface Time-of-flight mass spectrometer) technique with a nitrate ion (NO_3^-) based detection scheme (Jokinen *et al.* 2012). The detection scheme and the measurement routines have been described previously (Ehn *et al.* 2010, Jokinen *et al.* 2012, Junninen *et al.* 2010).

The setup used has three major advantages in studying oxidation reactions with atmospheric relevance: (i) the design of the atmospheric pressure interface (APi) allows the studies to be performed at ambient pressure, regardless of the mass spectrometric detection method – which significantly decreases uncertainties associated with extrapolating research results into atmospherically relevant conditions. (ii) The chemical ionization method is a fairly sensitive ionization method, and hence, enables the detection of molecular clusters that can provide insight into atmospheric new particle formation. (iii) Time-of-flight technique measures the whole mass spectrum at a time, up to a finite maximum mass, which helps in the product identification tremendously

In the experiments, alpha-pinene and limonene were exposed to differing levels of oxidants (O_3 and OH) in a flow tube coupled to the mass spectrometer. By varying the levels of oxidizers, the amount of organic precursor, their residence time in the reactor, as well as the water content, the important steps of the oxidation processes can be tracked.

The aim of the present experiments was to study the formation of highly oxidized molecules - HOMs – (Ehn *et al.* 2012) from two biogenic terpenes [terpene = organic hydrocarbon molecule with a chemical formula $(C_5H_8)_n$] limonene and alpha-pinene. The HOMs have recently started to attract considerable attention due to their possible relevance in the atmospheric new particle formation. Hence, the two reaction systems were investigated with the CI-APi-Tof, in order to gain insight into these processes.

Pressure dependency of ozonolysis product formation of α-pinene focusing on low volatile compounds such as organic acids and dimeric compounds

M. Beck[1], C. Keunecke[2], T. Zeuch[2] and T. Hoffmann[1]

[1]Institut für Anorganische und Analytische Chemie, Johannes Gutenberg-Universität Mainz, Mainz, 55128, Germany
[2]Institut für Physikalische Chemie, Georg-August-Universität Göttingen, Göttingen, 37077, Germany

Keywords: SOA, ozone, monoterpene oxidation, organic acids.
Presenting author email: hoffmant@uni-mainz.de

Secondary organic aerosols (SOA) are important for air quality and the global climate. Therefore, a better understanding of formation mechanism, growth, sources and also quantity of SOA is necessary. Today many details concerning these aspects are unknown.

SOA is formed by volatile organic compounds (VOCs) oxidized by ozone, OH- and NO_3-radicals in the atmosphere. The products of these oxidations have different kinds of functional groups (e.g. acid- and aldehyde-groups). Thus the volatility of the compounds decreases and nucleation or condensation on existing particles occurs. As monoterpenes are an important part of VOCs, the atmospheric oxidation is of high interest in aerosol research. α-Pinene is a very common monoterpene and therefore an often used model substance for mechanistic studies (Müller *et al.* 2009).

Besides oxidation products with monomeric structure, such as pinic acid for example, dimers were found in SOA. The formation of these is discussed intensively. Various reactions in the gas- and/or particle phase are possible. The dimers of α-pinene are of high interest due to the quantity of this terpene in the atmosphere. A lot of research hereby is focused on the compounds with the molecular mass 358 and 368. For the former very different formation pathways and chemical structures are suggested in the literature. These two dimers are of special interest because they were also observed in environmental samples. Therefore the possibility of using them as marker substances for various atmospheric conditions is discussed. A much higher number of dimeric compounds can be detected in atmospheric simulation chambers. This is due to the higher concentration of monoterpene and ozone used especially in mechanistic studies (Kundu *et al.* 2012).

Ozonolysis of α-pinene in the reaction chamber at the University of Göttingen, which can be operated at reduced pressures, is used to get more information about the formation process. This spheric reaction cell has a volume of 64 L with ozone and alkene premixing chambers, which allow well-controlled reactant mixing within two seconds. A FTIR- spectrometer for gas phase species analysis and a SMPS system for measuring particle size distributions and mass are attached to the chamber (Wolf *et al.* 2011). The aerosol particles were sampled on filters after the reaction in the chamber was finished (typically after five minutes) and the chamber was filled to ambient pressure. A methanol-water-solution was used for extraction of the filters. RP-HPLC-ESI-IT/MS^n was used for analysis.

Experiments were performed at three different reaction pressures (10, 20 and 460 mbar) with almost identically concentrations of ozone (5 ppm at 1 bar) and excess α-pinene. In general lower pressure yields lower particle number concentrations and smaller aerosol masses.

Therefore, the samples of the high pressure experiments at 460 mbar were used to identify the ozonolysis products. The often reported monomeric products such as terpenylic acid, pinic acid and hydroxypinonic acid were detected. About twenty dimeric compounds with a mass-to-charge ratio (m/z) between 300 and 400 were observed including the above mentioned dimers 358 and 368. For most of these dimers no confirmed or even suggested chemical structures are available in the literature. The MS/MS-experiments showed for the majority of the dimers a fragment with m/z 185 like pinic acid. Therefore, it is assumed that most of these compounds contain a pinic acid analogue or a closely related chemical structure.

The analysis of the filter samples confirmed a decreasing yield with decreasing reaction pressure for most of the compounds. Due to the lack of authentic standards for almost all substances only a semi-quantitative analysis was performed by comparison of the peak area. A roughly classification in six groups was performed (as shown in table 1).

The strong influence of pressure on the relative yields of SOA components seems to be related to the presence and absence of stabilized Criegee intermediates and different degrees of chemical activation of other intermediate species at high and low pressures. After further analysis the results are expected to provide constraints for suggested dimer formation mechanisms.

Table 1. Classification of pressure dependency. 100% represents the product yield at 460 mbar.

Group	1	2a	2	2b	3	4
10 mbar	< 1%	< 1%	1-3%	3-10%	3-25%	>50%
20 mbar	< 5%	5-20%	5-20%	5-20%	20-50%	>50%

Introduction

In the atmosphere, black carbon is known to reduce visibility and affect the global radiation budget. A recent study has estimated the direct radiative forcing due to present-day black carbon emissions to be in the range from +0.17 W/m² to +1.48 W/m², with a certainty of 90 % (Bond et al., 2013). In order to better understand the role of black carbon in the atmosphere, a detailed characterization of freshly emitted particles and their subsequent ageing processes, involving coating due to condensation of secondary material, and possible restructuring of soot agglomerates, is needed. The knowledge of the particles' density is crucial because it is directly influenced by restructuring of soot particles.

Herein, we present size, density and mass distributions of freshly produced soot particles from several sources. The particles are characterized using a Differential Mobility Sizer (DMA) system and a Centrifugal Particle Mass Analyzer (CPMA), in series.

Another reason for conducting these measurements are mass-based thresholds used in air quality monitoring. Since the CPMA classifies particles according to their mass-to-charge ratio (Olfert & Collings, 2005) the mass distribution measurements can be a powerful application to determine the mass-based net output from any source. The results could then be compared with values obtained from currently used instruments.

Experimental

The actual experiments were performed in our laboratory at ETHZ. Four types of soot particles were generated. In more detail, two types using a Combustion Aerosol Standard (CAST) burner (fuel-rich (1) and fuel-lean (2)), one type (3) from a PALAS GFG aerosol generator and a (4) carbon black (Cabot Regal Black). Soot type 1, 2 and 3 are especially marked as surrogates for diesel soot by the manufacturers. In addition, soot particles from aircraft engine exhaust were investigated at the airport in Zurich during the Aviation Particle Regulatory Instrumentation Demonstration Experiments (A-PRIDE) campaign in November 2012. Here, sampling was performed directly behind the engine.

The freshly generated soot particles are first charge equilibrated to account for multiple charging and selected according to their mobility size (d_m) by a DMA. The monodisperse flow then enters the CPMA that records the mass distribution by scanning over the relevant mass range. A condensation particle counter counts the corresponding particle number concentration.

Results

Fig. 1 exemplarily depicts the effective density (ρ_{eff}) of soot from aircraft engine exhaust for different selected d_m measured during A-PRIDE. This can be mathematically derived by using the fractal relationship between the mass and the mobility size and the definition of the effective density. As can be seen, the effective density decreases with increasing mobility diameter. This effect will be discussed in detail for all datasets.

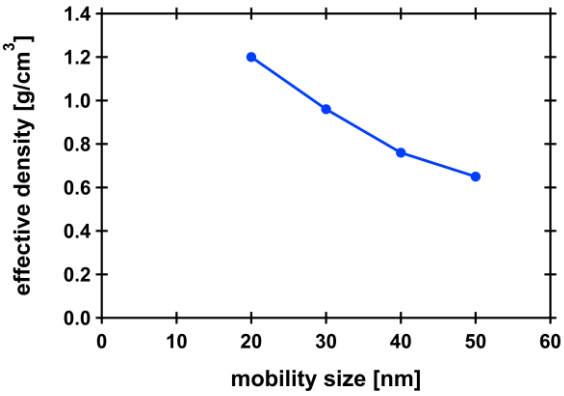

Fig. 1 Effective density of aircraft engine exhaust particles

Furthermore, we will compare our data to those from Gysel et al., 2012, who used an Aerosol Particle Mass analyser (APM) based on a very similar working principle as the CPMA.

Atmospheric aerosol size distribution during winter period in Ostrava-Radvanice

A. Baranova, J. Hovorka

Institute for Environmental Studies, Faculty of Science, Charles University in Prague, Prague 2, 12801, Czech Republic

Keywords: urban atmosphere, smog, SMPS, APS

Presenting author email: alexandra.baranova@natur.cuni.cz

Airborne particulate matter is one of the most important components of urban air pollution that affects health condition of human population. Fine aerosol particles have the highest impact on human health s, since they can bind carcinogenic substances and cause severe respiratory problems (Kim *et al.* 2007). Submicron particles are also substantial atmospheric component of urban smog. However, coarse aerosol particles contribute to air pollution level as well. With this reason, atmospheric aerosol investigation and aerosol size distribution particularly is considered to be very important. The location in the center of the Moravian-Silesian region - the city of Ostrava – was selected for measuring campaign. According to numerous studies, Ostrava is a city with the worst air quality not only in the Czech Republic, but in Europe as well (Rossnerova *et al*. 2011).

The measurement was performed using isothermal mobile container of the Laboratory for air quality measurements of the Institute for Environmental Studies, Faculty of Science, Charles University in Prague. It was located in Ostrava-Radvanice and Bartovice (49°48'40.4"N, 18°20'15.8"E) during the winter period 25.1-22.02.2012. 5 minute integrates of number size distribution of particles with aerodynamic diameter 14-10000 nm were determined, by combination of Scanning Mobility Particle Sizer (SMPS 3936L25) and Aerodynamic Particle Sizer (APS 3321). Also 5 min concentrations of gaseous components NO_x, O_3, CO, SO_2, CH_4 and NMHC and meteorological parameters: wind speed, wind direction, temperature, relative humidity and global radiation were determined.

Two periods can be distinguished within the campaign: smog and after smog. Smog period (25.01.-15.02.) is characterized by low air temperature (median T = -14.8 °C), low wind speed (median WS = 0,7 ms^{-1}) and inverse layering of atmospheric boundary layer. As results, high median concentrations of $PM_{2.5}$ = 104 μgm^{-3} were observed. Smog period continued until a warm front moved over the locality. Air temperature and wind speed increased (median T = -1.7 °C, median WS = 1.1ms^{-1}) substantially. Also heavy snow storms occurred at the beginning of the period. As result, median concentration of $PM_{2.5}$ dropped to 38 μgm^{-3}.

Particle number concentrations are dominated by particles of less than 0.6µm of aerodynamic diameter both in smog and after smog periods (Fig.1). Nevertheless, number size distribution averaged over smog period was found near monomodal with mode at 150 nm, while there was clear bimodality, the first mode at 25nm and the second at 55 nm, for the distribution in after smog period (Fig.1). Both disappearance of the first mode and the increase in particle diameter of the second mode are consequences of ultrafine particle coagulation on particles of accumulation mode produced during the smog period.

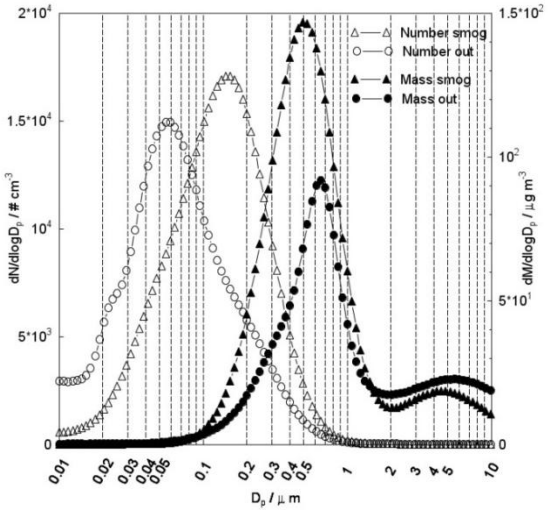

Figure.1 Aerosol particle number and mass size distributions during smog (25.1-15.2) and after smog (15.2.-22.2) periods in Ostrava-Radvanice, in winter 2012

Similarly to particle number submicron particles aerosol particles dominated the aerosol mass. But contrary to number size distributions, mass size distributions were bimodal for both the periods. The first mode was at 0.5µm for smog period and 0.65 µm for after smog period respectively while the second mode at about 5 µm was common to both the periods. The increased mass due to coarse aerosol after smog period is caused by meteorological changes when particles of greater size could be raised upwards because of increased wind speed.

Two aerosol types have been traditionally reported over the Brazilian area. On the one hand, it is well recognized that the biomass burning activity has an important impact on the air quality in Brazil. According to CPTEC/INPE (www.cptec.inpe.br/queimadas), between $11.5 \cdot 10^4$ and $20.5 \cdot 10^4$ actives fires per year were detected in 2006-2012 period. In particular, biomass burning activities related to sugarcane crops is especially relevant in the Northeastern and Southeastern areas. Several works reported studies related to biomass burning covering different aspects such as gases, particulate matter and their transport. On the other hand, the largely local emission sources determine the chemical composition of the atmospheric aerosol in all metropolitan regions, with the most populated and industrialized areas in the Southeastern Brazil. This results in a small influence of long-range transported particles from elsewhere in term of aerosol load in Brazil and traditionally other different long-range transported aerosol types have been ignored over the Southeastern metropolitan areas as the State of São Paulo. However, it is possible to detect their presence on intensive optical properties such as the lidar ratio.

In order to achieve a better understanding of the spatial and temporal variability of the complex aerosol distributions on both regional and global scales, the transcontinental transport of different aerosol types is of the special importance and must be understood. Regarding Saharan dust, many field campaigns and studies have been conducted during the last years. However, most of them were performed close to source regions or considering short-range transport, and therefore the evolution of dust properties during transport is still misunderstood. The Atlantic Ocean is the major pathway of dust transport from North Africa, the latter being the Earth's largest source of mineral dust. Several studies have already been conducted to understand the physic-chemical properties of Saharan mineral dust. However, most of them were performed close to source regions or considering short-range transport, therefore the evolution of dust properties during transport is still misunderstood and many examples illustrate the need of a thoroughly understanding on the transcontinental transport of aerosols. Although the location of the Inter Tropical Convergence Zone (ITCZ) can be an indicator of the dust meteorology as a rough approximation, both meteorology and source features are the overriding factors determining the transport of dust in the atmosphere. Synoptic scale system provides a mechanism in the western Atlantic to inject dust across an active ITCZ. Up to now, the vertical distribution of Saharan mineral dust over South America is almost limited to a case study and a medium-term analysis of systematic (1 year) multiwavelength polarization Raman lidar observations of optical and microphysical particle properties, both over the Amazon Basin.

The analyses presented in this study are an evidence of the arrival of the transcontinental advection of Saharan dust and its subsequent detection in São Paulo, at latitudes very far from the Equator. For that goal, the synergetic combination of several approaches, including active (lidar) and passive (sun-photometer) remote sensing from ground and satellite platform (CALIPSO), were used.

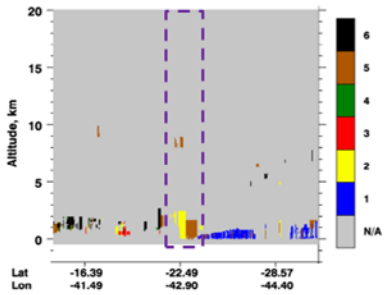

Figure 1. Aerosol subtype from CALIPSO on 26/12/2007 (night) around São Paulo (shaded box) detecting dust (yellow) and polluted dust (brown).

Presenting author email: alados@ugr.es

Microphysical and optical properties of aerosol particles present a strong dependence on relative humidity (RH). A better understanding of this RH effect is, therefore, very important for climate forcing calculations. Here, we present results from a campaign performed in an urban environment in southern Spain (Granada, 37.18ºN, 3.58ºW, 680 m a.s.l) during winter season. The aerosol light-scattering coefficient ($\sigma_{sp}(\lambda)$) was measured with two integrating nephelometers (TSI 3563) at dry (Dry-neph) and at a predefined RH (Wet-neph). The light scattering enhancement factor (f(RH) = σ_{sp}(RH)/ σ_{sp}(dry)) was used to quantify the dependence of σ_{sp} on RH. We defined two operation procedures: 1) Keep the RH of the Wet-neph at a constant value (85%) and 2) Scan the RH between 30-90%. Additionally, the aerosol light-absorption coefficient was measured with a MAAP (Multi-Angle Absorption Photometer) and an aethalometer AE-31. Filter samples were also collected in PM_1 and PM_{10} fractions for chemical analysis.

During the campaign, dry light-scattering and absorption coefficients showed a mean value (± standard deviation) of 40±40 Mm^{-1} at 550 nm and 17±18 Mm^{-1} at 637 nm, respectively. Both coefficients showed a high variability due to the diurnal changes in the local emissions (mainly caused by traffic) and in the meteorological conditions during the campaign. The dry scattering Angstrom exponent calculated between 450 and 700 nm was 1.7±0.4 and the single scattering albedo at 637 nm was 0.7±0.1, denoting a predominance of fine particles and a significant fraction of absorbing particles. These values are typical of our urban station during winter season (Lymani et al., 2010; Titos et al., 2012). f(RH=85%) at 550 nm presented a mean value of 1.5±0.2, reaching values up to 3.4. The mean value is in accordance with the value of 1.4 reported by Yan et al. (2009) at an urban station in Beijing. The average diurnal evolution of f(RH=85%) and the single scattering albedo is shown in Figure 1. f(RH=85%) presented two minima during morning and afternoon traffic rush hours, probably due to the relative increase of non-hygroscopic fraction (like black carbon) due to traffic emissions. This fact can be observed in the diurnal evolution of ω_0(637 nm) that also presented two minima denoting an increase in the relative contribution of absorbing particles during the traffic rush hours. The afternoon minimum in the f(RH=85%) is lower than the morning minimum in contrast with the single scattering albedo which presented the minimum value during the morning. This fact evidences that not only the increase in the contribution of BC to the total aerosol load is responsible of the decrease of f(RH=85%). In this sense, it could be related to aging processes that lead to lower f(RH) during the afternoon than during the morning. In the early morning (around 3-4 GMT) the f(RH=85%) reached it maximum value, probably due to the decrease in BC concentrations as a result of the reduction in local anthropogenic emissions and an increase in the water soluble fraction. This increase in the water soluble fraction can be related with higher levels of ammonium nitrate during the cooler time of the day (Park et al. 2005).

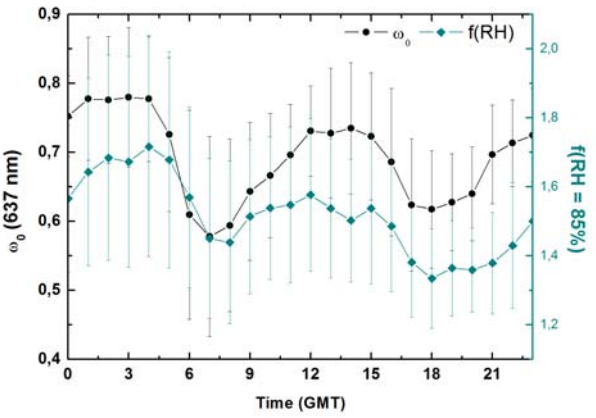

Figure 1. Average diurnal evolution of f(RH=85%) and single scattering albedo at 637 nm. The error bars represent the standard deviations.

Relating the wavelength dependency of the absorption coefficient and the aerosol type

A. Cazorla[1,2], G. Titos[1,2], H. Lyamani[1,2] and L. Alados-Arboledas[1,2]

[1]Centro andaluz de Medio Ambiente, University of Granada, Junta de Andalucía, Granada, 18006, Spain
[2]Departmento de Física Aplicada, University of Granada, Granada, 18071, Spain
Keywords: absorption coefficient, absorption Ångström exponent, aerosol type.
Presenting author email: alados@ugr.es

Absorption of solar radiation due to aerosol particles is mainly caused by carbonaceous particles and mineral dust. The Absorption Ångström Exponent (AAE) describes the wavelength dependency of the absorption coefficient and it can give information about the type of aerosol or source (Cazorla et al., 2013). In this sense, black carbon (BC) absorption follows a λ^{-1} spectral dependency, yielding an AAE equal to 1 (Bergstrom et al., 2002), while brown carbon and mineral dust have a higher contribution to absorption in the ultraviolet and blue spectral regions yielding an AAE greater than 1 (Kirchstetter et al., 2004).

In this study, we analyzed data from an aethalometer AE31, that measures the aerosol light-absorption coefficient at 7 wavelengths (370, 470, 520, 590, 660, 880, 950 nm), installed in Granada; an urban city in the southeast of Spain (37.18ºN, 3.58ºW, 680 m a.s.l). The period of study comprises from September 2012 to January 2013.

We calculated the AAE using all the aethalometer wavelengths (AAE), using the three shorter wavelengths (AAE_UV), and using the three longer wavelengths (AAE_IR). Daily AAE values reveal that there are two distinct periods, one comprised from the beginning of the study period to November 15, and another from November 16 to the end of the study period (Fig.1).

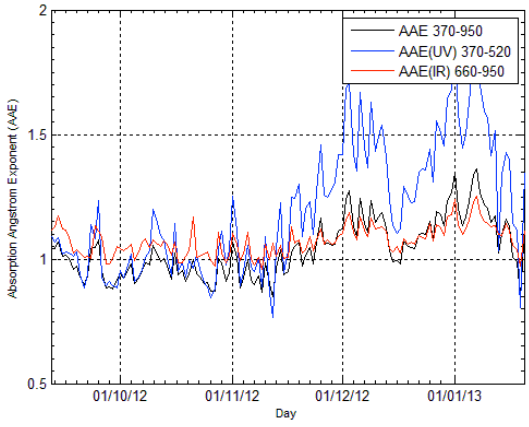

Figure 1. Aethalometer daily AAE

The first period has an AAE, AAE_UV and AAE_IR mean value of 1.0±0.3, 1.0±0.5 and 1.0±0.5 respectively; indicating the predominance of BC particles emitted by traffic source. On the other hand the second period presents an AAE, AAE_UV and AAE_IR mean value of 1.1±0.3, 1.4±0.5 and 1.1±0.3. A value of AAE greater than 1 indicates a change in the dominant absorbing type of aerosol. This change is related to seasonal changes in the emission sources; in winter domestic heating (based on fuel-oil and biomass combustion) is an additional local anthropogenic source. As we can see, this change is more pronounced for AAE calculated using the shorter wavelengths (AAE_UV), pointing out an increased contribution of brown carbon to aerosol population.

The results show the importance of measuring absorption coefficient in a wide range of wavelengths (from UV to near IR) for identifying aerosol types.

Measurements of the precipitable water vapour (*W*), defined as the total amount of water vapour in the atmospheric column, are being very important to characterize water vapour role in radiative forcing, hydrological cycle and climate. From several decades ago sun-photometry measurements at the water vapour absorption bands around 940 nm are being used to retrieve W. But it faced with problems related to an appropriate methodology and calibration. AERONET network addresses those problems and standardizes calibration and measurement protocols, as well as data quality [Smirnov et al., 2004]. But to date, evaluation of AERONET retrievals of W are sparse.

Balloon-borne radiosondes have been used as standard to retrieve W from decades ago, but faces with problems as the drift of the sonde, the 'dry' bias or the batch dependence [Milosevich et al., 2006]. Moreover, zenith wet delays measured by GPS allow the retrievals of W under almost all weather conditions. Similarly, W retrievals (and also atmospheric profiles of water vapour) can be obtained from sky brightness temperature measurements around 22.235 GHz water vapour absorption band by microwave radiometers. The uncertainties of these techniques to retrieve W stated in the bibliography are of ~5% for MWR and GPS and ~10-15% for balloon-borne.

The scope of this work is to evaluate AERONET retrievals of W versus those by MWRs, GPS and balloon borne. To this end, we use the large database of MWRs and balloon-borne measurements made at the three major sites of the U.S. Department of Energy Atmospheric Radiation Measurement (ARM), located at Southern Great Plains (36.61ºN, 97.49 ºW, 318 m a.s.l.), Nauru Islands (0.52 ºS, 166.92 ºE, 7 m a.s.l.) and Barrow (71.31 ºN, 156.67 ºW, 0 m a.s.l.). GPS retrievals of W at these sites are provided by SUOMINET network managed by the University Corporation for Atmospheric Research (UCAR).

For 10 years of correlative measurements between the different instrumentation at the Southern Great Plain, Figure 1 present number density plots of W obtained by MWRs, GPS and balloon-borne as function of those obtained by AERONET. The linear fits forced through zero revealed slopes of 1.10 ± 0.01, 1.05 ± 0.01 and 1.04 ± 0.01 for the evaluations versus MWR, GPS and balloon-borne. These values indicate underestimation of W retrieved by AERONET. The extended study, including also the other ARM sites, indicates underestimations by AERONET of ~7.8% versus MWR, ~3.8% versus GPS and ~4.8% versus balloon-borne radiosondes. But assuming an the uncertainty of AERONET retrievals of W is ~10%, the stated differences within the different instrumentation are within the error margins. Therefore, we conclude that within a 10% uncertainty there is no golden instrument to retrieve precipitable water vapour. The largest differences found between AERONET sun-photometers and MWRs can be explained by the differences in the spectral databases and radiative transfer models between sun-photometry and microwave radiometry. Actually, the strength of the water vapor absorption currently remains a subject of discussion in the scientific community [e.g. Alexandrov et al., 2009]. A better agreement between these two techniques should imply combined efforts to use the same spectral database with similar constraints.

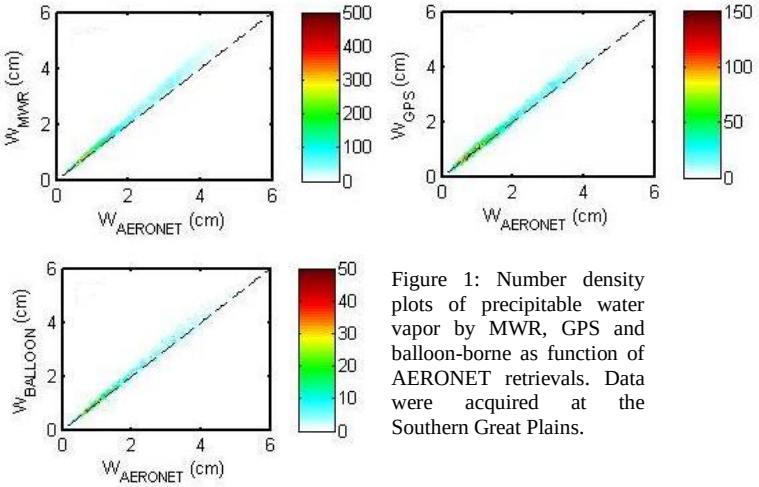

Figure 1: Number density plots of precipitable water vapor by MWR, GPS and balloon-borne as function of AERONET retrievals. Data were acquired at the Southern Great Plains.

Aerosol Impact on cloud properties in Pakistan

K. Alam[1,2], R. Khan[1]

[1]Institute of Physics & Electronics, University of Peshawar, Peshawar,25120, Pakistan
[2]Higher education commission (HEC), Pakistan

Keywords: Aerosol, Cloud, Cloud fraction, Liquid water path, Pakistan.
Presenting author email: khanalamso@gmail.com

This study investigates aerosol impact on various properties of clouds over different cities of Pakistan using Moderate Resolution Imaging Spectroradiometer (MODIS) data during the period (2001-2011). The relationship between AOD and other cloud parameters, namely water vapor (WV), cloud fraction (CF), cloud optical thickness (COT), cloud liquid water path (CLWP), cloud top temperature (CTT), and cloud top pressure (CTP) were analyzed. On smaller temporal scales, latitudinal variations of both WV and AOD produce high correlations (> 0.8) in some regions and moderate (> 0.6) in the other regions. An increasing trend in CF with AOD was found over urban region in the period of observations. The CF values were higher for Lahore than the other selected regions during the whole period.

The correlation between AOD and CWPL was found to be positive during autumn and winter seasons, while negative correlation was observed during the other seasons for all the selected regions. COT showed negative correlation with AOD at all locations except Karachi during spring and summer seasons. AOD showed a positive correlation with CTP and CTT for spring season and a negative correlation was observed for summer for the all investigated regions. Furthermore, in warm clouds AOD and CTP were negatively correlated for all regions except Peshawar, whereas AOD and CTT were positively correlated for all regions except Karachi. In cold clouds the relationships between AOD and CTP, and AOD and CTT were negative except Karachi. Thus meteorological parameters, geographical conditions, as well as warm and cold clouds are the causative factors for AOD and CTP, and AOD and CTT variations.

Remote Sensing of Aerosol optical property Over the Arabian Gulf

F.M. Al-Kandari, H.K. Al-Jassar and K.S. Rao

Department of Physics, University of Kuwait, Khaldiya, Kuwait, 13060, Kuwait
Keywords: Aerosol Optical depth, sun photometer, Aeronet, Absorption factor
Presenting author email: fatma.alkandri@gmail.com

The aim of the study is to detect the pollution periods associated with dust emissions according to aerosols spectral behaviour and the change of wind regimes over the Arabian Gulf. Three Aerosol Robotic Network (AERONET) sites are involved in the study - Kuwait University, Kuwait (29.32°N, 47.97°E), Solar Village, Riyadh (24.91°N, 46.41°E) and Dhadnah Al Fujairah, UAE (25.51°N, 56.327°E).

In Gulf sites fine mode particles lie in a geometric mean radius range of $0.05 < r < 0.33 - 0.44$ μm, while coarse mode lie particles in the range $0.33 - 0.44 < 1 < 15$ μm (figure 1).

Clarke et. Al., (2004) separated soot from dust by taking into assumption that sub micrometer particles have radii within range ≤ 0.75 μ. Sub micrometer particles are divided into two categories. In Kuwait site we found particles with radii between 0.75 and 0.35 μm have positive significant correlation ~ 0.4 between total volume concentration and absorption factor σ_{abs} in Kuwait. Such trend is related to existence of urban dust. The results of the other sites are demonstrated in Table (1).

Single Scattering Albedo (SSA) is retrieved for wavelengths corresponding to sky radiance measurements. SSA daily averages are computed from hourly data of level 1.5 with solar zenith angle $\leq 55^{o}$. In Kuwait SSA increases with wavelength in spring and summer with associated high absorption at 470 nm wavelength. This situation occur when dust work as a carrier for soot. Soot signature is found in winter season. In Solar village SSA has almost neutral trend in all seasons. Finally in Dhadnah SSA reveal dust dominance with soot emissions in spring and dry summer interval and neutral in humid summer & autumn.

Table 1: Summarize the results of the urban dust correlation with absorption factor as well as the soot percentage in AERONET data.

Aeronet Site	Radii (μm) Division	$r_{VOL-\sigma abs}$	Aerosol Load Percentage
Kuwait	$0.35 \leq r < 0.75$	0.40**	Urban dust
	$r < 0.35$	0.05**	5.5% (soot)
Solar Village	$0.35 \leq r < 0.75$	0.525**	Urban dust
	$r < 0.35$	0.41*	2.9% (dust carrying soot)
Dhadnah	$0.35 \leq r \leq 0.75$	0.632*	Urban dust
	$r < 0.35$	0.005	4.87%

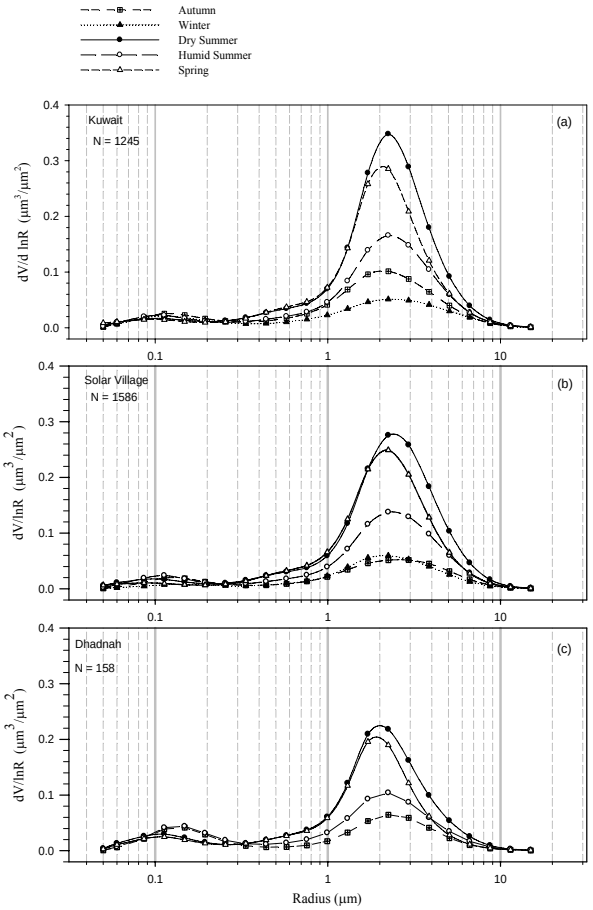

Figure 1: Seasonal aerosol volume size distribution versus geometric mean radius in Kuwait, Solar village and Dhadnah. The number for averaged retrieval is shown for each season.

Organic Fraction of Laboratory Generated Primary Marine Aerosol

A. C. Butcher[1], S. M. King[2], T. Rosenoern[3], and M. Bilde[4]

Presenting author email: andrew@chem.ku.dk

Marine aerosols are an important source of aerosols in the Earth's climate system. Despite their importance, much remains unknown about the characteristics of these aerosols. The largest uncertainty remains in the submicron aerosol size range, where flux estimates span several orders of magnitude (de Leeuw *et al.* 2011). In addition to this, the organic fraction of these particles remains a large open question.

Building on previous work with a simulated sea spray aerosol tank at the University of Copenhagen (King *et al.* 2012), the organic fraction of laboratory produced aerosol is probed with the use of a thermo-denuder forming a Volatility-Tandem Differential Mobility Analyzer (VTDMA) operating at high temperatures (∼400°C). By selecting specific proxy sea water solutions with known organics and salts, the organic volume fraction volatilized from aerosols at specific mobility sizes can be determined, yielding the organic fraction of aerosols.

Several organic-salt systems were investigated, with results presented here from L-Serine, an amino acid found in the sea micro layer, with respect to varying concentrations of sodium chloride (NaCl) and an artificial sea salt, Tropic Marin Sea Salt (TMSS). A 1 g sample of organic in 10 L of Milli-Q (18MΩ) is bubbled using a vertical plunging jet producing bubble burst-aerosols characteristic of primary marine aerosols. Salt concentration is increased in the tank while the first DMA is set to several diameters with sufficient concentration for VTDMA study. Resulting modal diameters of the size distribution before and after the thermo-denuder are then used to calculate the volume fraction remaining (VFR). This results in the VFR plot shown in Figure 1.

Figure 1 shows that the volume fraction remaining, following passage of aerosols through the thrermodenude, decreases for all sample aerosols. For the TMSS:Serine system, the volume fraction remaining increases with increase in salt:organic ratio. A similar trend is seen for the NaCl:Serine system, however less pronounced.

A trend of volume fraction remaining with particle diameter is seen for TMSS:Serine ratios of 10:1 and 100:1, repectively, with a slight decrease in VFR near 100 nm. The low VFR for 20 nm particles implies a high organic fraction in the original particles and when considered relative to VFR of 60 nm particles, gives evidence for a size dependent organic fraction.

These results indicate a promising avenue with which to investigate the organic fraction of laboratory produced aerosols, which allows for the careful control of the precise organic and salt concentrations of a sea water proxy. Estimates of specific organics within the surface layer of the ocean can then be tied to aerosol production and organic mass flux over the ocean. Further work is to include more sample matrices and characterization of experimental error.

Keywords: PM_{10}, Source Apportionment, Cape Verde, Sahara Desert.
Presenting author email: smarta@ctn.ist.utl.pt

Sahara Desert is the most important source of mineral dust, contributing more than 1900 million tons per year (Goudie, 2009; Goudie and Middleton, 2006; Prospero, 1996; D'Almeida, 1986) and responsible for almost half of all the aeolian material provided to the world's oceans. Due to its geographical position, Cape Verde is highly affected by the transport of dust from the Sahara desert. Therefore, it is essential to elucidate the role of Saharan dust may play in the degradation of Cape Verde air quality, human health, wellbeing, visibility, tourism and economy.

The objective of this study was (1) to perform a chemical characterization of the airborne particles sampled in Cape Verde, (2) to identify the main sources and origins of the particles and (3) to assess the influence of Sahara desert on local suspended particles.

PM10 was sampled during 2011 and chemical characterization of particles was performed by Neutron Activation Analysis and Particle Induced X-ray Emission for elemental measurements, by Ion Chromatography for the determination of water soluble ions and by a Thermal-optical system for the measurement of carbonaceous aerosol. Source apportionment was performed by integrating Principal Component Analysis with Multilinear Regression Analysis, Positive Matrix Factorization and Cluster Analysis of Backward Trajectory.

Results showed that Cape Verde aerosol is affected principally by natural sources: dust coming from Sahara desert contributes on average to 48% of the total PM_{10} mass and sea salt spray contributes on average to 20%. During air mass trajectories from Sahara, dust contribution increases to more than 60% and PM_{10} reach concentrations 10 times higher than the EC limit values and WHO guidelines.

This work was supported by the Portuguese Fundação para a Ciência e Tecnologia – FCT, under the project CVDust: Atmospheric Aerosol in Cape Verde Region: Seasonal Evaluation of Composition, Sources and Transport, PTDC/AAC-CLI/100331/2008. J. Cardoso and M. Almeida-Silva acknowledge the FCT PhD grants SFRH/BD/6105/2009 and SFRH/BD/69700/2010, respectively.

[3]Institute of Chemistry, São Paulo State University, Araraquara, SP, 14800-900, Brazil
Keywords: TSP, sugar cane burning, organic speciation, homologous compounds.
Presenting author email: celia.alves@ua.pt

Sugar cane burning is carried out before manual harvesting to make the process easier and less labour-intensive. It takes place during the dry season, lasting from May to November. São Paulo State is the largest sugar cane producer in Brazil, accounting for 51% of the total production. The planted area in the State was 4.6 million hectares in 2010/2011 (IBGE, 2011). Around 40-50% of this area was burned before manual harvesting.

To evaluate the impact of sugar cane burning emissions on the atmospheric aerosol composition, samples of total suspended particles (TSP) were collected in two agricultural regions of São Paulo State (Araraquara and Ourinhos) using a high-volume sampler at a flow rate of 1140 L min^{-1}. Punches of the filters were solvent-extracted and fractionated into different classes of organic compounds by vacuum flash chromatography. The detailed organic speciation was performed by gas chromatography-mass spectrometry. Polar oxygenated compounds bearing carboxylic or hydroxyl groups were derivatised prior to injection into the chromatograph.

A series of *n*-alkanes were identified in the aerosol samples, ranging from C_{11} to C_{36}. The highest concentrations were observed for the C_{24}-C_{30} homologues. All the samples presented carbon preference indices (the ratio between odd and even carbon number homologues) around 1, which have been described as typical of petrogenic inputs (Alves, 2008). Vascular plants synthesise epicuticular waxes containing odd C number *n*-alkanes, usually in the C_{25} to C_{33} range with C_{29} or C_{31} as dominant homologues. The lack of odd C number predominance in this study could be due to the lesser amount of waxy hydrocarbons in the stems and leaves of the herbaceous biomass crops. The *n*-alkanes derived from plant waxes were calculated by subtraction of the average of the next higher and lower even carbon numbered homologues, taking as zero the negative values. Except for one sample (13/08/2010), in which 33% of the *n*-alkane content was attributable to plant waxes, the waxy fraction of aliphatics in the remaining samples ranged from 4.5 to 7%. The highest concentrations of *n*-alkanes were observed in samples more impacted by emissions from sugar cane burning at nighttime (Figure 1). These concentrations are much higher than those obtained in 24-h samples of PM_{10} in Piracicaba, a city in São Paulo State impacted by the same agricultural activities (Vasconcellos *et al*., 2010).

A discontinuous series of *n*-alkanols (C_{10}-C_{30}) was detected, peaking at C_{18}, C_{28} and C_{30}. Total concentrations ranged from 9.37 to 161 ng m^{-3}. The lowest level of *n*-alkanoic acids (9.66 ng m^{-3}) was obtained during the non-harvest period, while values up to 374 ng m^{-3} were reached in samples strongly impacted by smoke. In the aerosol samples of the harvest season, the homologous series encompassed acids from C_8 to C_{24} with a strong even carbon number predominance, currently associated with vegetative detritus. A series of *n*-di-acids, ranging from propanedioic to hexadecanedioic, were also present in TSP. Malic acid varied from undetectable levels for the non-harvest period to nearly 3300 ng m^{-3} during the dry season.

Taking into account the high concentrations observed for many of the homologous compounds, the exposure to these aerosols by inhalation or skin contact may be of concern due to the hazardous properties of some constituents (e.g. *n*-alkanes > C_{16}).

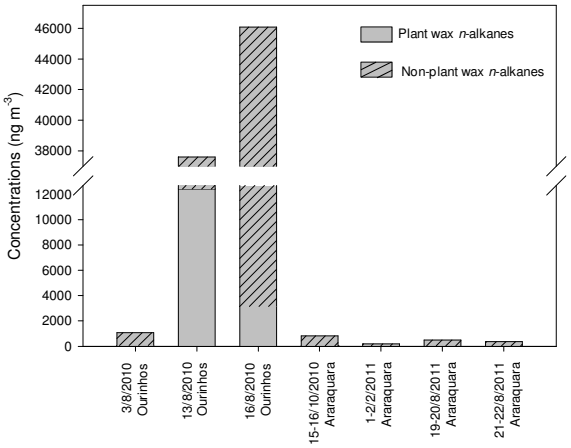

Figure 1. Concentrations of *n*-alkanes in samples from Ourinhos (nighttime samples) and Araraquara (24-h samples).

Presenting author email: celia.alves@ua.pt

While advances in engine technology have led to considerable improvements in emissions in recent years, particulate matter (PM) from motor vehicles, especially from diesel, continues to be a major source of urban aerosol pollution. PM has been identified as one of the priority mobile source air toxics. Motor exhaust also contains volatile organic compounds (VOCs) that have direct health implications and act as precursors to photochemical ozone formation.

In this study, a total of 8 light-duty diesel and gasoline vehicles representative of the Southern European fleet were tested on a chassis dynamometer. Sampling of vehicle exhausts was performed using two real-world driving cycles: the ARTEMIS Road (ArtRoad with cold and hot starts) and the ARTEMIS Urban (ArtUrb) (André *et al*., 2006). The organic and elemental carbon (OC and EC) content in the PM filters was determined by a thermal-optical transmission technique. VOCs sampled in sorbent tubes were analysed by a thermal desorption/cryogenic concentration method on a gas chromatograph equipped with a thermal desorption injector and a flame ionisation detector.

The particulate carbon emission factors were significantly lower under the ArtRoad compared to ArtUrb driving cycle with cold start. In general, hot start-up driving conditions produced the lowest emission factors (Fig. 1). A tendency to the decline of carbonaceous emissions from Euro 3 to Euro 5 diesel vehicles is observed, whereas this trend is not registered for petrol-powered cars. The fraction of TC composed of EC is much lower in particles emitted by petrol vehicles (< 10%) than by diesel engines (50-95%). However, the EC content in emissions from more modern vehicles equipped with DPF (diesel particulate filter) is almost negligible.

The measurement of unregulated pollutants comprised about 20 different VOCs in the C_5–C_{11} range. Among these, benzene, toluene and xylenes (BTX) were generally the dominant species. A significant decrease in emissions from Euro 4 to Euro 5 petrol-powered vehicles was observed (Table 1). The trend in VOC emissions is unclear when diesel engines are considered. During DPF regeneration cycles, emissions are several times larger than those during normal engine operation.

Taking into account the small number of vehicles per category, these results should be faced as indicative and complementary tests are strongly encouraged.

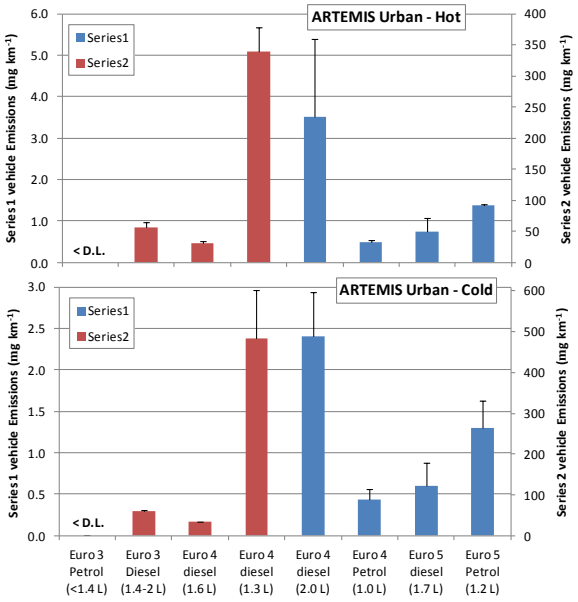

Figure 1. Total carbon (TC=OC+EC) emission factors (< D.L. means lower than detection limit)

Table 1. BTX emission factors (μg km^{-1}) for petrol-powered vehicles.

Keywords: wildfires, $PM_{2.5}$, $PM_{2.5-10}$, hydrocarbons
Presenting author email: celia.alves@ua.pt

In summer 2010, smoke samples were collected from six wildfires occurring over central Portugal.

In order to collect sequentially, on pre-fired quartz fibre filters, coarse ($PM_{2.5-10}$) and fine ($PM_{2.5}$) smoke particles from the plumes, a tripod high volume sampler operating at a flow of 1.13 m^3 min^{-1} was used. Sampling was performed at 1.5 m above ground, downwind from the burning areas, at distances of 10-100 m from the fire fronts. The organic and elemental carbon content (OC and EC) of particulate matter was analysed by a thermal-optical transmission technique. The detailed speciation of organic compounds in smoke samples was carried out by gas chromatography-mass spectrometry (Alves *et al*., 2011).

The chromatographically resolved organics, object of this study, are *n*-alkanes, *n*-alkenes, polycyclic aromatic hydrocarbons (PAHs), carbonyl compounds and acid methyl esters.

The smoke particle concentrations were in the ranges 0.69-12 mg m^{-3} for $PM_{2.5}$ and 0.085-0.66 mg m^{-3} for $PM_{2.5-10}$. Fine particles represented 92±4.1% of the PM_{10} mass. On average, 47±13% of the $PM_{2.5}$ emissions consisted of organic carbon, whilst the OC mass fraction obtained for coarse particles was 27±13%.

Aliphatic compounds comprised the *n*-alkane homologous series from C_{10} to C_{34} without a clear odd-to-even carbon number predominance. The homologues with the highest concentrations (C_{max}) were C_{22}, for fine particles, and C_{29}, for coarse particles. The *n*-alkene homologous series ranged from C_{14} to C_{30}, with C_{max} at C_{20}, for both size fractions, showing an even-to-odd carbon number predominance. *n*-Alkenes derive mostly from the thermal dehydration of *n*-alkanols and, in smaller amounts, from the oxidation of *n*-alkanes during incomplete combustion (Oros and Simoneit, 2001). The *n*-alkane and *n*-alkene contents in the wildfire smoke particles were in the ranges 0.0022-1.2 mg g^{-1} OC and 0.0035-0.37 mg g^{-1} OC, respectively.

PAHs are formed as a result of incomplete combustion or thermal decomposition (pyrolysis) of the organic material. The OC-normalised concentrations of the dominant PAHs identified in coarse and fine smoke particles are presented in Figure 1. Retene was the dominant polyaromatic hydrocarbon found in both particle sizes. It is the fully aromatised thermal alteration product of the resin acids present in conifer woods (Ramdahl, 1983). Besides retene, fluoranthene and chrysene were the most abundant PAHs found in both size fractions. Benzo[a]anthacene, benzo[a]pyrene and benzo[e]pyrene, components with high mutagenic and genotoxic potential (Medeiros and Simoneit, 2008), were also identified in smoke samples. PAHs in biomass burning emissions are common to those emitted by other combustion sources. Diagnostic ratios are used as a tool for assessing the possible contribution of different sources (Alves, 2008). The ratios obtained in this study are listed in Table 1.

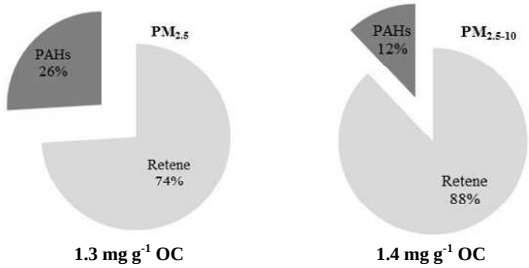

Figure 1.OC-normalised concentrations of PAHs detected in fine and coarse particles.

The dominant carbonyl compound in the wildfire aerosols was 6,10,14-trimethyl-2-pentadecanone. Alkanoates and vanillin were also found to be abundant in the majority of samples.

Table 1. PAH diagnostic ratios obtained in this study.

[3]TNO, Applied Research Organization, The Netherlands

Keywords: road dust, mitigation, resuspension, PM10.
Presenting author email: fulvio.amato@idaea.csic.es

Calcium-Magnesium Acetate (CMA) has been proposed as dust binder and its application on paved roads was recently tested in Sweden, Austria, Germany and UK in order to mitigate road dust emissions (Norman and Johansson, 2006; www.life-cma.at; www.tfl.gov.uk/corporate/projectsandschemes/17246.aspx). These previous studies showed that in most cases a reduction of kerbside PM10 concentrations was reached, even if short lived (few hours). The effectiveness of CMA in binding deposited particles seems to be closely related to the degree of road moisture (Gustafsson et al., 2010). This is a crucial aspect, mostly when evaluating the potential effectiveness in South European environments, where the higher solar radiation might further reduce the life-time of the air quality benefit.

In the framework of the LIFE+ AIRUSE project (www.airuse.eu), a measurement campaign will be carried out in April-May 2013 in the city of Barcelona (NE Spain), a typical Mediterranean city, spreading a 25% CMA aqueous solution (ICE & DUST-AWAY, Nordisk Aluminat) on a 1400 m stretch of a centric street (*Industria Av.*) counting typically 18000 vehicles/day. During the two months measurements the CMA solution will be spread 10 times during different mornings.

Given that the air quality benefit is expected to be short lived, CMA will be applied at 6 am local time, in order to exploit its effectiveness during the most-polluted hours due to traffic emissions (7-10 am).

Air pollutants will be monitored continuously at five monitoring sites:

- Two kerbside mobile laboratory vans installed at the kerbside of the road stretch treated with CMA;
- One control kerbside mobile laboratory van installed at the same road but on an untreated stretch, located 1 km away from the CMA stretch;
- One control kerbside mobile laboratory van installed at a parallel road (*Valencia Av.*) also untreated at a perpendicular distance of 650 m from *Industria Av.;*
- One control urban background monitoring station, located 5.5 km away from *Industria Av.*

Each monitoring site will be equipped with the following instrumentation:

- Optical counters (TSI Dust Track, TEOM and GRIMM);
- High volume samplers for PM10 (DIGITEL and MCV). PM10 samples will be chemical characterized for elemental composition (ICP-AES and ICP-MS), ECOC (thermo-optical analysis) and ions (HPLC and specific electrode for ammonium), following the procedure of Querol et al., (2001);
- Streaker low-volume samplers for hourly elemental composition of $PM_{2.5}$ and $PM_{2.5-10}$ by means of PIXE at two sites (Chiari et al., 2005);
- BC monitors (Mini-Aethalometers and Multi Angle Absorption Photometers);
- NOx, O_3 and SO_2 monitors;
- Meteo towers.

After the CMA treatment, conductivity tests will be carried out by means of the SOBO sensor (Boschung) to monitor the residual amount of CMA on the road surface. For traffic safety, friction tests will be also carried out following the UNE-EN 13036 protocol.

Results on air quality benefits will be shown.

Temporal variation of urban atmospheric aerosol during smog episodes in Debrecen, Hungary

A.Angyal[1], Zs. Kertész[1], Z. Ferenczi[2], E. Furu[13], Z. Szoboszlai[1], Zs. Török[13] and Z. Szikszai[1]

[3]University of Debrecen, H-4032 Debrecen, Egyetem tér 1, Hungary
Keywords: smog, source, PBL, PMF.
email: angyal.aniko@atomki.mta.hu

One of the leading environmental problems is the atmospheric particle matter (APM) in densely populated urban. High pollution levels regularly occur in most cities all around the world. Debrecen, the second largest city in Hungary and the regional centre of the Northern Great Plain region is no exception. There are several days every year when the particle matter concentration level exceeds the alarm threshold value (100 μg/m^3 for PM_{10} in 24- hours average). It is called "smog" by the authorities when the increased pollution level remains over the limit value for days.

The aim of this work was to study the variation of elemental components and sources of PM_{10}, $PM_{2.5}$ and $PM_{2.5-10}$ as well as their dependence on meteorological conditions during two smog episodes occurred in November 2011.

Aerosol samples were collected with two-stage PIXE International sequential streaker to study the hourly evolution of atmospheric aerosol concentration. Furthermore, 9-stage cascade impactors were also applied to get information about the size distribution of the elemental components.

Particle Induced X-ray Emission (PIXE) at IBA Laboratory (MTA Atomki) was employed to determine the elemental composition ($Z \geq 13$). Concentrations of black carbon were evaluated by smoke stain reflectometer. Weather prediction model (WRF) was applied to determine the planetary boundary layer (PBL) height values. Source apportionment was carried out on obtained data using the positive matrix factorisation (PMF) method.

The result of the elemental mass size distributions indicates that the elements can be classified into three groups. The first group comprising of minerals is with a dominant peak at the 8-16 μm range. The second group composed of K, Cl, S and Zn. One prevalent peak can be found in the droplet mode (0.5-1 μm) and another lower peak at 4-8 μm. High temperature processes such as combustion processes, particularly woody biomass burning release these elements. The third group contains Br and Pb. The low concentration of these elements seems to be considerable in droplet mode (0.5-1 μm) too, implying that these particles (comprising Br, Pb) used to have a major common source in gasoline.

The time pattern of the aerosol elemental components and PM sources exhibited strong dependence on the planetary boundary layer thickness. The concentration of some elements (K, Cl, BC) showed inverse tendency compared to PBL in the fine fraction in the first week (2-8 November 2011). This result is represented in Figure 1.

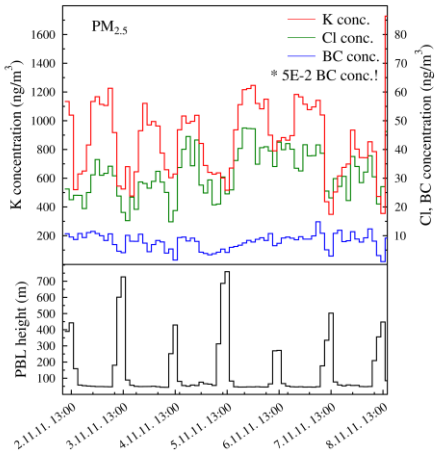

Figure 1. Temporal variation of the concentrations of the elements (K, Cl, BC) and the planetary boundary layer from the 2nd till 8th of November

Traffic derived elements (Fe, Cu, Zn, Pb) and elements from combustion processes (K, Cl, BC) showed also negative correlations with the PBL in the second week (15-21 November 2011).

PMF modelling determined four factors in both size fractions. The sources were identified as soil, biomass burning, traffic and oil combustion in case of fine fraction. Soil with soil improvement agent, two biomass burning, and road dust were recognised in $PM_{2.5-10}$. Due to above mentioned reasons, biomass burning as domestic heating was the main contributor to formation of smog and the meteorological condition was responsible for the accumulation of combustion aerosols during nights when the planetary boundary layer was the lowest.

Aerosol profile retrieval algorithm development and validation for Sentinel-4

Arnoud Apituley[1], Ofelia Vieitez[1], Bram Sanders[1], Piet Stammes[1], Ben Veihelmann[2], Yasjka Meijer[2], Rob Koopman[2]

[1]Royal Netherlands Meteorological Institute (KNMI), De Bilt, The Netherlands
[2]ESA-ESTEC, Noordwijk, The Netherlands
Keywords: aerosol layer height, oxygen A-band, validation, Sentinel-4, GOSAT, lidar
Presenting author email: apituley@knmi.nl

In the ESA AEROPRO project we develop and validate an oxygen A-band aerosol profile retrieval concept for ESA's Sentinel-4 mission.

Sentinel-4

Sentinel-4 is an ESA mission (Ingmann, 2012) that is part of of the Global Monitoring for Environment and Security (GMES) space component. The primary mission objective is the observation of the diurnal cycle of the tropospheric composition in support of the operational air quality applications of the GMES Atmosphere Services. The Sentinel-4 instrument is an Ultra-violet Visible Near infrared spectrometer (S4/UVN) which is embarked on the geostationary Meteosat Third Generation-Sounder (MTG-S) platforms. Key features of the S4/UVN instrument are the spectral range from 305 nm to 500 nm with a spectral resolution of 0.5 nm, and from 750 nm to 775 nm with a spectral resolution of 0.12 nm. The instrument shall observe Europe with a revisit time of one hour. The spatial sampling distance varies across the geographic coverage area and takes a value of 8 km at a reference location at 45° N. The expected launch date of the first MTG-S platform is 2019, and the expected lifetime is 15 years (two S4/UVN instruments in sequence on two MTG-S platforms).

Aerosol Layer Height Retrieval

In the AEROPRO project measured oxygen A-band spectra (758–778 nm) from the Japanese GOSAT Fourier Transform Spectrometer (Kuze, 2009) are being used as proxy for the Sentinel-4 data. The spectral resolution of GOSAT is downgraded to 0.12 nm, which is the Sentinel-4 resolution. This also helps to improve the Signal-to-Noise ratio of GOSAT data. The AEROPRO O_2 A-band algorithm, with heritage from the Sentinel-5P/Tropomi (Veefkind, 2012) algorithm (Sanders, 2012), is based on optimal estimation and a forward model with full multiple scattering, using a simple aerosol microphysics model. The basic set of fit parameters comprises aerosol optical thickness, aerosol layer pressure and surface albedo. For vegetated land, we also fit fluorescence emission. Sensitivity studies show that aerosol cases for which the algorithm will be specifically suited include elevated, optically thick aerosols, such as volcanic ash plumes, desert dust and biomass burning aerosols. The retrieval is independent of the aerosol microphysics assumption.

Validation Approach

Since the altitude of aerosols is difficult to determine from space using passive sensors, validation of the AEROPRO algorithm is essential. During the ESA CarbonExp aircraft campaign, which took place over Greece and Turkey in August-September 2011, a GOSAT special pointed observation request was executed. This campaign offered a unique opportunity to validate the O_2 A-band aerosol profile retrievals from GOSAT, since the aircraft's actively sensed lidar data give the vertical structure of the atmosphere in an unambiguous way. Additional ground-based lidar data from the European Aerosol Research Lidar Network (Earlinet) and the Micropulse Lidar network (MPLnet) are used to validate the aerosol height retrievals from GOSAT for selected cases of strong aerosol events in between July 2010 and June 2012.

First results from the AEROPRO study will be shown.

The direct and inderect effects of aerosols lead the reductions in the amount of solar radiation reaching Earth's surface, thus causing a nagative radiative forcing . Atmospheric aerosols are still considered one of the main sources of uncertainty in the climate change (IPCC 2007). To study the climate feedback of aerosols, it is necessary to couple climate and aerosol models. However, the relatively short lifetime of aerosols, in the order of a few days and their inhomogeneity indicates the importance of regional scales when studying aerosol effects.

Our work investigated the effect of aerosols on the surface temperatures over Centra Africa based on simulation performed by the regional climate model RegCM4.

Subgrid variability of CCN sized aerosol

A. Asmi[1], R. Väänänen[1] and R. Kredji[1,2], A. Minikin[3], and airborne aerosol data providers

General Circulation Models (GCMs) are the key method to figure out the impacts of atmospheric aerosol to climate system. Unfortunately, the computational limitations require such models to use relatively large grid sizes, typically of kilometres. Many clouds are much smaller than this, and such parameterizations are already used to approach the subgrid scale cloud formation for e.g. convective clouds (see e.g. Lohmann et al, 2007). However, the subgrid scale variation of cloud condensation nuclei (CCN) sized aerosol is far less studied.

We approach this issue by analysing the spatial variability of CCN sized aerosol from several aircraft campaigns around the world, mainly from EUCAARI LONGREX, ATAR, INCA, INDOEX, CLAIRE and several national aircraft campaigns in Finland. The aim is to find out the typical distribution shapes and usable mean parameters to describe such distributions. These values could then be used to parameterize such variability in GCMs, or at least diagnose potential variability in the results from this variation.

Analysing the aerosol measurements in the aircraft data shows a clear lognormal distribution of values, although with variable and location dependent modal parameters. The shape of the distribution is maintained in smaller scales (representing finer resolution models), but naturally with smaller geometric standard deviations as the variability is reduced. Figure 1 shows an example of gained coefficients of variation calculated from EUCAARI Falcon OPC datasets during 2008 LONGREX experiments (Hamburger et al., 2012).

The modelled grid box concentration is often assumed to be arithmetic mean value of the concentrations within the grid-box. Using such mean value (if correctly modelled, of course) could then significantly vary from the true number concentration of CCN sized particles on the most cases where the cloud activation would happen in the grid box. Thus, there might be a bias in aerosol-cloud interactions in GCMs and Chemical Transport Models (CTMs) related to the representation of aerosol number concentration spatial variability.

We will also evaluate the possibility to include Eulerian (fixed station) measurements to approximate spatial variability. This approach, if found feasible, will increase the temporal coverage significantly from individual aircraft campaigns to decades.

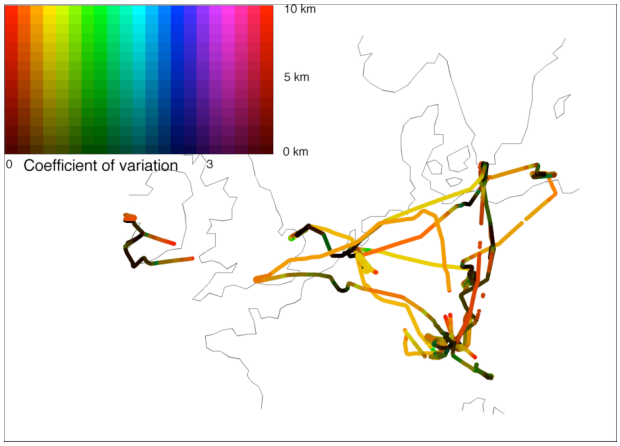

Figure 1. Example of spatial scale dependent differences around Europe, based on EUCAARI DLR Falcon measurements. Plotted is the coefficient of variation (CV=STD(x)/MEAN(x)) of the OPC aerosol concentrations (approx.. 250 nm to 1.1 µm), corrected to STP conditions, from 100 km spatial and 1 km vertical distance from each measurement point. The hue gives CV values, and the colour brightness is related to altitude. Only cloud-free data is shown.

This work was supported by the ATM Finnish National Centre of Excellence program. The measurements presented are from EUCAARI LONGREX campaigns, part of FP6 project EUCAARI.

Multi-criteria ranking and source apportionment of airborne particles

Godwin A. Ayoko[1*] and Adrian J. Friend[1]

[1]*International Laboratory for Air Quality and Health, School of Chemistry, Physics and Mechanical Engineering, Science and Engineering Faculty, Queensland University of Technology, Brisbane QLD 4001, Australia*

Keywords : airborne particles, multicriteria ranking, source apportionment.

Presenting author email: g.ayoko@qu.edu.au

Source apportionment studies have become very widespread since the availability of EPA PMF. Some of the drivers for such studies include the desire for (a) source identification and (b) quantification of the contribution of each of the identified sources to the pollution level at a receptor site. In addition to the information on source profile and source contribution obtained from receptor modeling such PMF analyses, the results can be coupled with meteorological data, in order to estimate the location of each of the sources resolved by the receptor model.

Based on the above outcomes, it may be necessary to devise source control strategies and where there are multiple sites, the next logical step is to work out which of the affected sites should be addressed first. Fortunately, formal procedures for multi-criteria decision-making are available (e.g. Massart *et al* 1997). One of these multi-criteria decision making methods, the Preference Ranking Organization METHods for Enrichment Evaluation (PROMETHEE) and Graphical Analysis for Interactive Assistance (GAIA) PROMETHEE was originally developed to aid the selection of the best location for factories (Brans & Mareschall, 1989) but it is finding increasing application in air quality research. PROMETHEE is an outranking method that ranks alternatives on the basis of a set of criteria. GAIA (Graphical Analysis for Interactive Assistance), on the other hand, is a visual display tool.

This paper reports the application of multicriteria decision making techniques, PROMETHEE and GAIA, and receptor models (such as Principal Component Analysis/ Absolute Principal Component Scores (PCA/APCS) and Positive Matrix Factorization (PMF) to data air quality data collected at various locations. The data consisted of the concentrations of elemental species, gaseous species or particle number concentration and meteorological data.

Each factor obtained by PCA/APCS and PMF had distinctive compositions that suggested that motor vehicle emissions, controlled burning of forests, secondary sulfate, sea salt, and road dust/soil were the most important sources of fine particulate matter in the sites. The most plausible locations of the sources were identified by combining the results obtained from the receptor models with meteorological data.

Then the air quality data were further analysed with PROMETHEE to facilitate multi-criteria ranking and the choice of the least and the most polluted sites based on several air quality indicators. This procedure compared all objects (e.g. sites or years that sampling was conducted) based on the values of the variables (e.g. chemical species, particle number concentrations), and ranks the objects (e.g. sites) from the least to the most polluted (Ayoko et al., 2004; Friend and Ayoko, 2009).

The overall results provided insights which can aid the prioritization mitigation measures not only for outdoor (Friend and Ayoko, 2009, Friend et al, 2011a, Friend et al, 2011b) but also indoor (Ayoko et al, 2004) microenvironments. In addition, the studies demonstrated the potential benefits of combining results from multi-criteria decision making analyses with those from receptor models to enhance the development of air pollution control measures.

Presenting author email: NBabkovskaia@gmail.com

Introduction

Aerosol clouds are dynamic systems with spatially and temporally varying properties. More cloud droplets may form due to in-cloud activation or due to entrainment of air from cloud edges that might lead to formation of fresh cloud droplets. On the other hand, cloud droplets may be evaporated because of mixing at cloud boundaries or in-cloud dynamics causing part of droplets to evaporate. The latter of these can be important in stratus type clouds with long in-cloud residence time of air parcel. The mixing at cloud boundaries takes place in all clouds, and the type of mixing is dependent on the conditions and mixing time scales.

Methods

To study the structure of the cloud edge area we use the direct numerical simulation (DNS) high-order public domain finite-difference PENCIL Code for compressible hydrodynamic flows. The PENCIL Code is a powerful tool for studying the aerosol dynamics in a turbulent medium with complicated chemical composition (PENCIL Code, 2001; Babkovskaia et al., 2011). The scientific goals for the construction of the new model are to investigate the spatial distribution of aerosol particles, turbulent mixing of clouds with the environment and the influence of turbulence on aerosol dynamics (and vice versa).

Results

We study the activation process at the cloud edge. We consider the flux of aerosol particles, which goes through the boundary between the dry and wet air. For a test purpose we start from a zero-dimentional problem. Following by Andrejczuk et al. (2004), we take into account the condensation and evaporation of the aerosol particles covered by liquid water. Next, we consider a one dimensional problem to study a motion and evolution of the front between the dry and wet air. This approach allows us to analyze the effect of the fluid mechanics on the aerosol dynamics (and vice versa) in a laminar regime. Finally, we make two- and three-dimentional simulation with a more complicated velocity field at the cloud edge. We assume that the dry air flux is coming into the computational domain in its middle part and coming out near its boundaries. Wet air is moving in horizontal direction with velocity $U_x = 50 - 100$ cm/s. The third velocity component initially equals to zero, $U_z = 0$ cm/s. We study the effect of air mixing, comparing the results of simulation with zero, $U_{in} = 0$ cm/s, and non-zero, $U_{in} = 20$ cm/s, inlet velocity. We find that for $U_{in} = 0$ cm/s (no mixing) the most efficient growing of particles due to condensation occurs inside the front. In a case of $U_{in} = 20$ cm/s the intensive mixing of air results to evaporation and increasing of the supersaturation in the front area. Additionally, comparing the results of simulation for such two cases (with $U_{in} = 0$ cm/s and $U_{in} = 20$ cm/s) we conclude that the air mixing leads to increase of the number of activated particles (with the size larger than 5 μm). It happens because of extending of the front area where the most efficient growing of particles occurs. Also, we compare the results of 2D and 3D simulations and of the 3D simulations with different grid sizes and analyze how such approaches are valid for the correct description of aerosol production at the cloud edge.

Presenting author email: elham.baranizadeh@uef.fi

The importance of solar radiation as a driver of new particle formation has been firmly confirmed in the literature. Boy and Kulmala (2002) showed that appearance of clouds during new particle formation (NPF) events in May 1999 did sometimes stop the nucleation. However, seasonal cloud effects on NPF events have not been systematically investigated. In this research, we look into this question by analysis of the ratio Half-hourly measured global-radiation (I) divided by calculated half-hourly clear-sky global radiation (I_{max}) during NPF events recorded at Hyytiälä station in 2008-2011. The time during which the ratio I/I_{max} was analyzed (hereafter the time range) for each NPF event corresponded to the period of appearance of newly formed 3nm particles. The time range was defined visually from the so called banana. The global radiation (I) data are actual measurement data downloaded from SMEAR II station and I_{max} data are modelled data downloaded from AERONET website (http://aeronet.gsfc.nasa.gov/).

We classified the event days as "quantifiable" and a "Non-quantifiable" according the criterion introduced by Dal Maso *et al* (2005) which is whether the event is homogeneous enough to quantify the basic characteristics such as formation rate and growth rate or not. The half-hourly ratio of I/I_{max} on event days versus hour of day has been plotted for four seasons winter (Dec-Jan-Feb), spring (Mar-Apr-May), summer (Jun-Jul-Aug), see Fig. 1, and autumn (Sep-Oct-Nov). The results show that in the winter, the NPF events only start when I/I_{max} have high values (> 0.65). Also, in the three other seasons the radiation level is mostly high at the start time of the NPF events.

Table 1. Frequency (%) of ratio (I/I_{max}) values in the given ranges, at start time of event days

Season	[0-0.5] Quant	[0.5-1] Quant	[0-0.5] Non-Quant	[0.5-1] Non-Quant
Winter	0	100	0	100
Spring	11.11	88.9	5.26	94.8
Summer	0	100	8	92
Autumn	20	80	25	75

Table 1 shows that in the summer, all quantifiable events and 94.8% of non-quantifiable events happen when I/I_{max} > 0.5. The frequency of quantifiable events in the range [0-0.5] is 11.11% and 20 % in spring and autumn, respectively. This means there is a possibility that NPF events occur also at cloudy conditions in spring and autumn (note, however, that the amount of data is limited so that we cannot exclude the possibility of NPF in cloudy conditions also in winter and summer).

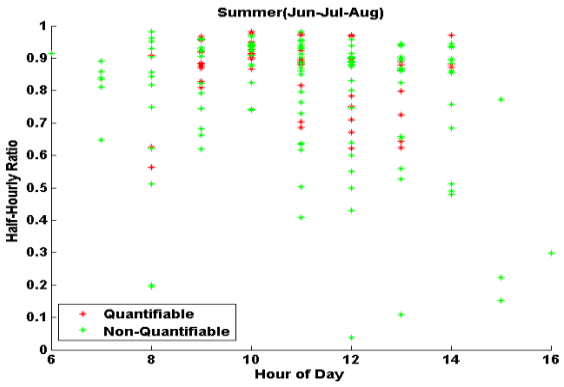

Figure 1. Half-hourly ratio (I/I_{max}) during the time range during 2008-2011at Hyytiälä .

In future work we will extend the study to longer periods and other stations beside Hyytiälä. We will also investigate the relations between I/I_{max} and particle formation and growth rates.

Keywords: Aerosol Size Distribution, Mineral Dust, PCASP-X
Presenting author email: acasi@unileon.es

During the summer months, the Iberian Peninsula is exposed to intrusions of mineral dust from North Africa. These intrusions lead to an alteration in the atmospheric particulate content, contributing to coarse sized particles mainly composed of minerals. Mineral dust makes the highest contribution to atmospheric particulate material at global level (IPCC, 2001), which means that characterising its properties is essential to understand its repercussions on the climate.

This study presents a series of particle measurements made in the city of Léon, in north western Spain, on the 28th and 29th of June 2012, during the final stage of an event involving the arrival of Saharan dust into the Iberian Peninsula.

In order to characterise the atmospheric particle content, a laser spectrometer (Passive Cavity Aerosol Spectrometer Probe, PMS Model PCASP-X) was set up in the north east of the city. This device makes it possible to measure discrete particle sizes ranging between 0.1 and 10 μm in 31 channels. During the study period, measurements were taken at 15-minute intervals each hour. As environmental particles present a different refractive index to that used for PCASP-X calibration (latex particles: 1.59 -0 i), raw size bins were corrected using a program based on Mie Theory. Different refractive indices were used: i) $1.59 - 9\times10^{-3}$ i for measurements affected by mineral dust intrusions (Kandler *et al*., 2007) and ii) $1.574 - 9.13\times10^{-2}$ i for urban aerosol measurements not affected by dust intrusions and considering the relative humidity (Kim and Boatman, 1990).

The meteorological data used in this study were obtained from a weather station located next to the probe, which allowed us to gather one-minute measurements of the pressure, temperature, humidity, precipitation and wind speed and direction.

The PM_{10} measurements recorded at the three air quality stations in the city of Léon were also taken into account.

This study examined the incidence of the mineral dust on the number of particles and their size distributions in the city of León, and the influence of meteorological variables in recovering the atmospheric particle content. An analysis was also made of the implications of this intrusion of Saharan dust on the legal air quality controls in relation to PM_{10} concentrations.

On the 24th of June 2013, the first mass of Saharan dust of the summer entered the Iberian Peninsula from the south west, remaining until the 29th of June 2012. From the 27th of June onwards, this intrusion began to affect the atmospheric particle content of the city of Léon. The highest particle concentrations were recorded on the 28th, with an average daily value of 535 ± 220 particles cm^{-3}. From the aerosol size distributions, it was observed that these particles corresponded to sizes in excess of 0.3 μm. This increase corresponds to the largest fraction of fine mode and coarse mode.

The recovery of the local particulate content was conditioned by the wind speed and direction recorded on the 28th. Between 1759 UTC and 1800 UTC, predominant winds from the WSW and W were recorded, with an average speed of 3.9 ± 0.1 m s^{-1}. These winds blew the mineral dust towards the city, as a result of which the average number of particles for this time interval was very high: 790 ± 210 particles cm^{-3}. However, between 1800 UTC and 2300 UTC, the average wind speed was 2.6 ± 1.1 m s^{-1} from the WSW, allowing clean air to enter and facilitating the recovery of the local particulate content. During this time interval, an average number of particles of 420 ± 80 particles cm^{-3} was recorded.

On the 29th of June, the local particulate content was fully recovered. During this day, the average number of particles recorded was 320 ± 80 particles cm^{-3}.

The arrival of this intrusion of Saharan dust in the city affected the legal controls of air quality. On the 28th of June it exceeded the daily PM_{10} limit (defined in Royal Decree 102/2011 as 50 μg m^{-3}) in the three air quality stations of León City Council, with values of 122, 155 and 139 μg m^{-3}. On the 29th of June this value did not exceed 20 μg m^{-3} in any of the air quality stations, which confirms the recovery that was observed in the numeric concentration of particles.

Keywords: ambient particle number concentrations, air quality, health effects
Presenting author email: susanne.bastian@smul.sachsen.de

Information on health impacts of ultrafine particles (UFP) is still limited. Only few studies have been conducted so far. Therefore, the aim of the UFIREG-project which started in July 2011 is to investigate short-term effects of different size classes of (ultra)fine particles on mortality and morbidity, especially on cardiovascular and respiratory diseases. Further objectives of UFIREG are the preparation of a cost-efficient UFP measurement strategy applicable in European cities, analyzing temporal and spatial variation of UFP among the cities and raising the overall awareness of the population as well as environmental and public health authorities.

UFP measurements within UFIREG are performed using Differential or Scanning Mobility Particle Sizer (DMPS/SMPS) in five cities: Dresden, Augsburg, Prague, Ljubljana, and Chernivtsi. In addition, two Ultrafine Particle Monitors, recently developed within the former EU project UFIPOLNET, are operated in Prague and Augsburg. Most of the measurement stations are integrated in local air quality monitoring networks and are located at urban background sites. At these sites, other air pollution parameters such as PM_{10}, $PM_{2.5}$, NO_x, SO_2, O_3, and partially black carbon as well as meteorological parameters are determined. On the basis of the measured air quality data, epidemiological studies will be carried out in all participating cities.

An extensive quality assurance program is an essential part of UFIREG aiming at a high and comparable data quality. It comprises staff training, an initial intercomparison of all SMPS used in UFIREG, frequent on-site comparisons against reference instruments and automatic control units at two sites. During the initial intercomparison and the on-site comparisons which have been carried out so far, none of the SMPS deviated more than 20 % against the reference instrument in the size range from 20 to 200 nm.

Preliminary results of the year 2012 indicate no large differences between annual averages of particle number concentrations (PNC) in a size range from 20 to 200 nm at all stations (except Chernivtsi). The annual means ranged between 6.000 and 6.500 particles per cm³. However, more pronounced differences were observed for monthly averages. First measurements in Chernivtsi where the SMPS could be installed only in January 2013 showed a greater fraction of particles larger than 100 nm in comparison to the other cities.

As shown in Table 1 for Dresden and Ljubljana the coefficients of determination between PNC and other air pollutants varied between different sites. For Dresden the highest R^2 was observed for PNC (20-200 nm) and NO_2 during the colder months (Nov to Apr, Fig.1).

Table 1. Coefficients for determination (R^2) for linear regression (y=ax+b) for Dresden and Ljubljana, April to December 2012, preliminary data

	PM_{10}	NO	NO_2
PNC Dresden	0.11	0.09	0.15
PNC Ljubljana	0.39	0.49	0.56

Further analyses of the air pollution data within UFIREG will include meteorological cluster analysis based on backtrajectories and source apportionment by applying Positive Matrix Factorization.

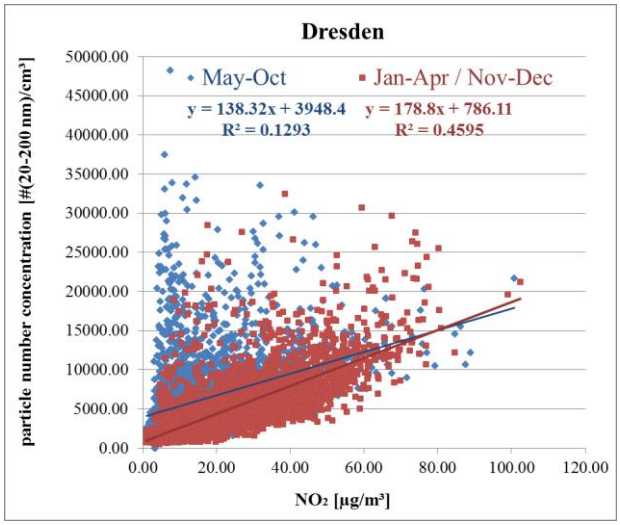

Figure 1. Correlation of PNC and NO_2 for Dresden, blue: May to October 2012, red: January to April and November to December 2012

This project is funded by the European Regional Development Fund Financing Programme Central Europe and led by the Technische Universität Dresden. Many thanks to Vladimir Zdimal from the Institute for Chemical Process Fundamentals, AS CR, for providing the SMPS data from Prague and to the research group "Tropospheric Aerosol" from TROPOS for scientific and technical support of the project.

Influence of stable weather on aerosol concentration and size distribution at K-puszta, Hungary

A. Molnár[1] and Zs. Bécsi[2]

[1]MTA-PE Air Chemistry Research Group, Veszprém, P.O. Box 158, H-8201, Hungary
[2]Department of Earth and Environmental Sciences, University of Pannonia, Veszprém, P.O. Box 158, H-8201, Hungary
Keywords: aerosol, ageing, dry deposition.
Presenting author email: becsi.zsuzsanna@gmail.com

Living in the Anthropocene, among the Earth-system processes climate change is already beyond our planetary boundaries (Rockström *et al* (2009). Changing climate leads to changes in the frequency, intensity, temporal and spatial extent of extreme weather and climate events (IPCC, 2012). Some of these extreme events – e.g. heat waves, droughts – are frequently connected to high atmospheric stability that inhibits the vertical and horizontal mixing of the air in the lower troposphere.

It is well known that physical characteristics of the atmosphere (meteorological parameters) can significantly affect the air quality. In summer the high pressure weather systems may lead to deterioration of air quality resulting in very high concentrations of atmospheric trace constituents. On the other hand, air pollution episodes can also be formed in winter due to persistent stable weather. These episodes can cause serious air pollution mainly in urban environments; however, persistent anticyclones with large spatial extent can result in high level of air pollutants even in regional background air.

Beside ground level ozone, aerosol particles play an important role in air pollution episodes with special regard to their adverse health effects (IPCC, 2012). The number and mass concentration, as well as the size distribution of the particles are the most important parameters which affect significantly the human respiratory system; and their ecological influence due to aerosol deposition is also important.

In this work the change in aerosol size distribution and dry deposition velocity is studied as a function of weather conditions in background air. We focus mainly on the changes of aerosol size distribution under stable atmospheric conditions both in summer and winter.

The aerosol size distribution has been monitored at K-puszta, Hungary between 2010 and 2012. The weather in 2010 was rather changeable with extremely high amount of precipitation, while 2011 and 2012 were excessively dry and warm resulting severe drought and heat-waves. For the selection of periods with stable weather conditions, meteorological data (temperature, precipitation, air pressure) (Hungarian Meteorological Service) and the synoptic weather maps (www.met.hu) are evaluated.

Aerosol data are obtained by means of DMPS and ELPI samplers. The size distribution of the particles between 3-800nm as well as in the size range of 30nm and 10.8μm is monitored by the DMPS and ELPI, respectively.

The aerosol size distribution is controlled by a number of different processes as new particle formation, condensation and coagulation, cloud and photochemical ageing processes, hygroscopicity, etc. In this work the results of these complex processes are discussed in detail.

The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement n° [262254], [ACTRIS]; and TÁMOP-4.2.2.A-11/1/KONV-2012-0064 (The project is realized with the support of the European Union, with the co-funding of the European Social Fund). The authors also gratefully acknowledge the Hungarian Meteorological Service for providing meteorological data.

Wintertime distribution of PAH with aerosol particle size in two cities in the Czech Republic

J. Bendl[1], J. Hovorka[1], J. Topinka[2]

[1] Institute for Environmental Studies, Faculty of Science, Charles University in Prague, Albertov 6, Prague 2, 128 34, Czech Republic

Presenting author email: honzabendl@seznam.cz

Distribution of Polycyclic Aromatic Hydrocarbons - PAH with aerosol particles is part of the comprehensive characterization of winter urban aerosol conducted in two cities in the Czech Republic – Ostrava and Mladá Boleslav. Both cities are industrial, but air pollution in each has a different source. Measurements were conducted during smog and non-smog periods in both cities.

In Ostrava, steel industry is supposed to be a major source of nanoparticles with high amount of carcinogenic c-PAH. Concentrations of B(a)P were measured in winter 2012 and reached up to 300 ng/m^3. Such concentration represents one of the worst situations in Central Europe.

Large industry (Škoda auto a.s.) is also located in the city of Mladá Boleslav. However, this automotive industry is not expected to be a significant air polluter. We assume that transportation and local heating in suburb areas are the main sources of air pollution in Mladá Boleslav. Measurements were conducted in winter 2013 and our results will be concluded soon.

In both cities, daily characterizations of aerosol were carried out for at least 14 day-long periods, including measuring with high-volume cascade impactor BGI 900 used for analyzing amount and distribution of c-PAH. Subsequently, our samples are used for a toxicology study of c-PAHs within the CENATOX project. Other measured parameters were NOx, O_3, CO, SO_2, CH_4, NMHC, PM_{10}, $PM_{2,5}$, and particle number concentrations of 14-20 000 nm with integrating time of 5 minutes. With integrating time of 1 hour, $PM_{2,5}$ OC/EC and 27 chemical elements were recorded.

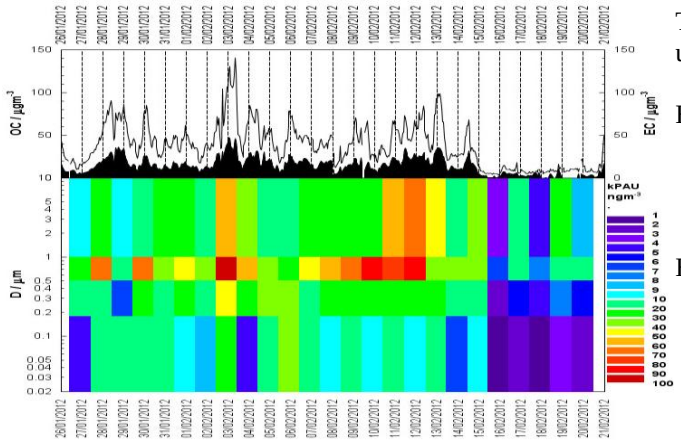

Figure 1. Temporal variation of c-PAH size-distribution and OC/EC concentration in Ostrava (26.1.-26.2. 2012)

For spatial variability assessment and verification of correctness, a network of DustTrak's ($PM_{2,5}$) was deployed in strategic places of both cities.

Remarkable positive sampling artifact - PSA for the high-volume cascade impactor BGI 900 was evaluated in Ostrava (2012). Significant amounts of gaseous phase of phenanthrene, anthracene, fluoranthene, pyrene and benzo(a)anthracene were captured in the experimental PUF (polyurethane foam) after 24 hour air exposure. The extent of the captured gaseous PAHs positively correlated with their individual vapor pressures (ranging from 10^{-4} to 10^{-1} Pa). Other measured PAHs (coronene, benzo(ghi)perylene, chrysene, benzo(b)fluoranthene, benzo(k)fluoranthene, benzo(a)pyrene, dibenzo(a,h)anthracene and indeno(1,2,3-cd)pyrene) with vapor pressures from 10^{-5} to 10^{-10} Pa did not exhibit the PSA. Based on this finding, a correction for the capture of gaseous phase in the particle size fractions of PAHs captured in BGI 900 was calculated. The deduction for the captured gaseous volatile PAHs ranged from units to tens of percent of measured particle size fractions of PAHs.

In Mladá Boleslav (2013), the same experiment was conducted in larger extent, and we are looking forward to the laboratory results. Afterwards, a general model will be designed for calculating the ratio between solid and gaseous fractions of PAHs captured on the PUF substrates in Hi-Vol BGI 900. This ratio is temperature dependent and will be applicable to future measurements of PAHs by HiVol BGI 900 using the PUF substrates.

This work was supported by the project CENATOX under grant GAČR P503/12/G147.

Quantifying the contribution of aerosol particles on local and regional climate is complex due to the diversity of their sources and the various physicochemical processes they participate during their lifetime (Hallquist et al., 2009). The Eastern Mediterranean for example is affected by anthropogenic and natural aerosol emissions (Mihalopoulos et al., 1997), which in many cases blend resulting in increased particle concentrations (Salisbury et al., 2003). In addition due to their interactions with the intense incident solar radiation of the area, the properties of airborne particles can change drastically with time. Having information about the variation of the physicochemical properties of the aerosol in this region is therefore very important for better understanding the contribution of atmospheric particles on climate.

In this work we report on measurements of the hygroscopicity of the particles observed in the atmosphere over a background site in eastern Mediterranean, and use them to determine their mixing state. The site of Finokalia is located on the north coast of Crete (35° 20'N, 25° 40'E) at 250 m a.s.l. Measurements were conducted from 21 August to 28 November 2012, using a Hygroscopic Tandem Differential Mobility Analyzer (HTDMA; Rader & McMurry, 1986). In brief, sampled air was first dried in a nafion tube humidity exchanger to ca. 40% relative humidity (RH). The voltage on the first DMA was adjusted to select and particles having mobility diameter of 40, 60, 80, 100, and 120 nm. The monodisperse particles downstream of DMA-1 were conditioned at a 86±2% RH and measured by the second DMA and the CPC. A curve-fitting algorithm was used to fit up to three lognormal to the measurements depending on their spread. The number of the fitted distributions to each sample was used to determine the mixing state of the particles.

Figure 1 gives an overview of the measurements throughout the whole period of the campaign. Figure 1a shows the daily average hygroscopic growth factor of particles having mobility diameter of 40 nm when selected by DMA-1, whereas Fig. 1b shows the occurrence of samples with more than one distinct modes that indicate externally mixed particles. Until the end of September almost all the samples exhibited internally mixed particles. From October until the end of the measuring period, however, externally mixed particles were more often observed, reaching up to 40% of the total samples on some days. The daily average hygroscopic growth factors of internally mixed particles were ranging from 1.11 to 1.27 with a median value of 1.23. Externally mixed particles average daily hygroscopic growth factors ranged from 1.01 to 1.27 with a median value of 1.08 and from 1.18 to 1.65 with a median value of 1.28 for the first and the second hygroscopic mode.

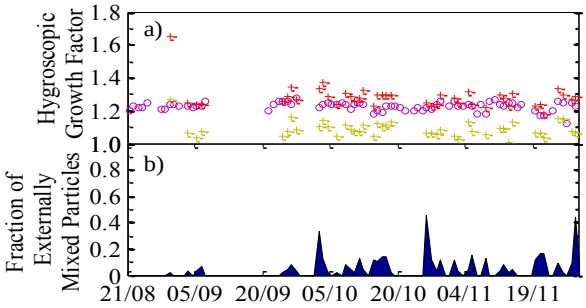

Fig. 1. Daily average hygroscopic growth factors of particles measured at Finokalia (a) and fraction of samples in which externally mixed particles were revealed (b). The hygroscopic growth factors correspond to particles having selected mobility diameter of 40 nm at 40% RH and then exposed to 86±2% RH. Circles indicate internally mixed particles and crosses externally mixed particles (bimodal).

Mediterranean basin is a key area in the climate studies, because of its high vulnerability and temperature rise predictions higher than the global average. Dust aerosol plays an important role in climate system, by affecting the radiation budget of the atmosphere. The optical and microphysical properties of aerosol particles are monitored since 2002 at global GAW station of Mt. Cimone (MTC; 44° 11' N, 10° 42' E). Its location in the Mediterranean region, its physical characteristics (highest peak of the Italian northern Apennines, 2165m a.s.l.), makes it particularly suitable to study the transport of air masses from the north African desert area to Europe.

The monitoring of the aerosol particle number with an optical particle counter (OPC-GRIMM 1108) has shown a mean concentration of 22.9 ± 28.6 # cm^{-3} for fine particles (Dp<1µm) and of 0.19 ± 0.41 # cm^{-3} for coarse particle (1µm<Dp<20µm). Particles number observed with the SMPS (1540 ± 1460 # cm^{-3}) was much higher due to the different size range of two instruments and in the same order that was has been observed at the remote station of puy de Dome (Venzac et al 2008). In addition, the mean scattering coefficient is 21 ± 24 Mm^{-1} and the mean absorption coefficient is 1.5 ± 5.0 Mm^{-1}.

Moreover, the analysis of back-trajectories allows us to make a statistical climatology of the optical and microphysical properties of the aerosol according to the origin of the air masses. We used the Lagrangian model FLEXTRA (Stohl et al 1995) to calculate three-dimensional 6-d back-trajectories (3d-BTJ) arriving at MTC every 6 h (00, 06, 12, 18 UTC).

In order to identify dust transport events (DTE) at MTC, we analysed the variability of number of coarse particles, considered a tracer for mineral dust. The analysis of 3D-BTJ and of transport model (NAAPS) was considered to identify the days characterized by transport of desert dust from North Africa.

We identified 380 DTE, corresponding to 15% of the days at MTC; in these days the coarse particle number is 685% higher than with respect to rest of the time (Fig 1). It can be noted that 65% of DTE occurs in spring and summer.

Regarding the aerosol particle number concentration, the coarse mode showed a spring-summer maximum and a winter minimum. In addition to this, the size distribution of dust particles evolves within the year, with a mean mode diameter higher in winter.

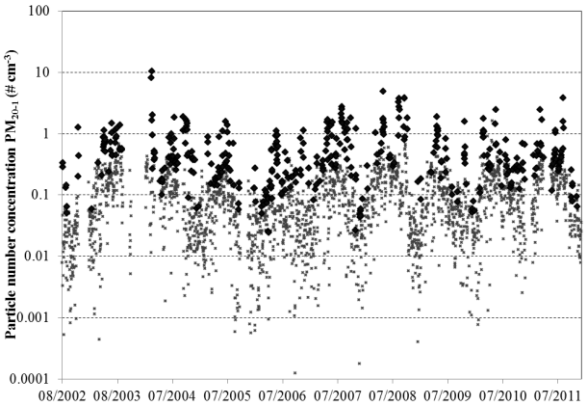

Figure 1. Time series of the coarse aerosol particle number concentrations (# cm^{-3}) at MTC for PM_{20-1}. The black diamond represents the DTE.

The absorption and scattering coefficients in DTE days have been calculated on a seasonal basis, with the aim to study the impact of dust transport on aerosol properties at MTC (Fig.2). It clearly shows an increase of the absorption coefficient in presence of dust, while the scattering coefficient is less affected.

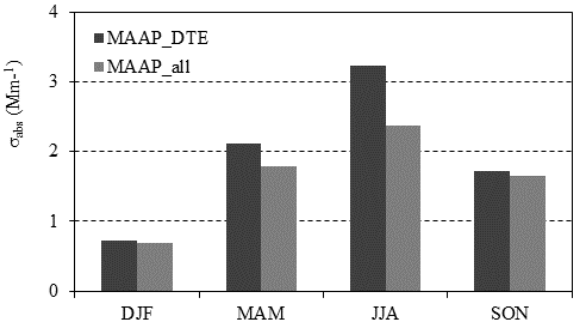

Figure 2. Seasonal average of the absorption coefficient (Mm^{-1}) during the dust events and in the rest of the year 2009 at MTC.

2011 Observations of Stratospheric Aerosol over Hampton, VA related to the Nabro volcanic Eruption in Africa

Boyouk, Neda[1], M. T. Hill[1], Kevin Leavor[1], M. Patrick McCormick[1]
[1]*Department of Atmospheric and Planetary Sciences, Hampton University, 23 Tyler St., Hampton, VA 23668, USA,*

Keywords: Nabro, Stratospheric aerosol
Presenting author email: neda.boyouk@gmail.com

Lidar observations from Hampton University, Hampton, VA (37.02°N, 76.33°W) show several stratospheric aerosol layers between 15.3 and 18.8 km altitude beginning 14 July 2011 and continuing throughout August, September and October. These layers are showed to be due to the June 2011 Nabro volcanic eruption, Africa (13.37° N and 41.70° E). A trajectory analysis was conducted using HYSPLIT to investigate the air mass history of the stratospheric layer and determine its source. Backtrajectories from observations made on 20 July clearly show the transport of stratospheric aerosol layers between 16 km and 18 km from Africa to Hampton. A nighttime CALIPSO overpass on 21 July, 327 km from Hampton, confirms a stratospheric layer at approximately the same height.. The backscatter and extinction coefficients of these stratospheric aerosols are reported using the Klett method and an estimated lidar ratio.

Three 20-day back trajectories were computed starting from 17.80, 17.83, and 17.86 km above mean sea level directly over Hampton University's observatory (37.02°N, 76.33°W) on 20 July 2011 at 1500 UTC. The distance between the HYSPLIT backtrajectories and same-day coincident CALIPSO overpasses is calculated. The closest CALIPSO overpasses to the backtrajectories are used to confirm the presence of stratospheric aerosols related to the Nabro eruption.

In figure 1 we present the range-corrected elastic backscatter signal on 20 July 2011, the day of the strongest observed range-corrected signal of stratospheric aerosol over Hampton. The lidar measurement starts at 10:30 and continues until 15:30 local time. An increase in the 1064 nm range-corrected backscatter signal was observed in the stratosphere between 17.3 and 18.3 km (Figure 1) with a peak signal observed at 17.8 km. For contrast, a cloud layer has also been observed between 12.7 km and 13.6 km from approximately 12:45 local time onward.

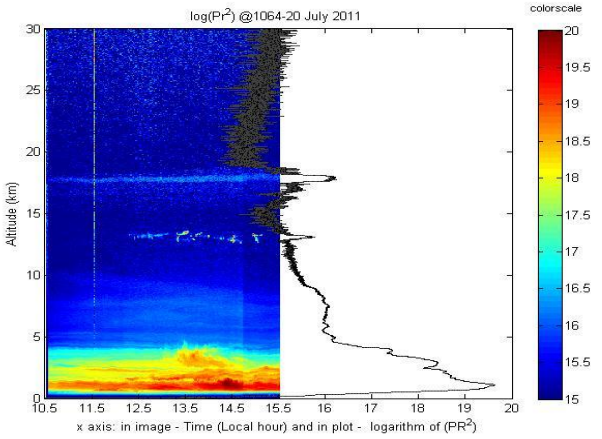

Figure 1 The range-corrected elastic backscatter signal measured on 20 July 2011 between 10:30 and 15:30 local time. The black line is the average of range-corrected signals between 14:00 and 15:00. The color scale is the Logarithm of PR2 in the image.

Multiple observations over different days show stratospheric aerosols in July, August, September and October, all of which appear to be related to aerosol produced by the Nabro eruption aerosol layer, corroborating the long life of these aerosols, the CALIOP lidar measurement aboard CALIPSO, and the HYSPLIT model of aerosol transport in the lower stratosphere.

Size-Resolved Source Apportionment of PM_{10} Organic Aerosol Measured with Aerosol Mass Spectrometry

Presenting author email: carlo.bozzetti@psi.ch

Atmospheric particles affect human health, climate and visibility. The extent and impact of these effects depend on both particle size and chemistry, which concurrently evolve in the atmosphere via direct emission or formation of new particles and subsequent condensation of semi-volatile species. Thus aerosol size and chemical composition are directly linked, and ideally should be measured simultaneously.

The Aerodyne aerosol mass spectrometer (AMS, DeCarlo et al., 2006) offers real-time, quantitative measurements of the size-resolved chemical composition of non-refractory submicron aerosol (organic aerosol (OA), Cl^-, NO_3^-, NH_4^+, SO_4^{2-}). The application of positive matrix factorization (PMF) techniques to AMS data have demonstrated that the mass spectra of bulk OA contain enough information to differentiate several factors, which can be related to different aerosol emission sources and/or formation processes. These factors typically include those related to primary emissions, such as hydrocarbon-like organic aerosol (HOA) from traffic, biomass smoke (BBOA), and cooking emission (COA). Secondary OA formed via the oxidation of volatile organic compounds can also be identified by this technique, termed oxygenated organic aerosol (OOA).

Most recently, the application of three dimensional PMF to online AMS data has been proposed to factorize the chemical composition data from particles in different size ranges (Ulbrich et al., 2012). However, such analysis is limited by the low signal-to-noise ratio of size-resolved AMS spectra (compared to those of bulk OA) and the negligible transmission efficiency of the conventional AMS for supermicron particles, although a newly developed aerodynamic lens system extends measurements into the $PM_{2.5}$ range (Williams et al., in prep). Although supermicron particles constitute a considerable fraction of the total suspendend particles, the chemical composition of their organic fraction remains largely unknown. It is thought that these particles include primary biological material (e.g. pollen, bacteria and spores) that can act as allergens and ice nuclei, affecting both public health and climate (Schneider et al., 2011).

In order to measure size-fractionated mass spectra, we explored the application of laboratory AMS measurements to aerosol filter samples. Such methodology based on offline sampling offers the separation of particles in discrete size ranges and allows measurement of particles through the PM_{10} size range. The approach involves water extraction of the particulate matter from quartz filters by sonication and subsequent nebulisation of the aerosol extract into the AMS. The OA extraction efficiency has been evaluated by comparison with AMS online measurements performed during the same period and is estimated at 80%. Method detection limits are estimated for organic aerosol, NO_3^-, SO_4^{2-}, and NH_4^+ as 410 mgL^{-1}, 210 mgL^{-1}, 260mgL^{-1}, and 200 $mg\ L^{-1}$, respectively. Here, we present the application of the offline AMS approach to PM_1, $PM_{2.5}$ and PM_{10} filter samples collected at a rural site in Switzerland during summer and winter. Differences in aerosol fingerprints across particle sizes are examined and indicate a significantly different composition of coarse particles with higher contributions from fragments that are likely related to carbohydrates (e.g. m/z 29 and 60). Size-resolved PMF applied to these measurements will be discussed and compared with online AMS measurements to identify the contribution of primary biological particles.

Lidar depolarization evolution during the CHARMEX intensive field campaign

J.A. Bravo-Aranda [1,2], M.J. Granados-Muñoz [1,2], F. Navas-Guzmán [1,2], J.L. Guerrero-Rascado [1,2], F. J. olmo [1,2] and L. Alados-Arboledas [1,2]

Keywords: aerosol, depolarization, lidar

Presenting author email: jabravo@ugr.es

Atmospheric aerosol directly and indirectly affects the Earth-Atmosphere energy budget. Regarding the direct effect, the uncertainties related to the radiative forcing of the atmospheric aerosol are still too large as the IPCC showed up in 2007. A better knowledge about the radiative and physical properties of the atmospheric aerosol (e.g. refractive index, volume size distribution and shape) is necessary to reduce these uncertainties. Particularly, microphysical inversion codes developed in recent years model aerosol particles as spheroids. In this sense, particle linear depolarization ratio (δ^p), directly related to its shape, is becoming a key property for the microphysical characterization.

The main objective of CHARMEX (Chemistry-Aerosol Mediterranean Experiment) is developing and coordinating regional research actions for a scientific assessment of the present and future state the atmospheric environment in the Mediterranean Basin, and of its impacts on the regional climate, air quality, and marine biogeochemistry. Concretely, CHARMEX intensive campaign provides a real data base with vertical resolution for checking 3-D modelling of African dust aerosol radiative impact. During this campaign, lidar measurements were performed continuously during 72 hours.

In this work, the temporal evolution of δ^p is analysed in order to investigate the variability of this property. δ^p is calibrated by means of ±45º-calibration method (Bravo-Aranda *et al.*, 2012) and only values where the backscattering ratio (aerosol-to-molecular backscatter coefficient ratio) is higher than 1.2 are used as the equation is instable for lower backscattering ratios. This property is analysed in synergy with the backscatter-related Angström exponent ($å_\beta$) derived from lidar. Also, air masses analysis is performed using the backward trajectories from HYSPLIT model (www.arl.noaa.gov/HYSPLIT.php).

Figure 1 shows δ^p at 532 nm obtained during CHARMEX campaign. The upper layer (3.52-5.49 km asl), detected at 12:30-13:00 on 9th July, presented δ^p and $å_\beta$ values with mean and standard deviation of 0.36±0.01 and -0.06±0.05, respectively. These values are typically representative of pure Saharan dust. In fact, backward trajectories show that air masses that reached Granada between 3 and 5 km asl came from the centre of the Sahara Desert between 2 and 4 km asl. However, during following days, δ^p in the upper layers decreases up to values around 0.25 whereas $å_\beta$ increases up to values around 0.5. This change can be related to mixing process of dust particles with marine or biomass burning aerosol. In this sense, backward trajectories show that air masses came from Atlantic Ocean or regions near to Central Africa where FIRMS locates several forest fires (http://firms.modaps.eosdis.nasa.gov/firemap).

In the lowermost troposphere, δ^p remains almost constant (during the whole period) around 0.12 with $å_\beta$ values around 2. Low values of $å_\beta$ indicate the predominance of the fine mode while lower δ^p indicate more spherical particles. Therefore, the mixing between the anthropogenic and Saharan aerosol was detected in these layers.

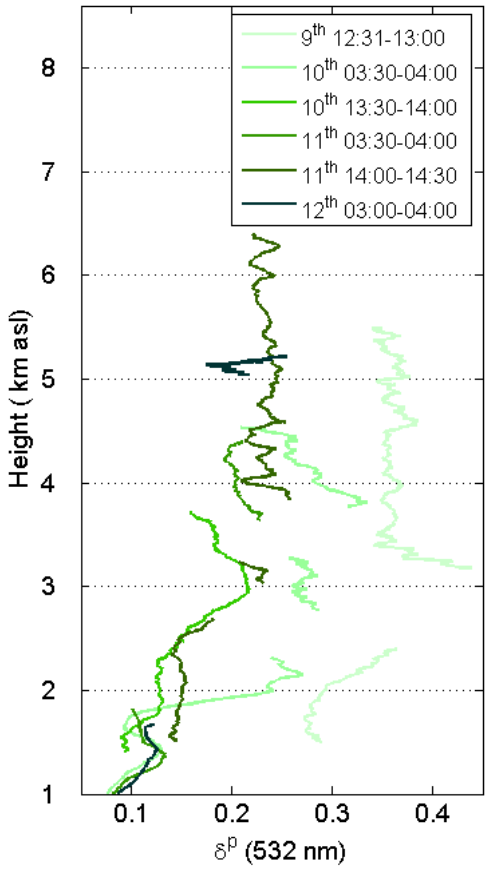

Figure 1: δ^pat 532 nm each ~15 hours during CHARMEX from 9th to 12th July 2012.

Clouds constitute perhaps the largest source of uncertainty in predicting the behaviour of the Earth's climate system. Vulnerable Arctic region is slowly heading towards a new climatic state with substantially decreased permanent ice cover. However, due to poorly understood feedback mechanisms, the rate of Arctic climate response to changes is very hard to predict with current global models. Arctic clouds are supposed to play a central role in these feedback processes (Vavrus, 2004).

The 4th cloud campaign was carried out six weeks, between September 17th and October 30th 2012, at Finnish Meteorological Institute's Pallas Global Atmosphere Watch (GAW) station in northern Finland (Hatakka et al., 2003). The measuring site - Sammaltunturi station (67°58′N, 24°07′E) - resides on a top of the second southernmost fjeld at an elevation of 565 m a.s.l. Sammaltunturi station is, due to topography of the surrounding terrain, a great place for ground-based observations of orographic clouds (Lihavainen et al., 2008; Anttila et al., 2012).

In autumn, probability the station to be inside cloud is high, during the campaign it was 50 % of time. The maximum and minimum temperatures were between 8 and -13 °C. The temperature was below 0 °C during half of time. The winds were mostly western and north-eastern with average wind speed of 6.5 m/s (1 m/s to 15.4 m/s). Time series of selected aerosol particle and CCN properties measured during the campaign are presented in Fig. 1.

The measurements at Pallas (GAW) station included instrumentation for: aerosol number size distribution with differential mobility particle sizers (DMPS), total number particle counters (CPC, TSI 3010), particle absorption with Aethalometer (model AE 31, Magee Scientific), Multi-Angle Absorption Photometer (MAAP, Thermo Scientific) and the Single Particle Soot Photometer (SP2, DMT), and particle scattering with the integrating Nephelometer (model 3563, TSI). The ambient RH was measured with Vaisala HUMICAP sensor, and visibility and temperature were measured with Vaisala FD12P weather sensor.

In addition to above mentioned equipment, the aerosol CCN and hygroscopic properties were measured with the HTDMA (Hygroscopicity Tandem Differential Mobilitity Analyzer) and the Cloud Condensation Nuclei Counter (CCNC, DMT model CCN-100). In situ cloud properties were measured with a Forward Scattering Spectrometer Probe (FSSP, 3-47µm, model SPP-100, DMT) and the Cloud, Aerosol and Precipitation Spectrometer (CAPS, DMT), which includes three instruments: the Cloud Imaging Probe (CIP, 12.5 µm-1.55 mm), the Cloud and Aerosol Spectrometer (CAS-DPOL, 0.51-50 µm) with depolarization feature, and the Hotwire Liquid Water Content Sensor (Hotwire LWC, 0 - 3 g/m^3).

Mass and chemical composition of non-refractory submicron particulate matter was characterized with Aerosol Chemical Speciation Monitor (ACSM, Aerodyne) and the chemical composition of gas and aerosol phase was measured with an online ion chromatograph for Measuring AeRosols and GAses (MARGA 2S ADI 2080, Metrohm Applikon Analytical BV).

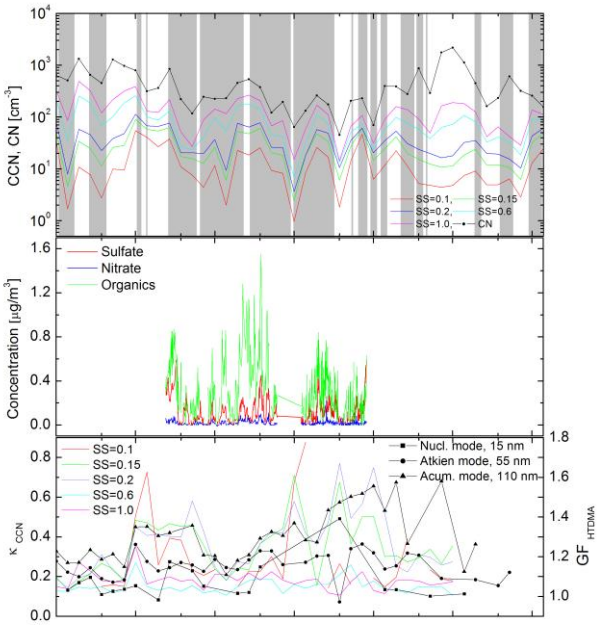

Figure 1. Example of measured properties: from the top total particle count CN together with CCN (gray areas represent cloud events), observed mass concentrations of sulfate, nitrate and organic aerosol, and derived kappa values from size-resolved CCN measurements together with growth factor from HTDMA measurements.

An extreme situation related to air pollution was recorded in Southwestern Siberia due to extensive forest fires in the summer of 2012. The paper presents the results of the study of atmospheric aerosol samples collected in 2 points separated by a distance of 80 km from each other. Previously it was shown (Buryak *et al.*, 2011) that the results of measurements in these points were highly correlated; therefore, they can be considered similarly. In the first point, samples were collected from June 20 to July 19, and in the second point series of observations were performed from June 21 to 30, from July 30 to August 10 and from August 30 to September 6.

Aerosol sampling was performed by pumping the air at a flow rate of 13 m^3/h for a day through fiber filters of AFA-HA-20 type and glass fiber filters.

Macc The mass of deposited aerosol was determined by the gravimetric method.

The concentrations of organic (OC) and elemental carbon (EC) were determined by the thermal method (reaction gas chromatography) described in (Popova *et al.*, 2007). The reaction chromatography method allows us to determine OC and EC concentrations by high-temperature separation in inert atmosphere. Each component is oxidized to CO_2, converted into CH_4 and recorded by a plasma-ionization detector. Thus, when the sample is heated (up to 700ºC) in inert atmosphere, organic substances evaporate and are determined as organic carbon, and elemental carbon is determined at burning in an oxidizing atmosphere.

The total protein masses in the samples were determined using a fluorescent dye (You *et al.*, 1997).

The measurement results are presented in Figures 1 and 2. During the period of the maximal smoke in the air in June and July, the total aerosol mass was always (and on some days exceeded) 100 μg/m^3. In August – September this concentration decreased to approximately 30 μg/m^3. OC and EC concentrations also changed during the period of the maximal smoke practically in proportion to the total mass of aerosol, and OC concentration was higher than that of EC during all days of observation. The concentration of the total protein in atmospheric aerosol remained at a normal level for this year all the time: 0.5 – 1.0 μg/m^3. Thus, forest fires in the region did not produce any significant influence on the total protein concentration in atmospheric aerosol.

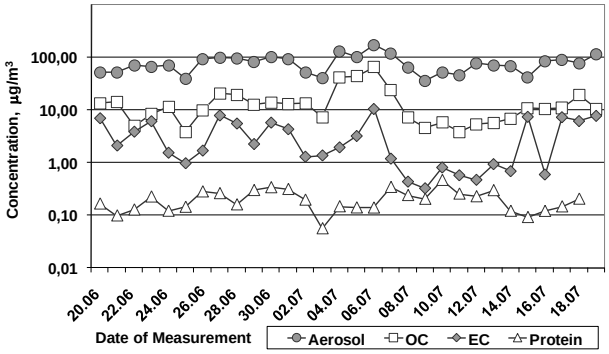

Figure 1. The results of measuring the concentrations of aerosol, organic/elemental carbon and total protein in 1 sampling point.

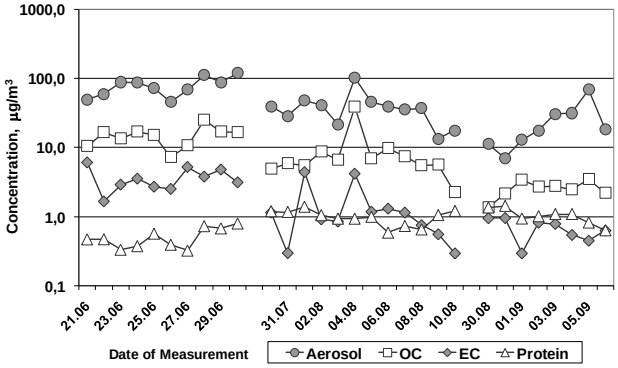

Figure 2. The same for sampling point 2.

Identification and characterization of black carbon aerosol sources in Lithuania

S. Byčenkienė, V. Ulevicius, V. Dudoitis, J. Andriejauskienė

Center for Physical Sciences and Technology, Vilnius, LT-02300, Lithuania
Keywords: black carbon aerosol, organic carbon, Ångström exponent of the absorption coefficient.
Presenting author email: bycenkiene@ar.fi.lt

Black carbon (BC) is the most ubiquitous aerosol component which absorbs visible light and affects climate through both direct and indirect mechanisms. The term BC refers to light absorbing carbon aerosols produced by incomplete combustion processes. Due to the molecular structure, which is characterized by valence electrons in π-orbitals, BC able to absorb visible light (380–880 nm). BC is a major component of "soot", a complex light-absorbing mixture that also contains organic carbon. Due to high sorption capacity and optical properties, BC originated from biomass burning (BB) is of great importance to the atmosphere processes. A carbonaceous aerosol component has been observed in fresh volcanic clouds from several volcanoes. The ash plume of the Grimsvötn eruption on 21 May 2011 offered an exceptional opportunity to characterize the volcanic aerosols.

The aim of this experimental study was to investigate BC aerosol source and particles size distributions and their dynamics in the marine environment.

Data set and methodology

The data from the monitoring site located at the EMEP Preila environmental pollution research station (55°55'N, 21°00'E, 5 m asl) in the coastal/marine environment were presented. This station is located on the Curonian Spit, which separates the Curonian Lagoon and the Baltic Sea, and thus can be characterized as a regionally representative background area.

A Magee Scientific Company AethalometerTM, Model AE31 Spectrum, manufactured by Aerosol d.o.o., Slovenia, was deployed at the site and provided real-time, continuous measurements of the BC mass concentration. The optical transmission of carbonaceous aerosol particles was measured sequentially at seven wavelengths λ (370, 450, 520, 590, 660, 880 and 950 nm). The concentration of BC corresponds to the 880 nm wavelength.

The aerosol size distribution was measured by using the Scanning Mobility Particle Sizer (SMPS) built by the Leibniz Institute for Tropospheric Research, Germany. The SMPS is composed of a differential mobility analyzer and CPC UF-02proto. This system had the following general specifications: size range 8 - 900 nm; scan time 5 min; resolution 71 size channels.

We analyzed the aerosol characteristics with respect to categorized air mass backward trajectories for the initial estimation of the BB potential source locations and quantitative contribution. Backward trajectories were produced using the Flextra model (NILU) and meteorological data provided from ECMWF (European Centre for Medium Range Weather Forcast).

Results

Discernible influence of the BB can be seen in Figure 1, where the exponents of the absorption coefficients $\alpha_{370-520}$ are depicted. This is a strong indication that the aerosol particles over the site containing the different amount of UV-absorbing material depend on the source. The Ångström exponent of the absorption coefficient for organic species depends on the wavelength. The dependence of α on the wavelength can be seen in Fig. 1.

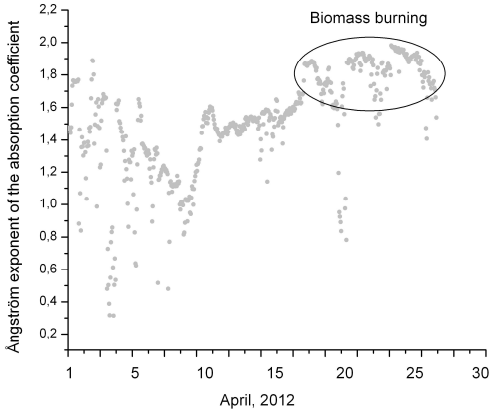

Figure 1. The spectral variation of instantaneous measurements of the Ångström exponent of the absorption coefficient for April 2012

The surface measurements and analysis of the Ångström exponent of the absorption coefficient done separately for shorter and longer wavelengths (i.e., α=370–520 nm and α=660–950 nm) showed that high levels of aerosol BC were related to the transport of air masses rich in BB products caused by active grass burning. During the events the highest mean values of the Ångström exponent of the absorption coefficient $\alpha_{370-520}$ and $\alpha_{590-950}$ nm were observed (2.4±0.1 and 1.5±0.1, respectively).

The observational data and analysis demonstrated that new secondary particle formation event could occur within the lower troposphere at a large distance from the eruptive activity.

Influence of humidity on aerosol concentrations in a subtropical region

L. Caetano-Silva, A. G. Allen, M. Lima-Souza and A. A. Cardoso

Department of Analytical Chemistry, Universidade Estadual Paulista, Araraquara, São Paulo, 14800-900, Brazil
Keywords: aerosol, hygroscopic growth, humidity, subtropical region
Presenting author email: leticiacaetanno@gmail.com

The climatic characteristics of subtropical southeast Brazil include large-amplitude fluctuations of relative humidity (RH), both diurnally and between seasons. This work investigated the influence of these shifts on ambient aerosol concentrations. Particle numbers were measured in six size fractions using an optical particle counter (Aerotrak, TSI), and the bulk aerosol chemical composition (soluble ions: sodium, ammonium, potassium, calcium, magnesium, formate, acetate, nitrate, sulfate, phosphate, and oxalate) was determined for 85 samples by ion chromatography (Dionex DX120). Meteorological parameters included relative humidity (RH), wind speed, and temperature. The measurements were made in August 2010. The data were treated by agglomerative hierarchical clustering (AHC), and comparison between wet (RH above 70%) and dry periods (RH below 50%) (Zentzsch *et al.*, 2013) enabled elucidation of the influence of relative humidity on aerosol growth and chemical composition.

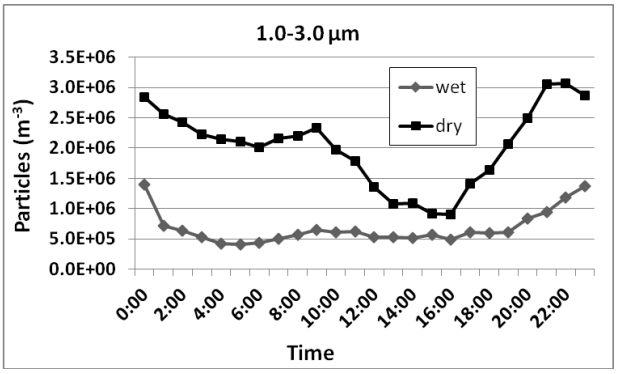

Figure 1. Diurnal number concentrations of aerosols in the size range 1.0-3.0 µm, during dry and wet periods.

Particle number concentrations (in the measured size range) were higher at night (higher RH) than during the daytime (lower RH), and diurnal fluctuations were lower under more humid conditions (Fig. 1). The 1.0-3.0 µm size fraction was most affected by RH, although aerosols of all sizes showed clear humidity-related trends, with number concentrations either increasing or decreasing (Fig. 2). The 1.0-3.0 µm size range appeared to represent a neo-equilibrium in terms of the uptake and loss of water vapor by the particles.

The shifts in RH (the minimum and maximum values were 12% and 95%, respectively) were sufficient to cover the range of deliquescence and efflorescence points (Freney *et al.*, 2009) of many of the salts present in the composition of the aerosols analyzed, including compounds of ammonium and potassium. NH_4^+ and K^+ accounted for 31.5% and 16.7% of the mass of measured cations, respectively, and the hygroscopic behavior of the corresponding compounds could explain the diurnal fluctuations in the number concentrations of aerosols in the 0.5-5.0 µm size range. Overall, there was an excess of cations, relative to anions (Table 1), which could be explained by the presence of calcium carbonate (carbonate was not determined), since this material is widely used in the region for soil pH correction, and was therefore probably the main source of aerosol basicity.

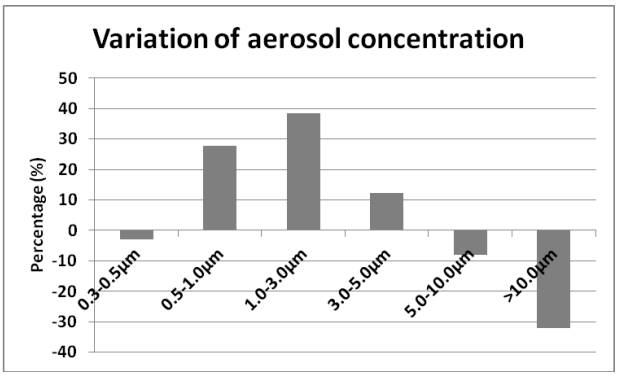

Figure 2. Percentage difference in aerosol concentrations, comparing wet periods (RH >70%) with dry periods (RH <50%).

Table 1. Ion balances for wet and dry periods.

Period	Anions neq/m^3	Cations neq/m^3	Cation/ Anion
Wet	52.7	199.7	3.8
Dry	47.6	226.5	4.8

The results revealed a substantial influence of diurnal changes in relative humidity on the hygroscopic growth of ambient aerosols derived predominantly from biomass burning and soil dust resuspension. Cyclical growth and evaporation of the particles favored both the production of secondary chemical species via aqueous phase reactions and the formation of internal mixtures of chemical components.

Keywords: levoglucosan, sugar cane, agricultural impact
Presenting author email: lcampos@ffclrp.usp.br

The State of São Paulo (SP) alone accounts for over 50% of the total area (96,166 km^2) used for sugar cane plantations in Brazil. Burning of the sugar cane foliage before harvesting still occurs in about 40% of the cultivated land in SP, and there is not an official program to phase out burning in other States. Consequently, large amounts of gases and aerosol are released into the atmosphere during the harvest period (April – November) each year. In addition to human health effects, these emissions potentially affect cloud formation, precipitation, and radiative fluxes.

In this study, sugar markers in total aerosol samples from highly impacted agro-industrial regions (Araraquara and Ourinhos - SP) were used to improve understanding of the contribution of smoke particles from sugar cane burning to the chemical composition of the lower troposphere. We also intend to discuss other markers (K^+, Ca^{2+}, Soluble Organic Carbon, PAHs) and solubility properties of the aerosol.

Aerosol samples (n = 112) were collected using a high-volume sampler fitted with glass fiber filters. Sugars were extracted with dichloromethane /methanol, and sugar speciation was conducted for seven samples (Alves *et al*., 2011).

Levoglucosan (L) was the anhydrosugar that most contributed to the aerosol mass. Concentrations were in the ranges (i) 25 - 1406 ng m^{-3} at night, (ii) 50 - 397 ng m^{-3} during the daytime, and (iii) 12 - 382 ng m^{-3} for 24-h averages. The latter range was similar to those obtained for other locations where there is intense sugar cane production (Urban *et al*., 2012; Souza, 2011). Concentrations of mannosan (M) (2.40 - 274 ng m^{-3}) and galactosan (G) (1.81 - 274 ng m^{-3}) were about 10 times lower than levoglucosan at all times. Since burning operations were normally conducted in the evening and during the sugar cane harvest period, there were distinct diurnal and seasonal trends that were similar for the three anhydrosugars (Figure 1).

Although the majority of fires occurred during the dry season, it was still possible to detect and quantify several biomass burning markers during the wet season (November–February; non-harvest period). This could be due to the use of fire for land clearance (rural and urban fires) and to the combustion of sugar cane bagasse (the crushed solid cane residue), which returns to the production process as an energy source or is used to generate electricity.

In addition to anhydrosugars, 17 other sugars were quantified. Four of these (erythrose, maltose, arabinose, and ribose) showed behavior similar to that of levoglucosan. Overall L/M and L/G ratios were 8.64 ± 5.70 (n = 109) and 12.1 ± 7.93 (n = 109), respectively. These values are similar to those obtained for controlled sugar cane burning (Hall *et al.*, 2012) and for other regions within the State of São Paulo (Vasconcellos *et al.*, 2010). The L/M ratios for the aerosols collected during the harvest period (9.54 ± 4.39) and the non-harvest wet season (7.60 ± 3.67) were not significantly different. An L/M ratio of 10.8 was obtained for aerosols collected near a fire on pasture with scrub, which is similar to that for sugar cane leaves. Aerosol from the Amazon region did not seem to affect the study region, given the much higher L/M ratios reported for Amazonia (ca. 20; Kundu *et al.*, 2010). Combustion of different types of wood from Europe and the USA resulted in L/M values that were mostly between 1 and 6 (Gonçalves *et al.*, 2011; Medeiros and Simoneit, 2008).

In conclusion, smoke particles were generated on a regional scale and were derived from agricultural practices. Burning of sugar cane leaves will be totally eliminated by the year 2017, which will result in a major shift in the trace component chemistry of the lower troposphere in rural areas of São Paulo State.

Long-term time series of daily PM_{10} chemical composition in the area of Rome, Italy

M. Catrambone[1], S. Dalla Torre[1], E. Rantica[1], T. Sargolini[1], C. Perrino[1], the Med-Particles Study Group

[1]CNR Institute of Atmospheric Pollution Research, Monterotondo St. (Rome), 00015, Italy
Keywords: macro-sources, mass closure, composition
Presenting author email: catrambone@iia.cnr.it

MED-PARTICLES (Particles size and composition in Mediterranean countries: geographical variability and short-term health effects, http://www.epidemiologia.lazio.it/medparticles/index.php/en/) is a LIFE+ project aimed to investigate the health effects of short-term exposure to ambient air pollution in the Mediterranean Basin and to obtain a better understanding of particulate air pollution characteristics in some cities of the Mediterranean area. In the framework of this project, particular attention is drawn to the study of the interconnections between respiratory / cardio-vascular health and chemical composition of atmospheric particulate matter. To obtain this goal of the project, long-term data series of PM components are required.

Two sites in Central Italy provided data to the MED-PARTICLES project: the urban background site of Villa Ada, located inside a green area in the centre of Rome and at the peri-urban site of Montelibretti, sited at the distance of 22 km, NW of the city. At these two sites, both run by the CNR Institute of Atmospheric Pollution Research, daily PM_{10} composition was continuously investigated for three years at Villa Ada (2005 – 2007) and for six years at Montelibretti (2005 – 2010).

Each day PM_{10} was sampled on two side-by-side membrane filters: the first one (quartz) was devoted to the determination of elemental and organic carbon by thermo-optical analysis, the second one (Teflon) was aimed at measuring the mass concentration by the beta attenuation method and at determining element concentration by energy dispersion X-ray fluorescence and ion concentration by ion chromatography. A total of 24 daily chemical determinations were carried out during the six investigated years.

By using a few simple algorithms, the obtained chemical composition data were re-arranged in order to obtain the mass closure (agreement between the determination of the PM mass and the sum of the chemical components) and to estimate the strength of the main PM macro-sources: soil, sea, secondary reactions of inorganic species, combustion processes, biosphere (primary and secondary organics), as described in Perrino *et al.* (2009) and Perrino *et al*. (2010).

Seasonal and annual variations of PM composition were evaluated, both as single chemical components and as macro-sources. Figure 1 reports an example of the variations in the strength of the five macro-sources during the years 2005 and 2006 at the Montelibretti site.

Seasonal variations were observed particularly for soil components (increase during the summer due to higher soil dryness) and for organics (higher values during the winter, up to reach about 50% of the total PM_{10} mass).

The differences in the PM_{10} mass concentration and chemical composition at the urban background and the peri-urban sites were also evaluated. Very similar results between the two sites were obtained for crustal components (mainly for Al, Si and Ti), for secondary species (ammonium, sulphate and, at a less extent, nitrate), which are almost homogeneous on a regional space scale, and for the main sea-spray components (sodium and chloride). Higher values were found at the urban background site for the species that are mainly generated by exhaust and non-exhaust traffic emission (elemental carbon, iron, copper, manganese, lead, zinc, Canepari *et al*., 2008), while variable difference were found for organic components, which are emitted by a variety of different sources.

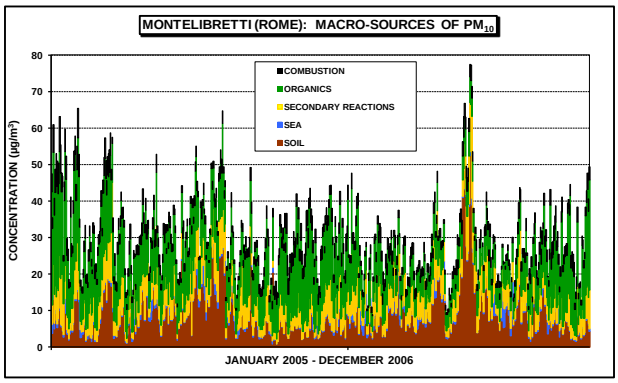

Figure 1. Macro-sources of PM_{10} in the peri-urban site of Montelibrettti during 2005 and 2006.

Biomass burning is widely used in Brazil for deforestation and in agricultural practices. Rural areas within São Paulo State emit large quantities of particulate matter to the atmosphere due to extensive biomass burning during sugar cane plantation management. This practice is used to remove the outer leaves of the cane and facilitate manual harvesting.

The objective here was to perform a chemical characterization (including marker compounds) of the atmospheric particulate matter in an agro-industrial region of Brazil impacted by biomass burning (Araraquara and Ourinhos - SP). Ultimately, better knowledge of the chemical composition of these aerosols should improve our understanding of the role played by biomass burning particles in terms of both the regional climate and human health.

Seven samples of ambient total particulate matter (TPM) were collected on glass fiber filters using a high-volume sampler. Samples were extracted using dichloromethane and methanol, fractionated into five different classes by vacuum flash chromatography, and analyzed by GC-MS (Alves *et al.*, 2011).

Hydroxy-acids, oxy-acids, and aromatic acids were found at relatively high concentrations, as expected for biomass burning particles (Graham *et al.*, 2002). The most abundant acid in the aerosol was glycolic acid (4.3 - 300 ng m^{-3}), which has been described as a product of the hydrolysis of hemicelluloses (Girisuta, 2007).

Among the phenolic compounds, coumaryl-type was the most abundant (60 - 94%), followed by syringyl (5.3 - 37%) and vanillyl (0.87 - 16%). Coumaryl compounds are formed preferentially during the burning of *Gramineae* species (Alves, 2008). The most abundant sterol was *β*-sitosterol (50 - 60%), also characteristic of *Gramineae* burning (Oros *et al.*, 2006), followed by cholesterol (4.0 - 33%) and stigmasterol (7.5 - 46%).

The concentrations of polycyclic aromatic hydrocarbons (PAH) ranged from 1.93 to 38.7 ng m^{-3} (average: 19.1 ± 16.1 ng m^{-3}). These values are similar to those reported for other regions where burning is used in sugar cane fields (Vasconcellos *et al.*, 2003).

Retene, a biomass-burning marker, was the most abundant PAH found in the samples (14 – 84%; Figure 1). Benzo[a]pyrene (BaP) concentrations ranged from 0.03 to 2.2 ng m^{-3}. This compound has carcinogenic and mutagenic characteristics, and the World Health Organization recommends a maximum limit concentration of 1 ng m^{-3}. Four out of six samples collected during the harvest period had BaP concentrations (0.94, 0.98, 1.1, and 2.2 ng m^{-3}) either close to or higher than the limit value. Similar observations were made in earlier work by Godoi *et al.* (2004).

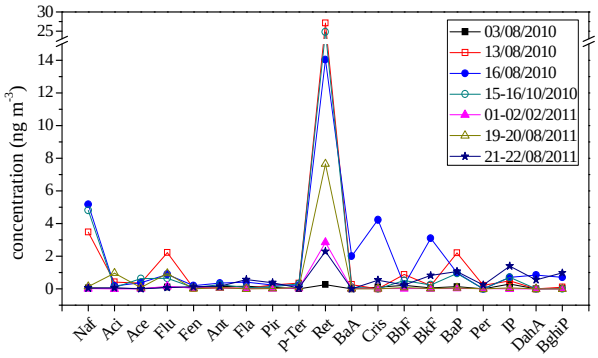

Figure 1. Concentrations of PAHs.

The most polar compounds extracted were alcohols (fraction 4) and sugars and acids (fraction 5). These two fractions corresponded to between 4.0 and 72% of the total measured mass of organic carbon. The lowest percentages of polar compounds (4.0 and 6.8%) were found in the two samples with the strongest influences of biomass burning (collected on 13/08/2010 and 16/08/2010). The percentages of *n*-alkanes in these samples were 95.7 and 92.7%, and the total concentrations of organic compounds were 115 and 123 µg m^{-3} respectively, compared to a range of 0.8 - 2.9 µg m^{-3} for the remaining samples. The highest percentage (72%) of polar compounds was found in a sample collected during the non-harvest period.

In conclusion, although biomass burning made an important contribution to the aerosol loading, the particles concerned were mostly non-polar and therefore might be unable to act effectively as cloud condensation nuclei. The proximity of plantations to urban areas could present a health hazard to the local population due to the emissions of carcinogenic compounds.

Thermal-optical analysis of elemental carbon (EC) in environmental samples – differences observed when using various protocols

E.C. Cetintas[1], M. Kistler[1], C. Schmidl[2], H. Bauer[1,†] and A. Kasper-Giebl[1]

[1]Institute of Chemical Technologies and Analytics, Vienna University of Technology, Vienna, A1060, Austria
[2]Bioenergy2020+, Wieselburg - Land, A3250, Austria
Keywords: EC, PM10, EUSAAR2, *quartz.par*.
Presenting author email: eylemcan@gmail.com

Several methods are used nowadays for assessing of elemental- and organic carbon (EC, OC) in the atmospheric samples. Their classification and selection depends on the principle of the measurement (e.g., thermal, optical) and furthermore also on the type (e.g., solid, liquid, gaseous), quality and quantity of the sample. Due to basic differences a comparison between methods need not result in perfect agreement, especially when analyzing environmental samples. More demanding is the task, that it was already noticed that even the same method reveals often not uniform resuts, depending on applied settings (e.g., Baumgardner *et al.*, 2012)

Thermal-optical carbon analysis is a standard method applied and recommended for analysis of EC and OC in atmospheric aerosols collected on filter media. For this purpose several protocols (IMPROVE, NIOSH 5040, EUSAAR2, NIOSH-like protocols - e.g., *quartz.par*) are available (Chow et al., 1993, Birch and Cary, 1996, Cavalli et al., 2009). Applying of different temperature steps with varying length and a diverse optical correction mode (transmission or reflection mode) might significantly affect the result.

With relation to the samples presented below following analytical questions are to be answered:

- How do pure wood burning emission PM10 behave during EC-OC analysis with different protocols?
- How do ambient particulate matter with a significant wood combustion PM10 behave during EC-OC analysis with different protocols?
- Which factors influence the observed differences (if any)?
- How could the choice of the protocol for analysis be simplified?

Wood burning emission samples (PM10) have been taken during stove tests conducted at TU Vienna (AQUELLIS FB Project, Schmidl *et al.*, 2008). Particles were sampled from a dilution exhaus on quartz fibre filters (Pall, 47mm), using Low-Vol PM10 separators (~1m³/h). The samples were highly loaded (3-5 mg/filter) with dark brown or black particles. Another set of emission samples was collected at Bioenergy 2020+. Again particles were sampled on quartz fibre filters (Pall, 47 mm) and were chosen to reflect different conditions of wood burning. Filters showed lower mass loadings during this smpling campaign.

Ambient air particulate matter (PM10) samples were collected on quartz fibre filters (Pallflex, 150 mm) with Hi-Vol samplers (~30m³/h) during winter (February 2011) and summer (July 2011) campaigns conducted in Austria and Slovenia (PMinter Project, Kistler *et al.*, 2013).

The winter samples were highly concentrated with dark brown/black loadings exceeding 35 mg/filter. Summer sample loadings were only about 10 mg/filter with no visible soot (grey dust).

Measurements of EC and OC in both ambient air and emission samples were conducted with an Sunset Laboratory Lab OCEC Analyser using EUSAAR2 and *quartz.par* temperature protocols. Measurements with *quartz.par* method were additionally evalueted in reflectance mode.

Aditional analyses of the filters (inorganic ions, saccharides, HULIS (humic like substances), selected elements) were performed and are available to gain a general chemical characteristic of the samples.

Among ambient air samples the problem of overloading did not occur. Nevertheless the agreement between results for measurement with both protocols was not constant. In several cases (concerning whole measurement series) EC differ more than 3 times, showing an evident coherrence with factors describing the collected aerosol (age and chemical composition).

Authors acknowledge a cooperation between TU Vienna, Bioenergy 2020+ and PMinter project consortium. We thank to the group members involved in the study.

Presenting author email: f.costabile@isac.cnr.it

Carbonaceous aerosol particles are one of the most abundant aerosol components in the urban atmosphere. They are composed by black carbon (BC) and organic carbon (OC) plus additional quantities of trace elements; their particle size ranges over several orders of magnitude from the ultrafine (particle diameter, $D_p < 100$nm) to the fine region ($< 100\text{nm} < D_p < 1\mu$m). Relating their optical properties to chemical properties is necessary to assess their contribution on air pollution and on the radiative balance in the atmosphere .

On one hand, BC-rich aerosols show high absorption: their BC content cause those aerosols to strongly absorb light with a flat spectral variability. On the other hand, optical properties of BC-rich aerosols do vary with varying D_p: their D_p vary from the ultrafine (soot mode, 60-100 nm in D_p, i.e., motor vehicle emissions) to the small accumulation mode (100-300 nm, typical of lower temperature combustion processes such as biomass smoke). Clearly defining BC-rich aerosol properties requires to separate them with regard to homogeneous properties (i.e.,D_p, chemical composition, and spectral optical properties). Similar definitions are still missing.

Aerosols with large OC content also exhibit a variety of optical properties varying with varying the type of organic molecular species. Some organic molecular species cause the aerosol to mainly produce light scattering effects. Other aerosol organic molecular species show, on the contrary, absorption effects with a strong spectral variability. The absorption spectral variability depends on the OC content referred to as brown carbon (BrC) (Kirchstetter et al., 2004). A clear understanding of optical properties in BrC-rich organic aerosols is still far to be reached.

In this work we analyze optical, chemical and microphysical properties of carbonaceous aerosol particle in the urban area of Bologna during an intensive campaign of the "Supersito" project. The objective is to relate aerosol spectral optical properties to relevant chemical properties for selected types of organic aerosols varying with varying BC and BrC contents, and particle diameters.

Aerosol chemical composition, species size distribution, and organic aerosol chemical properties are measured by an High Resolution Time of Flight Aerosol Mass Spectrometer (HR-TOF-AMS). Aerosol spectral optical properties are measured by a 3-wavelenght PSAP and a 3-wavelenght integrating nephelometer operating in the visible region. Particle number size distributions are measured by SMPS+APS (TSI).

The bulk aerosol is separated in primary and secondary carbonaceous aerosol populations through the analysis of the aerosol spectral optical properties: Scattering Angstrom Exponent (SAE), Absorption Angstrom Exponent (AAE), Single Scattering Albedo (SSA) and its variability dSSA. Aerosol absorption is separated in the absorption due to BC, and the one due to BrC. The identified aerosol types are analysed in terms of chemically-resolved size distributions (fig.1).

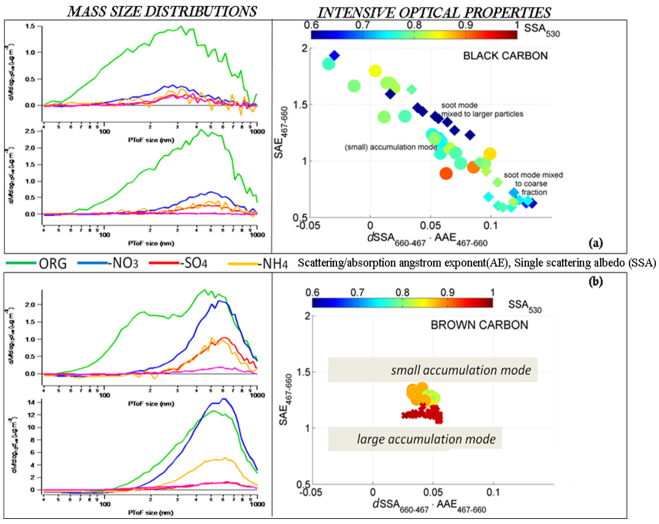

Figure 1: Optical properties and mass size distribution of major chemical constituents of: (a) mixed aerosols dominated by black carbon (soot-BC and not-soot-BC); (b) organic aerosols rich in Brown Carbon (small and large accumulation mode).

The results, still in progress, will be analyzed to obtain optical properties of carbonaceous aerosols concerning both freshly emitted particles (motor vehicles and biomass smoke), and aged secondary organic aerosols. Major conclusions will constrain spectral absorption properties of the selected aerosol types to estimate in particular refractive indices, Angstrom exponents, and mass absorption efficiencies. Conclusions will also target chemical properties of the organic molecular species contributing to the spectral absorption.

Black carbon contribution to the particle matter in Madrid City during a local winter episode

E. Coz[1], M. Becerril[1], Z. Chang[2], J. Pérez-Guldris[2], A.S.H. Prévôt[3], G. Ramos[2], B. Artiñano[1]

Presenting author email: esther.coz@ciemat.es

Black carbon (BC), a product of inefficient combustion from fossil fuel and/or biomass burning, is considered a major contributor to global warming (Ramanathan and Carmichael, 2008). In a highly populated urban metropolis, such as Madrid, with no industry nearby and where traffic and domestic activities are the dominant sources, BC can be regarded as one of the most important components within the chemical atmospheric pool. Thus, BC monitoring has become an urgent challenge to achieve for the city.

For the first time, PM_{10} BC concentrations have been recorded through aerosol light absorption using a 7 multi-wavelength Aethalometer (Magee Sci. mod. AE33, Aerosol d.o.o.) during a small thermal inversion period (Fig.1) -typical meteorological scenario from the winter season in Madrid-, at the CIEMAT urban background site (Plaza et al., 2011). The instrument took part in an ACTRIS intercomparison showing extremely good agreement with the other instruments (same and previous model, AE31) and the MAAP used as reference.

Results showed that the evolution of the BC concentrations during the sampling tests conducted at CIEMAT were in good agreement with the averaged $PM_{2.5}$ and PM_{10} concentration levels of all the stations from the city Authority air quality monitoring network (http://www.mambiente.munimadrid.es/svca/index.php?lang=en), confirming the site as representative of the atmospheric aerosol composition within the urban limits during this type of events. Hourly BC concentrations, which reached more than 20 $\mu g \cdot m^{-3}$ in part of the period, represented, on average, 40% of the network averaged $PM_{2.5}$ during the episode in comparison with 10% during the previous and subsequent days.

A first evaluation of the responses at the ultraviolet (UVPM, 370nm) and near-infrared (nIR-BC, 880nm) wavelengths (Sandradewi et al., 2008), suggests there was no important contribution from biomass burning origin to these high BC concentrations during the event. The mean UVPM/n-IR-BC ratio was 1.07±0.05. Relatively higher concentrations of the UVPM signal are expected from the derived organic compounds when the contribution of wood smoke aerosols becomes important. Nevertheless, further analysis ^{14}C analyses and further data analyses need to be done to quantitatively estimate each contribution.

This finding is of special importance since biomass burning seems to be a significant source in most of the European highly populated cities, giving Madrid a unique position regarding atmospheric aerosol /BC sources at least in this time of the year.

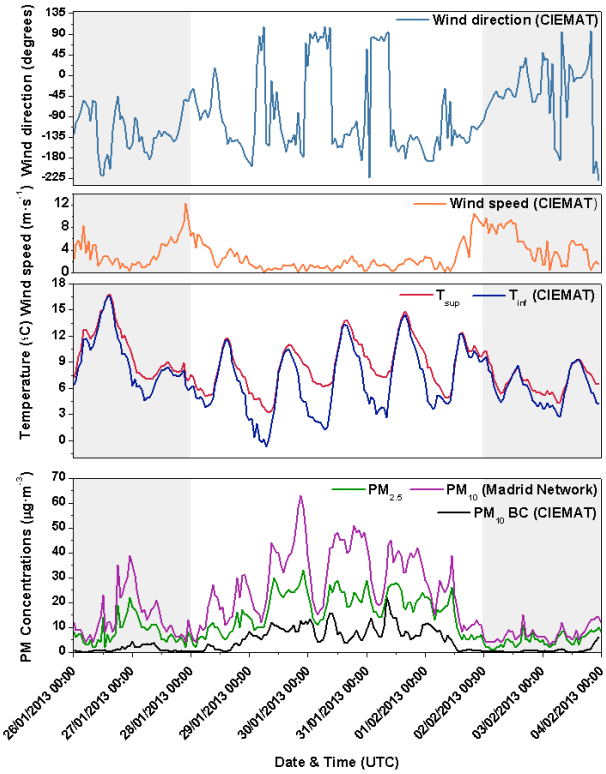

Fig 1. Meteorological parameters and BC concentrations during the thermal inversion in the station at Ciemat. T_{sup} and T_{inf} are temperature at high and low levels of the CIEMAT tower. Averaged PM_{10} and $PM_{2.5}$ concentration levels from the stations in the local Authority network.

Presenting author email: giseleor@ufba.br

Organic and inorganic ions are major particulate matter (PM) constitutents, being commonly used as source tracers. They may also be good representatives of secondary atmospheric pollutants mainly associated with crustal cations (Na^+, K^+, NH_4^+, Mg^{2+} and Ca^{2+}). Furthermore, major ions are ubiquitous in atmosphere. In terms of particle's size, it is accepted the following classification particles in nuclei mode (3 nm < dp < 30 nm), nanoparticles (dp < 50 nm), accumulation mode (0.1 µm < dp < 2.5 µm) and coarse mode (2.5 µm < dp < ~100 µm). Yet PM at dp < 1 µm are also called ultrafine particles. In this study, we studied major ions size distribution from three sites in Baia de Todos os Santos (BTS).

BTS is the second largest coastal bay in Brazil (Fig. 1). Its surroundings comprises an urban area with more than 3 million inhabitants with intense vehicular and port activities and an extensive industrial area. The bay is close to a Nave Base and the largest petrochemical complex in the southern hemisphere. Although all those activities in BTS are potential sources of compounds to be realeased to atmosphere, studies about PM size distribution and the content of major ions and other species on that are scarce.

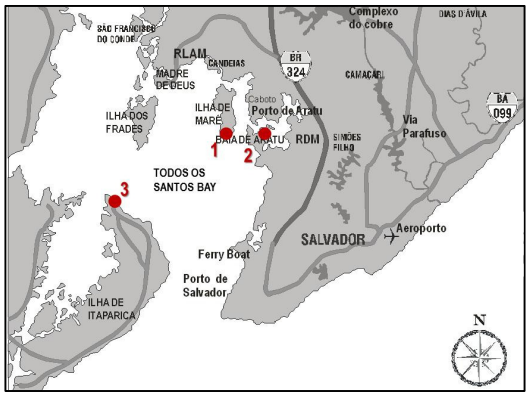

Fig. 1. Map of TSB and the three sampling sites: #1 is Botelho, #2 is Base Naval de Aratu (BNA) and #3 is Itaparica.

Samples were collected by using a NanoMOUDI sampler set with PTFE filters, at 30 L min^{-1}, during 7 days (n=2) in each site. Sampling was done during August 2010 in Botelho, September 2010 in Base Naval de Aratu (BNA), and October 2010 in Itaparica (Fig. 1). During sampling there were contributions of oceanic (90%) and continental (10%) air masses with prevailing NNE direction. Major ions analysis (F^-, Cl^-, NO_3^-, SO_4^{2-}, PO_4^{3-}, lactate, formate, acetate, succinate, oxalate, Na^+, K^+, NH_4^+, Mg^{2+}, and Ca^{2+}) was done by an ion chromatograph with conductivity detection (Domingos *et al,* 2012). Size distributions of selected ions are shown in Fig. 2.

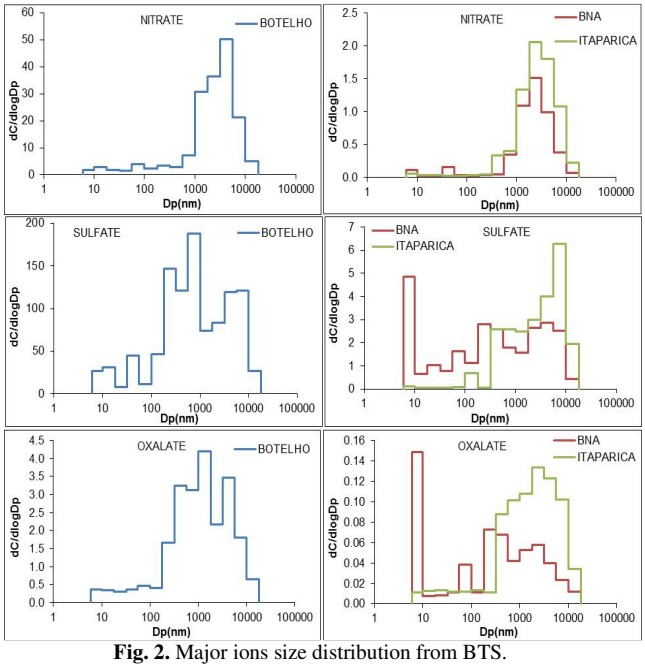

Fig. 2. Major ions size distribution from BTS.

It was observed that the ions Cl^-, NO_3^-, Na^+, K^+ and Ca^{2+} showed monomodal distribution (in the coarse fraction), SO_4^{2-}, PO_4^{3-} and oxalate had bimodal distribution (coarse fraction and in the range of accumulation), and succinate, formate, NH_4^+, Mg^{2+} and lactate showed trimodal distribution (coarse particles, nanoparticles, and accumulation mode). The species present in the coarse fraction showed biogenic sources (sea spray and resuspension of particles), while the source contributions for accumulation mode and nanoparticles were anthropogenic (fuel burning and industrial).

[4]Icelandic Meteorological Office, Reykjavik, 150, Iceland
Keywords: glaciogenic dust, HYSPLIT, volcanic ash, dust plume.
Presenting author email: e-mail: pavla@lbhi.is

Iceland, an island in the North Atlantic Ocean, is an active source of dust from glaciogenic and volcanic sediments. Frequent strong winds drive the soil into suspension and transport the dust several hundreds of km over the N-Atlantic Ocean and the Arctic Ocean.

We observed 1033 dust days from the meteorological observations in NE Iceland in 1949-2011. A total of 192 dust events were severe in the sense that the visibility was less than 5 km. An annual mean of 55 days of atmospheric dust observation was reported for the first decade of the 2000s in Iceland (our data and Georgsdottir, 2012). We chose two of the most severe dust storms for each region - N and S Iceland - with different dust sources and deposition areas. The South-Iceland Dust Storm (SDS) occurred on slope of the Eyjafjallajokull volcano five months after the eruption on September 14th 2010. The major source of resuspended material was volcanic ash and the deposition area was over the North Atlantic Ocean and further over Europe. We measured an aeolian particle transport with BSNE wind erosion samplers (Fryrear, 1986), total particle number with saltation sensor (SENSIT) and employed an automatic weather station *in situ* during this event. The North-Iceland Dust Storm (NDS) took place in outwash plains north of Vatnajokull glacier on September 17th 2008. The major source was glaciogenic dust and the deposition area was over the Arctic Ocean and Greenland. We calculated PM_{10} mass concentration from *in situ* meteorological and visibility observations. The aim of this study was to quantify aerosol particle transport of volcanic aerosol during extreme dust storms when the conventional aerosol measurements *in situ* fail. An attempt is made to detect the deposition area of dust storms by calculating forward trajectory and determining the Absorption Aerosol Index.

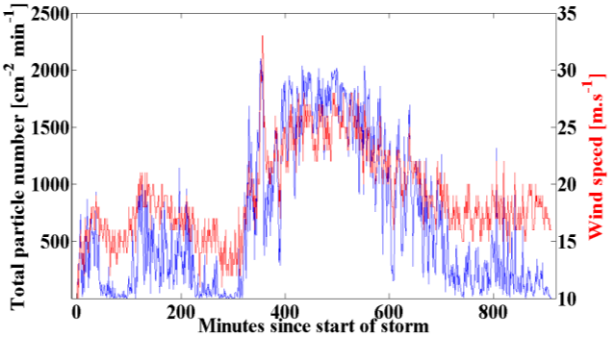

Figure 1. Total particle number measured with saltation sensor and mean wind speed during the SDS.

The SDS lasted for 23 hours and we measured max wind speed of 38.7 ms^{-1}, max total particle number of 2,100 $cm^{-2}min^{-1}$ and max saltation of 6,825 counts min^{-1} (Fig. 1). Total aeolian particle transport was calculated as 11,000 kg m^{-1} (Arnalds et al., 2013). The desposition area extended from the North Atlantic Ocean to Ireland, Great Britain and several trajectories arrived as far as to the Czech Republic. The NDS was observed for seven days with reduced visibility to 1500 m and calculated mean PM_{10} concentration of 231 µg m^{-3}. Depostion area was over the Greenland sea and air parcels travelled over northwestern Greenland (Fig. 2).

Icelandic dust storms are frequent and among the most severe dust storms observed on Earth (Arnalds et al., 2013). Fine glaciogenic particles can be rapidly activated and resuspended after recurrent flooding and travel over 1800 km within 24 hours. Deposition area is in the Arctic environment. Freshly deposited volcanic material under severe meteorological conditions such as in Iceland prolongs impacts of volcanic eruptions.

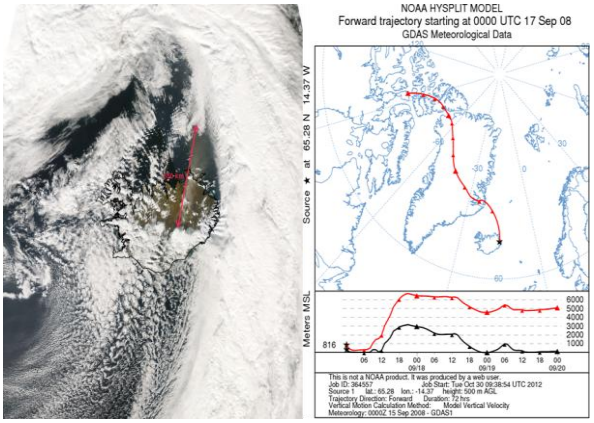

Figure 2. MODIS Aqua picture (left) and NOAA HYSPLIT 72-hr forward trajectory for air parcels released in Egilsstadir (right) during the NDS.

Measurements of particulate matter hygroscopicity in Aerosol Exposure Chamber to prevent atmospheric corrosion in Data Center

L. D'Angelo[1], G. Rovelli[1], L. Ferrero[1], G. Sangiorgi[1], M. G. Perrone[1], M. Moscatelli[1] and E. Bolzacchini[1]
[1] Environmental Science and Technologies, University of Milano-Bicocca, Piazza della Scienza 1, 20126, Milano, Italy
Keywords: hygroscopicity, deliquescence, crystallization, chamber.
Presenting author email: l.dangelo6@campus.unimib.it

Data Center energy consumption amounts to ~27% of energy demand in Western Europe. About 35-50% of this energy is used by air-cooling system to remove the heat generated by electronic circuit activities (Shehabi, 2009). A recent solution to save energy consists in using an outside airflow to cool informatic technology (IT) equipment. This system, called Direct Free-Cooling, involves the risk to introduce particulate matter (PM) which can operate electrochemical corrosion once it deposits on ITs and reaches deliquescence conditions. Furthermore PM can arrange electrical conductive bridges which can cause the failure of ITs (Shehabi et al., 2008). ASHRAE (American Society of Heating, Refrigerating and Air-Conditioning Engineers) Technical Committee 9.9 guidelines recommend air thermodynamic conditions only to prevent corrosion process. It suggests to estimate deliquescence relative humidity (DRH), but it avoids to consider both the aerosol chemical composition – which drives the aerosol DRH – and the crystallization relative humidity (CRH).
Systematic studies of DRH and CRH changes related to the aerosol chemical composition, which in turn varies in space and time, are missing.
For these reasons, DRH and CRH were experimentally investigated in this study by electrical conductive measurements. In this respect, PM2.5 atmospheric samples collected at two sites, Milan (45°31'19"N, 9°12'46"E) and Oasi Le Bine (45°8'17.24"N, 10°26'10.99"E), were used to characterize respectively the urban and rural PM hygroscopic behaviour in the Po Valley (North Italy). Conductivity was measured in an Aerosol Exposure Chamber (AEC) – specifically designed for this study by Atmospheric Chemistry Research Group in Milano–Bicocca University – as a function of the relative humidity (RH) which was controlled by 1% step. Conductivity measurements were carried out using the Hewlett-Packard 3421A Data Acquisition Module while RH was monitored by LSI-Lastem termoigrometer sensor.
The inorganic ionic chemical composition of the 15 samples was also determinated by ionic cromatography (for cations: Dionex ICS-90 and for anions: Dionex ICS-2000) system. Data from chemical analysis were used to model hygroscopicity of collected particles by using the water moles output of the thermodynamic Extended-Aerosol Inorganics Model (E-AIM II, Clegg et al., 1998) Experimental data from AEC and model result were then compared (Figure 1).
Conductivity analysis on PM2.5 show hysteresis behaviour (Figure 2).
Data from AEC analysis of the 15 $PM_{2.5}$ show an average DRH of 61.38±1.68% and CRH of 47.12±1.58%. E-AIM modelled results estimate an average DRH of 63.00±2.16%.
These results are very useful to improve knowledge about the thermodynamic conditions which can cause corrosion processes triggered by atmospheric aerosols.

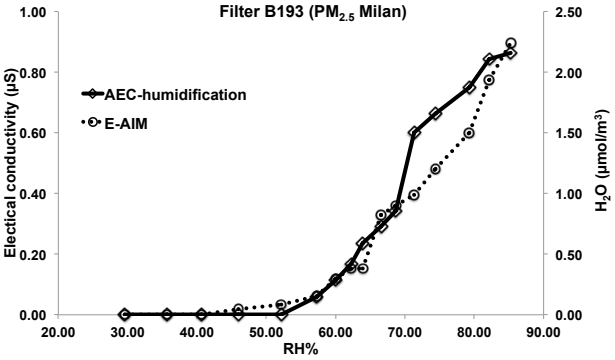

Figure 1. Aerosol conductivity curve (electrical conductivity; µS) during AEC air humidification and hygroscopic growth (H_2O; µmol/m^3) modelled by E-AIM II.

Effect of the extensive use of fireplaces on carbonaceous particle concentration levels in Athens, Greece

E. Diapouli, V. Vasilatou, S. Vratolis, M. Gini, D. Saraga, Th. Maggos, K. Eleftheriadis

Institute of Nuclear & Radiological Sciences & Technology, Energy & Safety,
National Centre of Scientific Research "Demokritos", 15310 Ag. Paraskevi, Attiki, Greece
Keywords: carbonaceous aerosol, biomass burning, urban background site, $PM_{2.5}/PM_{10}$.
Presenting author email: ldiapouli@ipta.demokritos.gr

The main factors contributing to reported exceedances of the particulate matter (PM) air quality limit values, in Athens are the high urbanization of the city, mostly reflected by intense traffic, along with meteorological conditions that favour the accumulation of the emitted pollutants. During the last two years, the financial crisis has greatly affected every aspect of the country's economic and other activity, including significant changes in the emission strength of certain sources. Instead of diesel fuel oil, which was traditionally used for residential heating, massive use of fireplaces or wood stoves became a regularphenomenon across the city. The objective of the present work was to investigate the long term effect of this intense biomass burning activity on the concentrations of PM and in particular its carbonaceous constituents.

The results presented correspond to winter measurements (November – January) collected during 2010 – 2013 at Demokritos urban background station (GAW-DEM, 2007). 24-hr $PM_{2.5}$ concentrations were measured gravimetrically, while elemental (EC) and organic (OC) carbon concentrations were monitored on a 3-hr basis by Semi-Continuous OCEC Field Instrument (Sunset Laboratory Inc.).

During January 10 – February 10, 2013 an intensive campaign was conducted, targeted specifically on the effects of biomass burning. $PM_{2.5}$ and $PM_{2.5\text{-}10}$ concentrations were measured gravimetrically by means of a low volume custom-made two stage impactor. Two samples were collected daily starting at 8:00 am and 6:00 pm, in order to characterize separately the day-time and night-time periods. In addition, 6-hr PM_{10} samples were collected on quartz filters, to be analyzed for OC and EC (Lab OC-EC Aerosol Analyzer, Sunset Laboratory, Inc.).

Initial results clearly demonstrated an increase in $PM_{2.5}$ and organic carbon concentrations during the present and last winter, in comparison to 2010-11 (Figure 1). The largest difference corresponded to the contribution of OC to $PM_{2.5}$ mass, which has more than doubled during the last two winter seasons (mean OC-to-$PM_{2.5}$ concentration ratios for the three consecutive periods: 0.21, 0.55 and 0.47). This effect was more pronounced in 2011-12 when temperatures were generally lower than the following year. January 2013 was rather mild (mean value around 10°C), with frequent south winds and a number of Sahara dust transport events. On the other hand, the drop of temperature was followed by a sharp increase in OC levels, especially during the night, clearly indicating the use of fireplaces (Figure 2).

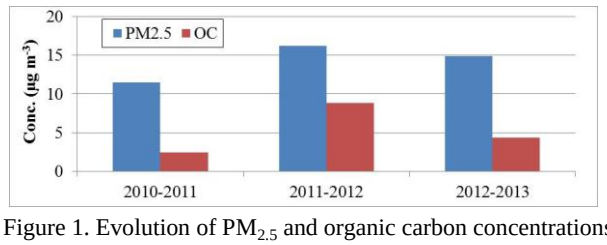

Figure 1. Evolution of $PM_{2.5}$ and organic carbon concentrations during wintertime of 2010 - 2013.

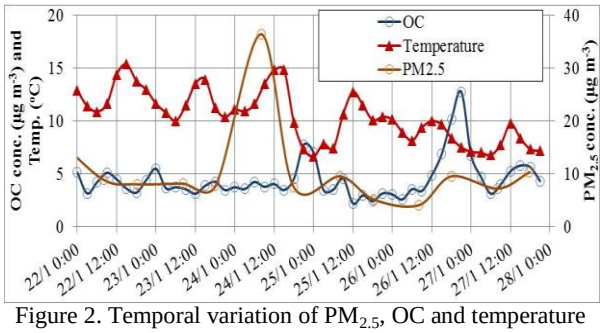

Figure 2. Temporal variation of $PM_{2.5}$, OC and temperature during 22 – 27/1/2013.

Elemental carbon concentrations were similar during 2010/11 and 2012/13(0.72 μg m^{-3} and 0.68 μg m^{-3} on average, respectively) and much higher during 2011/12 (2.53 μg m^{-3}). These results reflect changes in anthropogenic activities caused by the financial crisis of the two last years. In the previous years the main source of EC in the area was vehicular traffic. During winter of 2011/12 biomass burning emissions were added to traffic causing a great increase in concentration levels. During winter 2012/13 lower traffic densities were observed, while the change in source contributions is highlighted by the EC/OC concentrations ratio which has decreased from a value of 0.30 to 0.15, indicative of biomass burning aerosol (Schmidl et al., 2008).

Distribution of aerosol over coal strip mine

V. Docekalova[1], J. Hovorka[1], F. Kobrzek[2], P. Marecek[2]
[1]Institute for Environmental Studies, Faculty of Science, Charles University in Prague, Benatska 2, 128 01 Prague 2, Czech Republic
[2] AirshipClub.com, Nad Salkovnou 9, 147 00 Praha 4, Czech Republic

Keywords: coal strip mine, PM_{10}, flight measurement.
Presenting author email: venikae@gmail.com.

Coal strip mine is supposed to be significant source of coarse atmospheric aerosol to surroundings of the mine. Contribution of the mine aerosol to the air pollution in the surroundings are usually modelled (Chakraborty et al., 2002; Guidebook, 2009) and rarely directly measured (Hovorka et al., 2011), since vertical transport of the mine aerosol directly from the source is difficult to measure.

Therefore, objective of this study was to measure vertical and horizontal distribution of PM_{10}, PM_1 and coarse aerosol in atmospheric boundary layer above the area of coal strip mine through unique experimental flight measurements.

Electrically powered airship was used with specially designed gondola carrying aerosol monitors DustTrak DRX Aerosol Monitor 8533, TSI, P-Trak Ultrafine Particle Counter 8525, TSI. Temperature and relative humidity data were also recorded. Detailed information is summarised in table 1.

Table 1. Parameters measured during flights.

Parameter	Instrument	Logging interval
PM_{10}, $PM_{2,5}$, PM_1	DRX	1 s
20 nm – 1000 nm particles number concentration	P-Trak	1 s
Temperature, RH	Commeter	10 s

Repeated flights were carried out in several heights according to mine edge level (- 50 m, 0 m, 50 m, 100 m, 150 m). Airship position data were recorded also every second. Airship velocity was in the range from 2 to 7 ms^{-1}.

Figure 1 shows how mass concentration of coarse mode of aerosol depends on distance from the mine surface: the closer distance, the higher concentration.

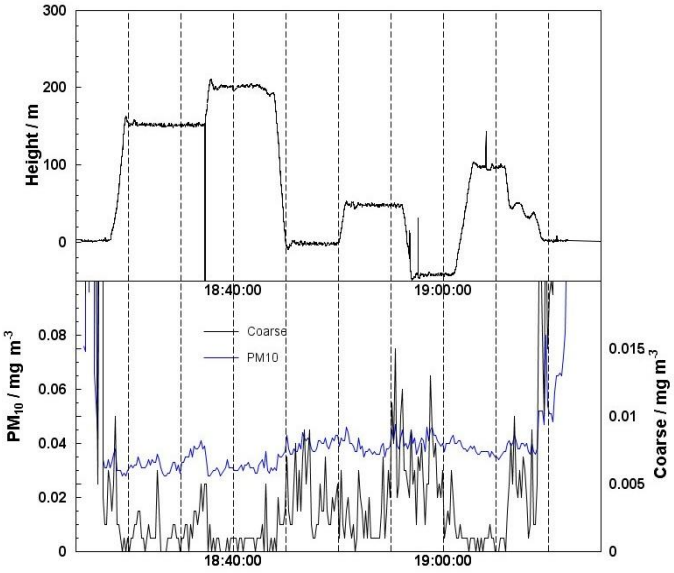

Figure 1. Vertical distribution of PM_{10} and coarse mode-particles over coal strip mine.

Flight measurements were also compared to ground-based measurements of PM_{10} and PM_1 and meteorological data.

Presenting author email: vanessa.dossantos-juusela@helsinki.fi

Road traffic is a major source of airborne ultrafine particles (UFP, diameter < 100 nm) in urban areas. As these particles concentrate close to the sources, their number can vary considerably from site to site (Seinfeld and Pandis, 2006). Since exposure to UFP is suspected to cause serious adverse health effects (Franck et al., 2011, Oberdörster et al., 2004), understanding the spatial-temporal variations of UFP in urban areas is of great importance, especially for epidemiological studies. We evaluated the spatial-temporal variations of UFP by measuring particle total number concentrations (PNC) continuously in a busy street canyon and an urban background site of Helsinki, from 20.01 to 10.06.2010, using condensation particle counters. In addition, we evaluated the influence of roof-top wind speed, wind direction and temperature on PNC inside the street canyon, as well as the correlation between PNC and PM_{10}, $PM_{2.5}$ and black carbon (BC).

We found that the median PNC in the street canyon (16 500 cm^{-3}) was 3 times higher than in the urban background (5 300 cm^{-3}) for 1-min time series, and were moderately correlated (R^2 = 0.50, for 1-hour medians time series). The peak median number concentration in the street canyon during the morning rush hours was 40 200 cm^{-3} while in the urban background it was nearly 5 times lower, 8 400 cm^{-3}. The analysis of meteorological conditions showed that PNC in the street canyon were inversely proportional to wind speed and temperature, and highly dependent on wind direction. The highest concentrations were during northeastern winds and the lowest during southwestern winds. As both directions are perpendicular to the street axes, we speculate that the higher PNC during northeastern winds may result from wind vortex formation inside the canyon, as suggested by previous studies. The PNC in the street canyon were best correlated with black carbon (R^2 = 0.78) than with $PM_{2.5}$ (R^2 = 0.34) or PM_{10} (R^2 = 0.05) for 1-hour medians of weekdays. The result was expected since $PM_{2.5}$ and PM_{10} are also affected by sources other than traffic, such as long range transport and street dust.

The results confirm that the combination of high traffic intensity and slow dispersion rates in the street canyon yield in PNC considerably higher than the urban background levels. This indicates that people spending time in the street canyon are exposed to considerably higher UFP concentrations than people spending time in the urban background. Thus, air pollution hotspots should be considered in epidemiological evaluations.

The aerosol data was partly produced in the MMEA Programme (Measurement, Monitoring and Environmental Assessment). MMEA is supported by TEKES (the Finnish Funding Agency for Technology and Innovation) and coordinated by the Finnish energy and environment cluster – CLEEN Ltd. We would like to thank the Helsinki City Planning Department for providing the traffic data and Pasi Aalto for providing the technical support.

Airborne Aldehydes as Altitude-Distributed Source of Particulate Matter in the Troposphere

S.N. Dubtsov, T.A. Maksimova, G.G. Dultseva

Institute of Chemical Kinetics and Combustion, Siberian Branch of the Russian Academy of Sciences, Novosibirsk, 630090, Russia

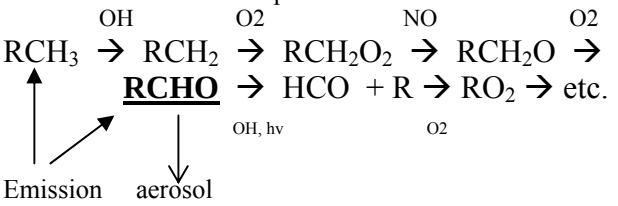
Keywords: atmospheric aerosol, aldehydes.

Presenting author email: dubtsov@kinetics.nsc.ru

Aldehydes emitted into the atmosphere from natural and anthropogenic sources, as well as aldehydes formed as secondary pollutants in the atmospheric photooxidation of various hydrocarbons, are precursors of particulate matter. Our previous studies proved that even the simplest aliphatic and aromatic aldehydes form aerosol particles of nanometer size under photolysis (Dultseva et al., 2008). Surface sources of aldehydes have been assessed by researchers but the vertical (altitudinal) distribution of aldehydes in the troposphere remains unknown though the local concentration of aerosol-forming species is a very important characteristic to evaluate the rates and mechanisms of atmospheric photonucleation. In the present study we describe our approach to process the data on aldehyde concentrations at different altitudes to reveal the contributions from ground-based sources and chemical transformations of hydrocarbons in the troposphere.

Airborne measurements of aldehyde concentrations were carried out over the southern part of West Siberia in summer and autumn 2012, and in winter-spring 2013. Air samples were collected with an aircraft-mounted sampling device at the altitudes of 500 to 7000 m. Aldehyde concentrations were measured by means of HPLC using the procedure based on the reaction with 2,4-dinitrophenylhydrazine. Measurements revealed episodes with unexpectedly high [H_2CO] at some altitudes up to 7000 m, with nonmonotonic dependence on altitude, while aromatic aldehydes were not detected at altitudes above 2000 m. Keeping in mind the fact that benzaldehyde can be considered as a marker of anthropogenic air pollution, and our previous results on urban air pollution indicating that benzaldehyde in cities with high traffic usually accounts for *ca.* 10 % of formalehyde concentration, we used the relations between measured [H_2CO] and [C_6H_5CHO] as the basis to distinguish between anthropogenic and natural formaldehyde sources.

Formaldehyde at the altitude of 7000 m was thus related to natural sources. To reveal whether natural sources may account for high (> 0.3 mg/m^3) formaldehyde concentrations, we carried out modelling of the chemical mechanism of hydrocarbon photooxidation at the level of elementary stages, leading to gas-to-particle conversion under tropospheric conditions. We chose isoprene as a model compound emitted by vegetation and compiled the scheme of its transformations in the atmosphere according to Carter (2007), with focus on aldehydes formed at some stages as intermediate products. Rate constants for elementary stages were taken from the NIST Database when available, and the values for unknown rate constants were chosen on the basis of known ones for similar stages with other hydrocarbon species. This approach, together with the simulation of nucleation according to Smolukhowski's algorithm, allowed us to assess the biogenic contribution into formaldehyde concentration in middle troposphere. The general scheme of transformations can be represented as



This general scheme involves specific stages for the cases of R = alkenyl (hydrocarbon radical with double bonds) and R = alkyl. Hydrocarbons present in industrial emissions and those emitted by the vegetation can be clearly distinguished from each other in the samples collected in winter when only the contribution from coniferous trees is to be taken into account, while foliaceous trees, bushes and herbs do not emit organic compounds into the atmosphere. Aldehydes also exhibit a clear distinction of natural origin from the industrial sources. This evaluation allowed us to state that the origin of substituted aromatic aldehydes in the atmosphere is commonly biogenic, while benzaldehyde is an industry-related pollutant. Aliphatic aldehydes, including formaldehyde, originate both from vegetation and from industry; these contributions can be quantified through a comparison between summer and winter samples. Our results suggest that in summer about 80 % of airborne formaldehyde in the troposphere at an altitude of 5000 m and above has the biogenic origin, and among this amount, more than a half is formed as the secondary pollutant in alkene and alkane photooxidation, while the fraction of industry-related contribution reaches more than 90 % in winter but accounts for notmore than 20 % in summer. This feature may be significant for any region with climatic conditions close to those existing in the southern part of West Siberia.

The comparison of the light scattering coefficient measured in urban and coastal environments

V. Dudoitis, V. Ulevicius, K. Plauškaitė and G. Mordas

Center for Physical Sciences and Technology, Savanoriu av. 231, LT-02300, Vilnius, Lithuania
Keywords: light scattering, angstrom exponent, nephelometer
Presenting author email: vadimas.dudoitis@ftmc.lt

Atmospheric aerosols affect the Earth's climate directly through absorbing and scattering the solar radiation. The light scattering coefficient is depended on the aerosol particle chemical composition and is different in various environments. In this work, we determined and compared light scattering coefficients for urban and coastal environments. The most common component of coastal aerosol is sea-salt, which has a significant influence on the light scattering properties Chamaillard *et al* (2006). One of such property is a wavelength dependence of the optical thickness described by the Ångström wavelength exponent α. According to Smirnov *et al* (2002) average α values estimated for marine environments were in range from 0.3 to 0.7.

Table 1. Monthly observations of aerosol light scattering coefficients.

	AVG, Mm^{-1}	MAX, Mm^{-1}	MIN, Mm^{-1}	25‰, Mm^{-1}	50‰ Mm^{-1}	75‰, Mm^{-1}
Vilnius city						
σ_{sp}^{450}	30.5	369.1	8.9	16.8	23.9	37.8
σ_{sp}^{550}	20.2	276.2	5.6	10.9	15.7	24.9
σ_{sp}^{700}	12.8	194.6	3.5	6.7	9.7	15.8
Environment Pollution Research station in Preila						
σ_{sp}^{450}	109.6	279.4	13.2	61.6	96.2	158.1
σ_{sp}^{550}	84.5	223.5	9.3	49.1	71.9	119.4
σ_{sp}^{700}	61.7	167.5	7.7	36.2	52.5	85.0

An integrating nephelometer TSI 3563 was used to measure the light scattering coefficient during the whole measurement campaign. Measurements were performed in Preila (55°22'39.24", 21°1'54.34"; coastal area; 2012 December) and Vilnius (54°38'36.31", 25°10'58.81"; urban-background area; 2012 July).

The statistical analysis (Table 1) revealed that almost all total scattering coefficient values were higher in Preila than in Vilnius. Though exceptionally high (MAX) values in Vilnius were reported during the Saharan dust event Mordas *et al* (2013). However, such event is not common for this area and doesn't correctly represent the monthly variations. Thus, the comparison of 99th percentile shows that the aerosol scattering coefficient in Preila is 2.4 times higher than in Vilnius.

Klaipėda meteorological station data and HYSPLIT4 air mass backward trajectories, were compared with α values in Preila and in Vilnius. Preila wind directions can be combined in two categories: from the sea (SW, W, NW, N) and from the land (NE, E, SE, S). Lowest α values were reported from the sea directions, except from the North. In this case, average Ångström values were in range: α_1 = 0.46 – 0.79; α_2 = 0.24 – 0.25; α_3 = 0.42 - 0.58. On the contrary, the wind direction from the land resulted in higher Ångström values, which can be classified as continental aerosol. Average α values for land directions were in range: $\alpha_1=\alpha_2=\alpha_3$=1.32 – 1.48.

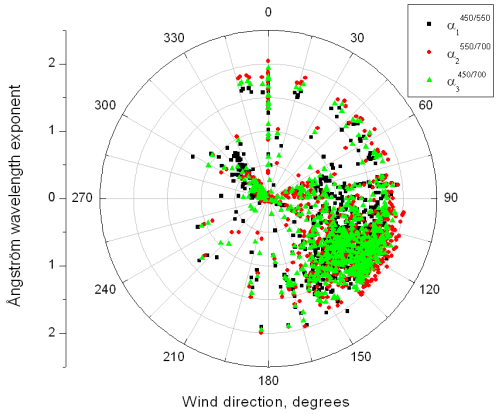

Fig. 1. The dependence of Ångström wavelength exponent α on the wind direction in Preila.

Variations of PM_{10} and its relationship with ^{7}Be and ^{210}Pb measurements at Malaga (Southeastern coast of Spain)

C. Dueñas[1], M.C. Fernández*[1], E. Gordo[1],E.Liger[2] S. Cañete[1] and M. Pérez[3]

[1]Department of Applied Physics I, Faculty of Science, [2]Department of Applied Physics II, Faculty of Computer Engineering, [3]Department of Radiology and Health Physics, Ophthalmology and OTL, Faculty of Medicine. University of Málaga, 29071 Málaga, Spain.

Keywords: ^{7}Be, ^{210}Pb, atmospheric aerosols, gamma spectrometry, particulate matter (PM_{10}).

*Presenting author email: mafeji@uma.es

Levels of particulate matter fraction PM_{10} were monitored between 2009 and 2011 in Málaga (Spain). PM_{10} concentrations were measured at "Carranque" station by the beta attenuation method. This station is one of the Atmospheric Pollution Monitoring network managed by the Environmental Health Service of the Andalusian Government.

Weekly ^{7}Be and ^{210}Pb concentrations in air were continuously monitored (4º 28' 4" W; 36º 43' 40"N) with a high-volume air sampler (ASS-500C). This sampler uses polypropylene square filters (44 x 44 cm^2) with a collection efficiency 93-99%, at a flow rate of 90,000 L min^{-1}. Measurements by gamma-spectrometry were performed to determine the activities of the samples using an intrinsic REGe detector.

Long-term measurements of cosmogenic radionuclides such as ^{7}Be provide an important data in studying global atmospheric processes and comparing environmental impact of radioactivity from man-made sources to natural ones. On the other hand, ^{210}Pb is produced by radioactive decay from its progenitor, ^{222}Rn, which emanates primarily from land surface. Therefore, ^{210}Pb in the air is an effective tracer of the continental surface air mass. The variation of the data with time was studied by time series analyses and seasonal patterns were identified. The study of air back-trajectories were computed by means of the Hybrid Single-Particle Lagrangian Integrated Trajectories (HYSPLIT) trajectory model (Draxler, 1994) using meteorological data supplied by the US National Climatic Data Centre.

Table 1 provides arithmetic mean (AM) and related statistical information such as geometric mean (GM), standard deviation (SD), variation coefficient (CV), maximum (MAX) and minimum (MIN) values.

Table 1. Statistical parameters of the different measurements.

	AM	GM	SD	CV(%)	MAX	MIN
^{7}Be (mBq/m^3)	5.1	4.8	1.7	34.7	10.2	2.1
^{210}Pb (mBq/m^3)	0.55		0.31		2.04	0.1
PM_{10} ($\mu g/m^3$)	40.3	37.8	14.3	35.5	86.3	17.4

The concentration data of ^{7}Be, ^{210}Pb and PM_{10} with meteorological variables were correlated to understand the weekly variation of these radionuclides in air. This study has shown that ^{7}Be and PM_{10} are associated with different sources in Málaga and they may reach high concentrations simultaneously. The reason for this is the concurrent occurrence of subsidence processes over North Africa (resulting in the downward transport of ^{7}Be from the mid-troposphere) and the suspension of mineral dust over desert region with a subsequent transport to Málaga. Additionally, in order to simplify the analysis, the events have been grouped into: (a) High PM_{10} and ^{210}Pb concentrations with low ^{7}Be concentrations; (b) High PM_{10} and ^{210}Pb concentrations with high ^{7}Be concentrations; (c) Low PM_{10} and ^{210}Pb concentrations with low ^{7}Be concentrations.

Several events of high ^{7}Be concentrations are mainly caused by downward transport of ^{7}Be from the mid-troposphere at mid-latitudes. The meteorological situation was characterised by an Atlantic anticyclone system with a low-pressure area over central European North Atlantic. High ^{7}Be concentrations were also found associated with low aerosol mass concentrations. These values were attributed to downward transport from mid-to-upper troposphere over the North Atlantic. The meteorological situation was characterised by a south Europe anticyclone located in the South Atlantic Ocean that favoured the development of a blocking system with a low-pressure area over north Europe. Under these conditions, a slanting stratospheric air mass can penetrate into the troposphere (Hernández et al., 2008). The distribution of ^{210}Pb in the atmosphere show both spatial and temporal variations depending on the geographical location, atmospheric circulation and scavenging processes. High concentrations for ^{210}Pb are obtained with air masses from the Sahara area.

ATMOSPHERIC FLUXES OF RADIONUCLIDES ON MONTHLY TIME -SCALE IN MALAGA (SPAIN)

C. Dueñas[1], M.C. Fernández[1], E. Gordo[1], S. Cañete[1], E. Liger[2] and M. Pérez[3]
1 Department of Applied Physics I, Faculty of Sciences, [2]Department of Applied Physics II, Faculty of Computer Engineering, [3]Department of Radiology and Health Physics, Ophthalmology and OTL, Faculty of Medicine. University of Málaga 29071 Málaga (SPAIN)
Keywords: atmospheric aerosol, deposition, ^{7}Be, ^{210}Pb, precipitation
E-mail: mcduenas@uma.es

ABSTRACT.- Bulk atmospheric deposition of gamma radionuclides (^{7}Be, ^{210}Pb and ^{40}K) has been measured at Málaga (4º 28′ 80″ W; 36º 43′ 40″ N) at a coastal Mediterranean station in the south of Spain, from January 2005 through December 2012 for monthly periods

INTRODUCTION Berylium-7 is one of the radionuclide produced by spallation reactions of cosmic rays with light atmospheric nuclei.^{7}Be rapidly associates primarily with submicron-sized aerosol particles. Lead-210 which is one of the natural radionuclide of the ^{238}U decay series is widely used as a tracer. ^{210}Pb depositional pattern gave us information on continental aerosols in lower troposphere. These two radionuclides with their different sources and therefore are useful to understand the mechanisms of aerosol removal from the atmosphere. These radionuclides have been measured routinely in many places of the word in order to study the description of environmental processes such as aerosol transit and residence times in the troposphere and aerosol deposition velocities. ^{40}K is found in most types of soil and can easily be transported by re-suspended material. Potassium is an important constituent of fertile soil and is an essential nutrient for plant growth and in the human diet. This nuclide has been previously associated with the arrival of coarse re-suspended material (PM10, particulate matter with diameter below 10 µm) from the African continent (Hernández et al., 2005).

MATERIAL AND METHODS.- The sampling site is one of the environmental radioactivity monitoring network stations operate by the Spanish Nuclear Security Council (CSN). The sampling point was located above the ground, on the roof of the Faculty of Sciences, University of Málaga.

Monthly precipitation and dry fallout samples were routinely collected using a steel tray 1m^2 in area as a collecting system and polyethylene vessels of 50 l capacity for rainwater samples reservoirs. Measurements by gamma spectrometry were performed to determine the ^{7}Be, ^{210}Pb and ^{40}K activities of the samples using an intrinsic REGe detector. The peak analysis of ^{7}Be (I= 10.52 %, 477.7 keV), ^{210}Pb (I = 4%, 45 keV) and ^{40}K (I = 11%, 1460.8 keV) was done using GENIE 2000 peak analysis software. The counting time was 172800s.

RESULTS.- Table 1 summarises the main statistical variables calculated for the measured gamma emitting radionuclides (^{7}Be, ^{210}Pb and ^{40}K) in Bq/l over the whole sampling period.

	^{7}Be	^{210}Pb	^{40}K
Average	2,66	0.41	0.23
Geometric mean	2.19	0.34	0.18
Standard deviation	1.70	0.24	0.15
Coeff. of variation	63.9 %	58.7%	68.0%
Minimum	0.6	0.05	0.02
Maximum	8.3	1.32	0.84

The results from fluxes of ^{7}Be, ^{210}Pb and ^{40}K were correlated with five parameters: rainfall amount, rainfall duration, number of dry days and number of wet days. The next table provides the correlation coefficients between the fluxes and the mentioned parameters.

	Flux ^{7}Be	Flux ^{210}Pb	Flux ^{40}K
Precipitation (mm)	0.84	0.89	0.66
Duration of precipitation (min)	0.7,	0.82	0.59
Number of dry days	-0.45	-0.63	0.55
Number of wet days	0.51	0.68	0.61

The depositions of ^{7}Be and ^{210}Pb were well correlated with the amount of precipitation . Such relations have been commonly observed and explained by the fact that rainfall constitutes the major depositional pathway of these radionuclides. As previously observed, correlation of rainfall with ^{210}Pb seems better than with ^{7}Be (Caillet el al., 2001) likely due to a relatively greater contribution of ^{210}Pb from dry deposition.

The comparative analysis of variations of background radiation components and atmospheric electrical parameters

M.S. Cherepnev[1], I.I. Ippolitov[2], M.V. Kabanov[2], P.M. Nagorsky[2], S.V. Smirnov[2], A.V. Vukolov[1], V.S. Yakovleva[1]

Keywords: background radiation, light ions, atmosphere, variation
Presenting author email: maxcherepnev@gmail.com

Interest to investigation of natural background radiation levels is caused by the need to assess the role of ionizing radiation variations in the dynamics of aerosol atmosphere. The main purpose of the work was a comparative evaluation of the spectral-temporal variations of the ionizing radiation measured at series of heights and depths, and identification of their mutual relations with meteorological and electrical parameters of the surface layer. The monitoring method and equipment are detail described in [1].

3-years experiment in Tomsk revealed that variations of β-background radiation of atmosphere are relatively poorly associated with pressure variations of synoptic-scale and is closely related to daily variations of temperature and moisture. Annual behavior of β-background changes from year to year as opposed to γ-background for which the maximum is observed in November and a minimum in February and March. Synchrony in the dynamics of β- and γ-radiation fields was registered in summer-autumn period.

In soil, the duration of increase of background radiation component levels was from 6 up to 12 hours, the duration of recovery was about some days. Variations of α-, β-and γ-radiation in atmosphere and soil with a one-day period were in opposition. Relationship of variations of atmospheric meteorological parameters and subsurface radiation components has fundamentally different nature in winter and summer conditions. Namely, in winter pressure increase is accompanied by an increase in the subsurface radiation components but in summer there is no such relationship between them. Typical example of the dynamics of atmospheric (height) and subsurface (depth) components of β-background in early winter is represented in Fig. 1. Here are the variations of: β-background levels at a height of 10 m (h=10 m) and at a depth of 50 cm (h=-0.5 m); positive and negative conductivities (light ions) $\lambda_{\pm}$ (data1 – λ_-; data2 – λ_+), pressure ***P*** and temperature ***T***.

If for $\lambda_{\pm}$ the correlation with variations of pressure is negative, then the β-background in the soil it is positive. A situation with variations in the temperature is reversed: the correlation between above mentioned parameters and the temperature changes its sign compared to the pressure. β-background radiation in the air rise sharply with amplitude of up to several hundred percent and duration from a few hours to half a day with changing pressure (temperature). Temporal variations of β-radiation in soil are not some hours but some days.

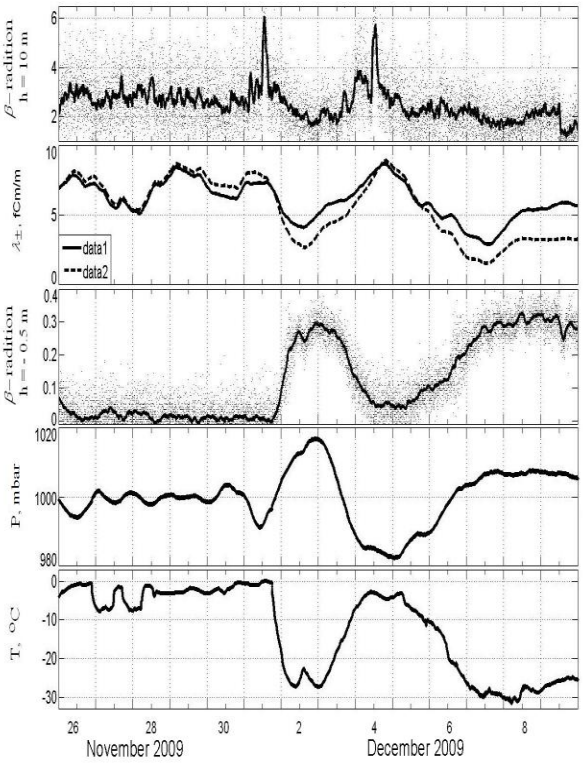

Figure 1. Variations β-background radiation and meteorological parameters in winter season

3-years monitoring revealed some important futures in variations of background ionizing radiation at series of heights and depths during such events as heavy rainfall.

It was also observed that on synoptic and annual scales the variations of atmosphere γ-background and the neutron component of cosmic rays are closely related with atmospheric pressure changes. As a result, cyclonic activity leads to concerted fluctuations in the γ-background levels of terrestrial origin and cosmic rays, and the restructuring of the atmospheric circulation in large areas, which is related with global climate changes, leads to concerted changes in the γ-background level.

Keywords: organic aerosol, carbon isotopes, volatility, SOA.
Presenting author email: u.dusek@uu.nl

The stable carbon isotopes ^{12}C and ^{13}C can be used to get information about sources and processing of organic aerosol (OA). We developed and tested a method to measure $\delta^{13}C$ values of OA collected on filter samples in different volatility classes. These filter samples are introduced into an oven, where organic compounds are thermally desorbed in He at different temperatures. The compounds released at each temperature step are oxidized to CO_2 using a platinum catalyst at 550 °C. The CO_2 is then passed on to an isotope ratio mass spectrometer (IRMS) to measure $\delta^{13}C$ ratios. With a similar setup the chemical composition at each temperature step can be determined using a Proton Transfer Reaction Time-of-Flight Mass Spectrometer (PTR-ToF-MS).

System evaluation with controlled test compounds showed that organic compounds usually start evaporating from the filter when their melting point is reached. Isotopic fractionation occurs only if one temperature step is within a few degrees of the melting point of the substance, so that the substance only partially evaporates. However, this effect should be limited in an ambient sample containing thousands of individual chemical compounds. $\delta^{13}C$ values of aerosol filter samples do not depend on the sample amount used, i.e. the system shows good linearity. The reproducibility depends somewhat on the sample amount and is usually $< \pm$ 0.3 ‰ for oven temperatures up to 200 °C and $< \pm$ 0.5 ‰ for oven temperatures greater than 200 °C.

We analysed aerosol samples collected in a tunnel in Brazil (vehicular emissions), laboratory generated secondary organic aerosol (SOA) from alpha-pinene ozonolysis, and ambient filter samples from a regional site in the Netherlands and an urban site in Belgium. First results indicate that the SOA produced in our experiments is slightly enriched in $\delta^{13}C$ compared to the precursor alpha-pinene. It is also more volatile than organic aerosol from ambient or tunnel filters. The $\delta^{13}C$ ratios of SOA and vehicular emissions do not change strongly with oven temperature, i.e. the more refractory organic compounds have similar isotopic composition as the more volatile compounds.

This is in contrast to many ambient organic aerosol samples, where the more volatile compounds evaporating below 200°C are often depleted with respect to the refractory compounds (see Figure 1).

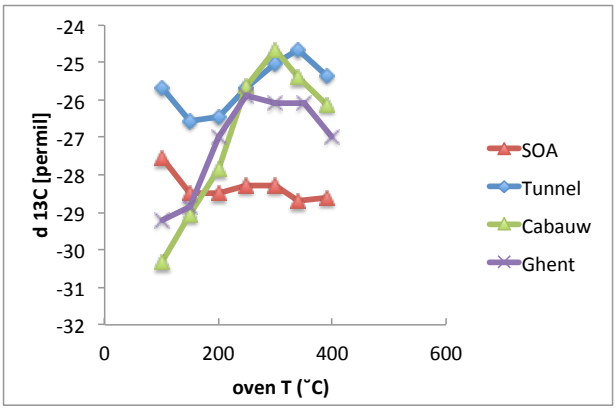

Figure 1. $\delta^{13}C$ of organic compounds released at a given oven temperature for aerosol filter samples taken in a tunnel in Brazil, SOA produced from alpha-pinene ozonolysis compared with typical ambient samples taken in the polluted regional background location of Cabauw, and the urban area of Ghent

Measurements at the Cabauw site show interesting differences between $\delta^{13}C$ measured in polluted air masses and relatively clean air with marine air mass origin. In polluted, continental air masses $\delta^{13}C$ is only weakly dependent on oven temperature, similar to the tunnel samples. In air masses with marine origin, organic compounds evaporating at low temperatures are strongly depleted in ^{13}C, see figure 1.

Possible reasons for the difference between source profiles and ambient samples (mixture of sources vs. the role of heterogeneous oxidation in the ambient filter samples vs. sampling artefacts) will be discussed and related to the chemical composition of the aerosol.

Road Pavement Abrasion as the Source of Particulate Matter

Dušan JANDAČKA, Daniela ĎURČANSKÁ

University of Žilina, Faculty of Civil Engineering, Department of Highway Engineering, Žilina, Slovakia
Key words: aerosol, particulate matter (PM), air pollution, asphalt mixture
Email: dusan.jandacka@fstav.uniza.sk

Sources of pollution with reference to particulate matter which originate from the automotive traffic can equally come from combustion processes or non-combustion processes. Non-combustion related emissions of particulate matter as of the automotive traffic may come from the tear and wear of tires, wear of the braking pads and callipers, lining of brakes [1], **abrasion of road pavement,** wear of mechanical clutches, car bodies and re-suspension of collected dust by virtue of the automotive traffic and their presence on the road, frequenting the road. It can prove rather complex and intricate to identify the road pavement abrasion directly in field as the source of particulate matter and separate it from other sources as well as quantify its share on the origination and presence of particulates. One of the possible ways is to approach the chemical analyses of particulate matter as well as multi-layer statistical analyses. But even then it is indispensable to be aware of which chemical substances are to be considered as prime suspects for a given source – to be contained and released by the road pavement, surface. The main goal of that experiment was to determine the presence, production or presence of aerosol in various samples of tarmac compounds (various in composition – hard-core aggregate and type of asphalt, tar used). Samples marked as A3 – tarmac concrete (AC), S3 – stone mastic asphalt (SMA), P3 – Single layer drainage asphalt (PA).

During the process of wearing the carriageways the ambient air was sampled inside the sampling device by means of the following apparatus - Aerodynamical Particle Sizer Spectrometer /APS/- Model 3321 and low volume flow sampler of Leckel LVS3.

Following the experimental measurements while focusing on the determination of the aerosol production originating in various road pavements and asphalt substances there were several differences uncovered among the tried samples. First of all the highest amount of the aerosol being released happened during the experimental phase, whereas it was determined to be with the sample of S3 – stone mastic asphalt (SMA). When comparing the overall mean concentrations, this was almost a twofold value. A numerous distribution of aerosol in all the three samples had a similar course. In relation to the weight distribution, a similar trend was carried over by samples of A3 and S3, the sample of P3 showed a more even weight distribution of aerosol without a significant peak values. At the same time, weight wise the most numerous aerodynamic diameter was greater than with A3 and S3 samples. In all the three cases of tested samples, the weight concentration when compared to the volumetric concentration of particulate matter, particulates were shifted towards the greater aerodynamic diameters. Each of the tested samples is a specific one, when relating to their composition – asphalt type, amount of asphalt, kind of aggregate, various lines of granularity and fraction in the composites. With regard to the materials used, there are various samples created observing similar surface structures, which can in the long run influence the abrasion of these road pavements.

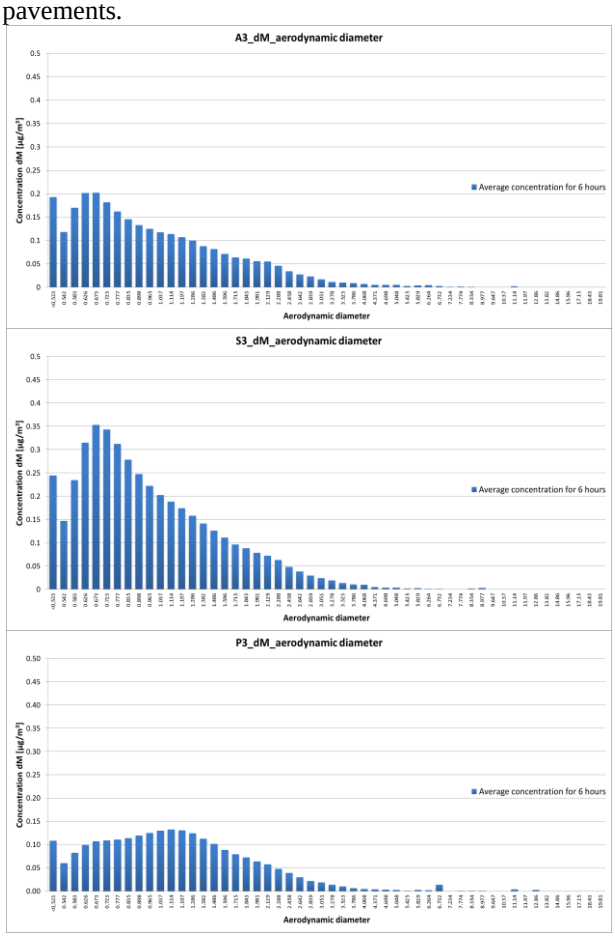

Figure 1 Mass concentration of aerosol from different asphalt mixture

National Parks and Wilderness Areas in United State possess many stunning vistas and scenery. Unfortunately, these scenes are diminished as result of increased air pollution. To maintain visual air quality, congress included legislation in the 1977 Clean Air Act to prevent future and remedy existing visibility problems. In 1985, the IMPROVE program (Interagency Monitoring of Protected Visual Environments) was initiated. This program implemented an extensive long term monitoring program to establish the current visibility conditions, track changes in visibility and determine causal mechanism for the visibility impairment in the National Parks and Wilderness Areas. (http://vista.cira.colostate.edu/improve/)

Since 2000 the total number of sites in the IMPROVE network is 110. These sites are under the supervision of the IMPROVE committee and represent 155 of the 156 areas of concern (figure 1).

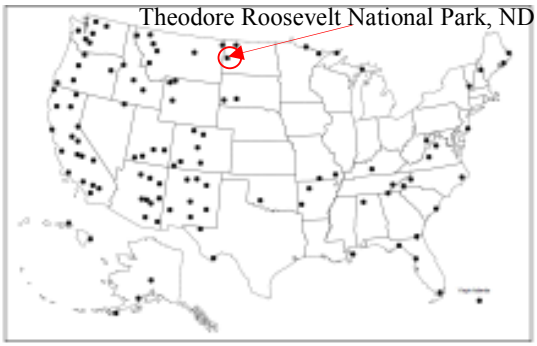

Figure 1. IMPROVE Monitoring Network (IMPROVE aerosol QMP, 2002) and location of this study's site.

The current study was focused on the Theodore Roosevelt National Park (North Dakota). This park is surrounded by oil and gas production wells (figure 2).

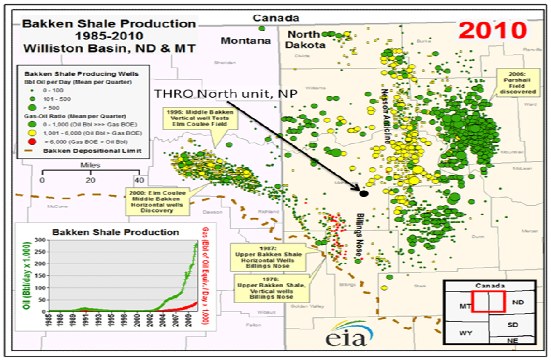

Figure 2. Distribution of Bakken Shale Producing Wells as 2010, and Monitoring Station location

Emissions from well development and production phases, including hydraulic fracturing "fracking" processes and open flame combustion of the extracted methane gas (figure 3), are not well characterized and their impact on visibility is unknown.

Figure 3. Oil wells and open flame near Watford City, ND

Three spot samplers have been deployed at the park's north site monitoring station, for the collection of time-resolved dry, concentrated $PM_{2.5}$ samples. Collection will be conducted from mid February to beginning of April. Samples for inorganic anion analysis (IC-ECD) are collected for 6 hr, and samples for polycyclic aromatic hydrocarbon characterization (HPLC-FL) and organic speciation by Thermo-desorption HR-GCxGC-MS are collected for 24hr.

Results obtained in this pilot study will help better understanding and characterizing emissions from oil production wells and fracking processes and their impact on the visibility and air quality of the park as well as surrounding communities.

Presenting Author e-mail: fhb487@alumni.ku.dk

Atmospheric aerosols play an important role on Earth's climate, atmospheric chemistry, visibility and human health. Aerosols are complex mixtures of organic and inorganic matters and several studies show that organic and inorganic constituents of the atmospheric aerosol are internally mixed.

The water activity of solutions comprising atmospheric particles is a key parameter to calculate the super-saturation required for particles to activate as cloud condensation nuclei (CCN). It is also needed to determine water uptake properties below 100% relative humidity which impacts visibility, direct radiative forcing, and hydrological cycle in the atmosphere.

Early experimental studies on the water activity of different constituents of the atmospheric aerosol acting as cloud condensation nuclei (CCN) mainly focused on common atmospheric inorganic salts such as ammonium sulfate and sodium chloride. However, organics have been shown to be a significant fraction of the aerosol mass (Kanakidou et al. 2005) in different environments, and the presence of organic species in atmospheric aerosol can affect both the aerosol hygroscopicity and the ability of mixed particles to serve as CCN (Raymond and Pandis, 2002, Kanakidou et al. 2005, Kristensen et al. 2012).

The focus of this study is to measure the water activity of several atmospherically relevant pure and mixed Organic/Inorganic systems in wide concentration range and provide data required to determine hygroscopic growth factor (Gf) and cloud-nucleating behavior of aerosol particles.

Methods

Water activities, a_w, are measured using an AquaLab water activity meter (Model 4TE, Decagon Devices, U.S.A.) covering the temperature range from 289-313K.

Results

Figure 1 shows measured water activity as a function of total concentration of solute for aqueous solutions of pure NaCl, solutions containing NaCl and the amino acid Glycine and pure Glycine.

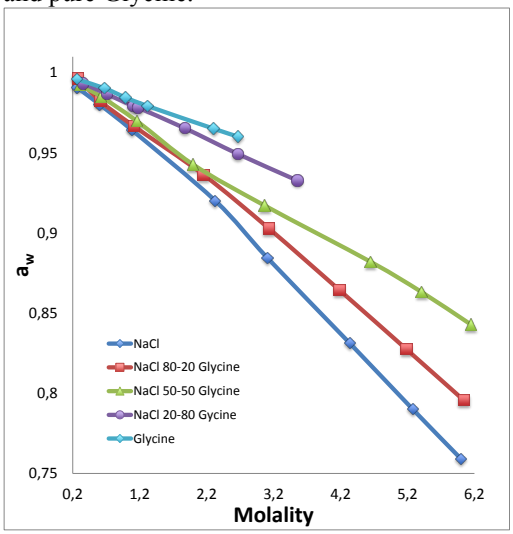

Figure 1: Water activity of pure and mixed NaCl/Glycine solutions (mass ratios are provided in the legends) measured at different concentrations at 298 K.

Measured water activities will be compared with thermodynamic modeling results. Hygroscopic growth factors calculated from the measured water activities will be presented and discussed.

We acknowledge the Carlsberg Foundation and the Nordic Center of Excellence on Cryosphere-atmosphere interactions in a changing Arctic climate (CRAICC).

Can lung-deposited surface area measurements serve as surrogate for black carbon?

M.Fierz[1,2], D.Meier[2], C.Hüglin[3] and H. Burtscher[1]

Mass-based limit values for particulate matter, based on size cut-offs at a few micron such as PM2.5 and PM10, are used all over the world for legal purposes, but the awareness is growing that these measurements may not adequately reflect the negative health impact of ultrafine particles. In particular, the world health organization (WHO) declared diesel soot particles to be carcinogenic in 2012, and these soot particles with typical diameters of around 70nm only contribute very little to PM2.5 and PM10 mass. Therefore, the search is on for alternative particle metrics that might be more health relevant with respect to ultrafine particles, and which could complement today's PMx standards. Due to the toxic properties of soot, the most obvious candidate is elemental carbon or black carbon (EC or BC), the latter can be continuously measured e.g. with an Aethalometer.

Another recent trend in urban air pollution monitoring is the move to multiple small and possibly mobile monitoring stations to complement today's fixed monitoring sites. These two trends are actually connected: The characteristic length scale over which PM mass based metrics vary is much larger than the length scale over which ultrafine particles vary, and therefore, if ultrafine particles are to be measured properly in an urban environment, a single fixed central measurement station – which was fine for PM10 - is no longer sufficient.

Since common instruments for BC measurements are bulky and expensive, they cannot be used in such sensor networks, and here we explore the use of another alternative metric, the lung-deposited surface area (LDSA), as a surrogate for BC in urban environments. LDSA is also interesting in its own, since the interaction of inhaled particles with the human body takes place on the particle surface; and a number of toxicology studies have found a better link between health effects and particle surface area than either particle mass or number (e.g. Waters, 2009). The lung-deposited surface area can be measured approximately with diffusion charging sensors (Wilson, 2007), which can be miniaturized easily. Such miniature diffusion charging sensors are interesting, because they can be incorporated in large numbers in sensor networks due to their low power consumption, comparatively low price, and long maintenance intervals. Moreover, they provide a much higher time resolution than common instruments for BC (on the order of seconds), which is necessary for mobile sensing platforms.

Our hypothesis is that LDSA and BC correlate well in urban environments, since both are dominated by combustion related aerosol. We verified the hypothesis by computing LDSA from SMPS data of the Swiss air pollution monitoring network (NABEL) and comparing it to BC. Figure 1 shows the two pollutants for the urban background site Zürich-Kaserne.

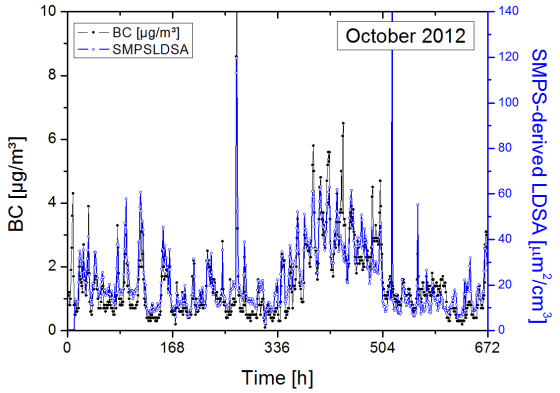

Figure 1. Time series of BC and SMPS-derived LDSA at the urban background site Zürich-Kaserne during 4 weeks in October 2012.

We have now deployed four miniature LDSA sensors (naneos partector) at four selected NABEL sites with BC monitoring (Basel, Bern, Lugano and Zürich). These four sites represent different environments: Lugano and Zürich are urban background sites; Bern is an urban street canyon site while Basel is a suburban site.

The LDSA sensors will run for the first half of 2013, providing us with a lot of useful information. We will learn more about the reliability and the applicability of these sensors for deployment in unattended sensor networks; and at the same time we will be able to answer the question whether or not BC can be approximated by LDSA as surrogate measurement in urban environments.

Regional-scale modeling of organic aerosol composition in Europe: Insights from comparison with aerosol mass spectrometer factor analysis

Recently, the volatility basis set framework (VBS) has been implemented in several Chemical Transport Models (CTMs) improving predictions of organic aerosol (OA) concentrations (Fountoukis et al., 2011). However, uncertainties still exist in these models regarding the volatility distribution of the primary OA emissions, the chemical aging of the OA or errors in either the anthropogenic or biogenic emissions.

The increasing availability of Aerosol Mass Spectrometer (AMS) field measurements analyzed by Positive Matrix Factorization (PMF) provides an opportunity to further evaluate and constraint CTMs based on their ability to predict concentrations of the different OA components. In this work we apply PMCAMx-2008 over Europe (Fountoukis et al., 2011) during 3 periods representative of different seasons, and use an extensive set of AMS measurements (15 datasets in total) to evaluate the model and (using PMF results) gain more insight into the sources and physical and chemical transformations of OA, as well as identify strengths and limitations of our current OA modeling framework.

In this study we simulate 3 periods (1–29 May 2008, 25 February – 24 March 2009, and 15 September – 17 October 2008) during which 3 intensive measurement campaigns took place as part of large-scale projects of the EU. During all three campaigns, AMS measurements of aerosol mass composition were performed at several sites in Europe while further analysis of the OA composition was performed using PMF. The modeling domain covers a 5400×5832 km^2 region in Europe with 36×36 km grid resolution and 14 vertical layers extending up to approximately 6 km in height with a surface layer depth of 55 m.

Fig. 1 shows a comparison of predicted vs. observed PM_1 oxygenated OA (OOA) from all three measurement datasets. The overall agreement between AMS measurements and model predictions is encouraging. The OA formation during the late spring and autumn period is mostly dominated by enhanced photochemical activity while during the winter period by direct primary emissions. Predictions of fresh primary OA (POA) are the highest during the winter period ranging from 0.5 to 1.5 μg m^{-3} on average, with peak values up to 10 μg m^{-3} at urban centers. On average, the model predicts that oxygenated OA contributes 93% to total OA during May, 87% during winter and 96% during autumn with the rest comprising fresh POA.

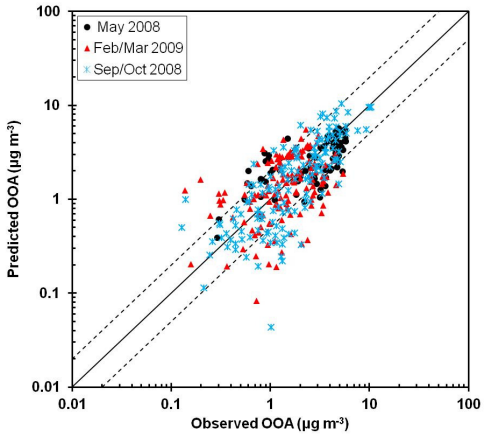

Figure 1. Comparison of predicted vs. observed PM_1 oxygenated organic aerosol from 3 measurement periods. Each point corresponds to a daily average value. Also shown the 1:1, 2:1 and 1:2 lines. Observed data represent AMS measurements. The slope of the line for OA is 0.893 (R^2 = 0.49).

Oxidized POA and OOA from intermediate volatility organic compounds (IVOCs) is predicted to be a major OA component with a contribution of ~50% to total OOA in all three periods. Biogenic SOA (BSOA) comprises around one third of OOA during May and around 40% during the other two periods. In each one of the simulation periods, the spatial pattern of concentrations for OPOA, ASOA and BSOA is quite similar, while the fresh POA pattern is different indicating differences in sources and production mechanisms. Inferences regarding the nature of LV-OOA and SV-OOA measured components and their representation in the model will be discussed.

This work was funded by the European Community's 7th Framework Programme EU project PEGASOS (contract 265307).

Presenting author email: roman.froehlich@psi.ch

The newly-developed Time-of-Flight Aerosol Chemical Speciation Monitor (ToF-ACSM) is conceptually related to the Q (quadrupole)-ACSM (Ng, 2011), which itself is based on Aerosol Mass Spectrometer (AMS, Jayne, 2000) technology. The ACSM systems are designed for long-term, low-maintenance operation. These features, combined with their lower cost relative to the AMS, makes them suitable for long-term deployment (> years) and integration into monitoring networks. The ToF-ACSM provides online measurements with high sensitivity (e.g. detection limit for sulfate: 3.1 ng/m^3 at 30 min time resolution) of the major non-refractory species of the submicron aerosol (organics, NO_3, SO_4, NH_4 and chloride).

Initial deployment of the ToF-ACSM was performed at the Sphinx research station on the Jungfraujoch (JFJ, 3570 m a.s.l.) in the Bernese Alps. For many years measurements at the JFJ have provided excellent insights into the properties of high alpine aerosols. Most of the winter the station lies within the free troposphere while in summer aerosol generated at lower altitudes can reach the Jungfraujoch due to vertical exchange processes (Henne, 2004). However, despite the vast number of experiments performed there, we here present the first dataset of an online year-round measurement (resolution: 15 - 30 min) of the aerosol chemical composition at the Jungfraujoch.

This one-year exercise proved the measurements and tested the operational stability of the new instrument. The deployment included an intercomparison between the ToF- and Q-ACSM for a period of five months. The instrument time series were strongly correlated (e.g. organics July 27 - August 05: slope = 0.98; R^2 = 0.95) and the ToF-ACSM improved on Q-ACSM detection limits by a factor of 4 to 62, depending on the species measured. Furthermore, we plan to report the correlation to a CToF-AMS instrument from measurements during the CLACE2013 campaign in the first months of 2013.

The aerosol data shows a distinct seasonal cycle with higher concentrations in summer ($C_{av(26Jun-07Sept)}$ = 3.3 μg/m^3, $C_{max(26Jun-07Sept)}$ = 27.8 μg/m^3)† and low concentrations during wintertime ($C_{av(01Nov-07Jan)}$ = 0.5 μg/m^3)†. In summer the aerosol consists mainly of organics (58 %) with some sulfate (25.2 %), ammonium (9.4 %) and nitrate (6.8 %) and exhibits a regular diurnal cycle corresponding to PBL movement; that is, the aerosol concentration increases during the day with a maximum around 16:00 and decreases again after sunset. The concentrations of all measured species follow this cycle more or less the same way. In winter this diurnal pattern disappears and the concentration stays relatively constant on a low level with the exception of a few rare pollution events (see Fig. 1). This suggests that the JFJ research station is situated in the free tropsphere during the cold season. Sulfate becomes the major fraction in winter with a share of 54.6 %. 30.1 % of the aerosol are organics and the fractions of ammonium and nitrate are similar to summer (8.7 % and 6.0 %)

Preliminary analyses with statistical techniques (Multilinear Engine version 2, Paatero, 1999) show that the organic fraction in summer mainly exists of highly oxidized species, i.e. "aged" aerosol (mostly LV-OOA, some SV-OOA). As expected, the influence of fresh aerosol from local sources like HOA or BBOA is low at the Jungfraujoch (< 15 % of total).

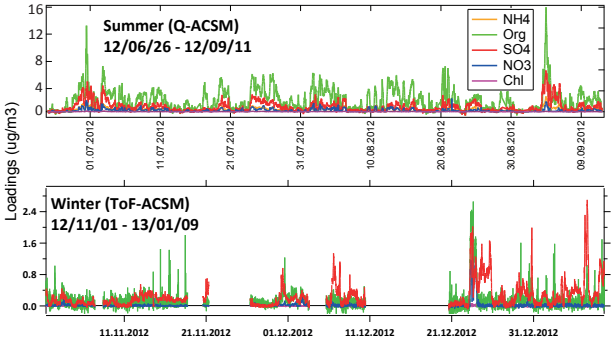

Figure 1: Sample time series recorded at the Jungfraujoch. Top: 2.5 months in summer measured with the Q-ACSM. Bottom: 2 months in winter measured with the ToF-ACSM. Note the different scaling of the y-axis.

Aerosol Activation and Scavenging during the Cloudy Test Campaign at the CERN CLOUD chamber

C. Fuchs[1], J. Tröstl[1], J. Duplissy[2], E. Weingartner[1], U. Baltensperger[1] and the CLOUD collaboration

[1]Laboratory of Atmospheric Chemistry, Paul Scherrer Institut, CH-5232 Villigen PSI, Switzerland
[2] Department of Physics, University of Helsinki, FI-00014 Helsinki, Finland
Keywords: cloud formation, aerosol growth, GCR, CLOUD.
Presenting author email: claudia.fuchs@psi.ch

Besides aerosol nucleation, which has been observed almost everywhere in the atmosphere (Kulmala et al., 2004), the growth of these newly formed aerosol particles and the formation of cloud droplets and ice crystals play a major role in atmospheric research. In previous studies at the CERN CLOUD chamber mainly nucleation events have been studied (Kirkby et al., 2011). However, the CLOUD 6 campaign mainly focused on the formation of cloud hydrometeors. The CLOUD chamber with a very low contaminant background, stable temperature conditions and a fast adiabatic expansion system allowed obtaining new scientific findings by determining which particles or particle fractions act as **c**loud **c**ondensation **n**uclei (CCN) and **i**ce **n**uclei (IN). Due to adiabatic expansion the relative humidity increases until the chamber is supersaturated and cloud droplets and ice crystals are formed. Cloud formation was investigated applying different pressure drops, expansion times and temperatures. In addition CERN's **P**roton **S**ynchrotron (PS) was used to simulate ion conditions of the atmosphere from ground level to the upper troposphere (Kirkby et al., 2011).

The purpose of this study was to investigate the activated fraction and the scavenging of aerosols during cloud events with a new CLOUD chamber setup. One SMPS and one TSI CPC 3010 were installed at the CERN CLOUD chamber to measure the aerosol particle size distribution and aerosol concentration. In addition, two cyclones were attached in order to remove all particles and hydrometeors larger than 1 µm from the sampling flow. Hence, the number concentration and the dry size distribution of interstitial aerosols (i.e. the non-activated particles) could be measured during the presence of clouds. During all other times the total dry size distribution was measured. By comparing the pre (total), inter (interstitial) and post (total) particle size distribution, aerosol activation and scavenging were investigated. In addition, charged and neutral conditions were tested.

Figure 1 shows an example of aerosol activation during a cloud event at T=-34°C. The concentration is plotted against the particle diameter where the green line denotes the concentration (dN/dlogD) before the cloud was formed and the red line the concentration while the cloud was present.

First tests of the new expansion system were successful, showing aerosol activation and scavenging. The cyclones removed droplets and ice crystals successfully to measure the interstitial aerosol concentration during cloud events.

For the upcoming campaign (CLOUD 8) further improvements of the system are planned to ensure that a longer cloud presence is possible. In addition, the possible influence of **g**alactic **c**osmic **r**ays (GCR) will be investigated.

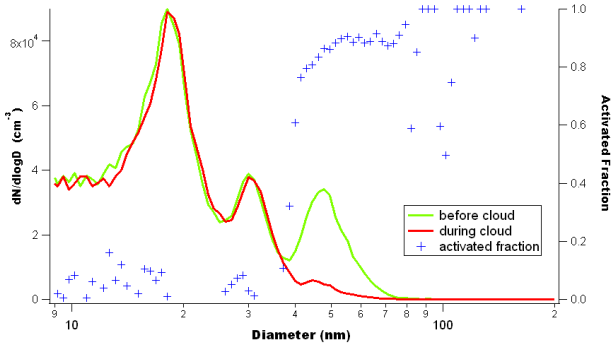

Figure 1. Number site distributions before and during the presence of a cloud. Particles larger than ~ 40 nm were activated to cloud droplets.

Keywords: urban aerosol pollution, tramway construction, PM concentration, PM elemental composition
Presenting author e-mail: furu.eniko@atomki.mta.hu

In this study atmospheric aerosol concentration and composition were investigated along the tramway track construction in Debrecen, Hungary. Aerosol samples were collected with personal samplers between 21. and 30. 09. 2011 - four hours a day, during working hours. The sample collection was made by walking on the pavement next to the building. The weather was dry and warm on the sampling days.

Nuclepore two-stage samplers equipped with Nuclepore polycarbonate filters of 8 μm and 0.4 μm pore diameter were used. Mass concentrations and elemental composition were determined separate for coarse (particles with aerodynamic diameter larger than 2.5 μm) and fine size fractions (particles with aerodynamic diameter smaller than 2.5 μm). The elemental composition ($Z \geq 13$) was determined by particle induced X-ray emission (PIXE) analytical method. The concentration of particulate matter (PM) was measured by gravimetry using a microbalance.

The measured PM10 and PM2.5 concentrations are shown in Table 1. PM10 concentrations were compared with the data of the Hungarian Air Quality Network (http://www.kvvm.hu/olm/index.php?lang=en). In every case the PM10 concentration were 8-20 times higher along the building than the data of the Hungarian Air Quality Network. In the second week the weather was rather windy which explains the increased PM10 level along the tramline building.

Table 1. PM2.5 and PM10 concentration data along the tramline track construction and at the AQ monitoring stations of the Hungarian Air Quality Network

Date	tramline building PM2.5 (μg/m^3)	tramline building PM10 (μg/m^3)	Hungarian Air Quality PM10(μg/m^3) average data
21.09.11	24	292	26
22.09.11	36	291	49
23.09.11	36	232	37
26.09.11	39	322	38
27.09.11	51	647	48
28.09.11	43	408	42
29.09.11	33	617	22
30.09.11	40	559	30

The elemental concentration of the samples which were collected along the building were compared with the elemental concentration of samples from our urban background station (garden of Atomki), which is situated ~ 500 m from the new tramline track building. For comparison we show data from September 2010 (no building), and from September 21-30. 2011 (Table 2). For both size fractions significant increase were observed from 2010 to 2011. In the case of PM2.5 the concentration of all measured elements increased by a factor between 8 and 15 in the garden of Atomki. The elemental concentrations measured along the tramline construction were 1.5-5 times higher than at the Atomki. In the case of the coarse fraction the increase from 2010 to 2011 were only around a factor of 2 at the garden of Atomki. However, along the tramline constructions we measured 10-100 times higher elemental concentration values than 500 m away.

Table 2. Average elemental concentrations in the coarse fraction at an urban background station in 2010 and 2011 (A) and along the tramway track construction (B)

Presenting author email: furu.eniko@atomki.mta.hu

Atmospheric fossil CO_2 observations have been running in Debrecen, Hungary since the autumn of 2008 (Molnár et al., 2010). From the winter of 2010 synchronized aerosol sampling and C-14 analyses started to compare the aerosol fossil carbon content to the fossil carbon-dioxide results in the same time period and the same location.

Integrated bulk aerosol PM2.5 samples were collected on prebaked quartz filers with 10 L/min flow rate over the months at an urban background site in Debrecen, Hungary. One or two weeks long integrated samples were collected on a filter and those periods were synchronized with the parallel monthly atmospheric CO_2 observations. The collected total aerosol mass was determined by gravimetry, and its carbon content was measured through the amount of CO_2 produced after its combustion in the AMS C-14 sample preparation line.

Atmospheric fossil CO_2 measurements were done using the ATOMKI gas proportional counting based C-14 dating facility. C-14 measurement of the aerosol samples was carried out at the new EnvironMICADAS AMS facility of ATOMKI. The applied sample pretreatment steps were tested by multiple pretreatment of different sections of several real samples. Test results showed very good reproducibility for the applied aerosol sample preparation method and AMS C-14 analyses.

During the year from November 2010 to November 2011 in Hungary there were very high PM concentrations in the city air several times, particularly during the heating season.

The atmospheric CO_2 and $PM_{2.5}$ concentrations showed high similarity for Debrecen. During the winter heating period significantly higher total $PM_{2.5}$ concentrations could be observed which was also reflected in the quantity of the total carbon. The fossil CO_2 excess was very similar to the fossil carbon content of the $PM_{2.5}$. In the case of CO_2 the role of fossil excess from natural gas, oil and carbon combustion was the dominant for the heating period. For PM2.5 the contribution of modern carbon from biomass burning seems to be the determinant, since not the fossil but the biogenic carbon caused the elevated PM concentrations in the city of Debrecen. In absolute terms, the fossil part of the $PM_{2.5}$ increased, as well, in the heating period, however, even this value was exceeded by the increment of the modern carbon showing that the dominant process of aerosol emission is biomass burning due to municipal wood combustion.

These results clearly show the very different fossil/biogenic contribution in the atmospheric aerosol compared to the carbon-dioxide fraction.

Our results are in good agreement with other published city fossil aerosol results (e.g.. from Zürich) (Szidat et al., 2004). To help the source apportionment of the collected urban aerosol samples also $\delta^{13}C$ stable isotope ratio of the combusted carbon fraction was measured using a Finningan Delta XP plus stable isotope mass spectrometer.

The impact of extreme weather events on air quality in Budapest, Hungary

V. Gácser[1], A. Molnár[2]

[1]Department of Earth and Environmental Sciences, University of Pannonia, Veszprém, P.O. Box 158, H-8201, Hungary

Presenting author email: gacserv@mk.uni-pannon.hu

Weather and climate extreme events frequently lead to negative effect on air quality, mainly in urban areas. It is well known, that atmospheric stability highly influences the concentrations of different air pollutants due to hindering both the vertical and the horizontal movements in the air. High pressure weather systems which bring typical stable situations occur frequently in the Carpathian Basin both in summer and wintertime.

In winter, when a high pressure builds over Hungary, it usually develops low-level inversion and fog that can become persistent. Consequently this results in extremely low visibility as well as elevated concentrations of the air pollutants, like PM10, SO_2, soot, etc., which frequently exceeds the health limit. High pressure system can also cause stable air stratification in summertime. Due to high irradiation and temperature intensive photochemical reactions take place in the lower troposphere. Among others the higher concentration of tropospheric O_3, NO_X, and decreasing visibility allude to development of photochemical smog. These air pollution episodes take place usually in dry, hot periods which frequently related to heat-waves. Climate simulations indicate a drying climate in Hungary with more extreme temperature events (IPCC 2012; HREX 2012). On the basis of long term data analysis more hot days, longer heat-waves and longer dry periods can already be registered in Hungary (Bartholy *et al*, 2007, 2010)

The aim of this work is to study how weather situations leading to extreme air pollution episodes. Two special years, 2010 and 2011 were chosen for this analysis. In 2010 excessively high amount of precipitation (170% of the yearly average amount) has occurred, while 2011 was extreme dry (yearly precipitation 70% of average amount) and warm with a few heat-waves. In this work the air quality (SO_2, NO_2, NO_x, O_3, PM10) (www.kvvm.hu/olm), as well as meteorological data (temperature, precipitation, air pressure, visibility) are evaluated (Integrated Surface Hourly Observations, NOAA National Data Center) at Marczell György Main Observatory, Budapest. In addition, the analyzed synoptic weather maps from these periods (www.met.hu) are also studied.

Our preliminary result show, that especially the concentration of the PM10 and tropospheric ozone follows the changing of the weather situation. PM10 episodes were monitored in both years that were connected to high pressure systems in fall and wintertime. During these events PM10 concentration frequently exceeded the heath limit (24-hours, 50 μgm^{-3}). On the other hand in summer the severe air pollution episodes can be characterized by ozone concentration. In 2010 – the whole summer was rather changeable and wet – the daily ozone concentration ranged between 40 and 70 $\mu g/m^3$; and during only two shorter stable periods the ozone concentration exceeded 70 $\mu g/m^3$. The summer in 2011 was much dryer with much more sunshine, and even the means daily ozone concentration was higher than in 2010; it ranged between 55 and 85 $\mu g/m^3$.

Keywords: $PM_{2.5}$, seasonal variation
Presenting author´s email: samuel.gaita@chem.gu.se

Seasonal variation of urban aerosols is poorly understood in sub-Saharan Africa due to lack of long-term measurement data. Available scientific information is usually based on short term measurement campaigns (e.g. Gatari and Boman, 2003; Kinney *et al.*, 2010). This predicament is further compounded by the fact that sub-Saharan cities are characterised by lack of long-term air pollution monitoring strategies and concrete policies on air quality and climate change, (UN, 2013).

In the view of the above, measurements of airborne fine particles (equivalent aerodynamic diameter < 2.5 µm, $PM_{2.5}$) were carried out from April, 2008 to May, 2010. The main objective was to get a better understanding of physical and chemical properties of Nairobi aerosol based on long-term measurement data. Observations would then be linked to perceived aerosol sources (local and regional) especially anthropogenic activities within the metropolitan area and their effects on urban air quality and local micro-climate.

Sampling was carried out at two sites within Nairobi metropolitan area. One site was at University of Nairobi main campus (UoN) and the other at the United Nation Environmental Programme (UNEP) headquarters, 5 km to the north of UoN site.

$PM_{2.5}$ samples were collected on pre-weighed polycarbonate filters using cyclone samplers for 24 h, per sample, at a flow rate of 3 L/min, except on weekend when samples were collected for 48 h. At the UoN site, a cyclone sampler was placed 17 m above the ground (agd), on the rooftop of Engineering building. This site being close to the central business district was a good representation of an urban background setting. At the UNEP site, a cyclone sampler placed on the rooftop of Urban Environment Unit offices, 10 m agd.

Particulate mass were determined using a Mettler Toledo TM5 microbalance, BC concentration using a black smoke detector (FH62 1-N) whereas elemental concentrations were analysed using an Energy Dispersive X-ray Fluorescence (EDXRF) spectrometer.

Results presented here are from the UoN site. Observed trend in $PM_{2.5}$ mass concentration (Figure 1), followed the normal rainfall pattern experienced in Kenya. Two troughs were observed and they coincided with two rainy seasons (long rains; March to May, Julian days 75 to 135: short rains; October to early December, Julian days 268 to 329). Importantly, higher concentrations were observed in 2009 due to draught that was being experienced in the country. WHO 24 h guideline limit of 25 µg/m^3 for $PM_{2.5}$ was frequently exceeded in 2009. This highlights the influence of natural phenomenon to air pollution monitoring. Results from elemental concentrations analysis and Positive Matrix Factorisation will be presented on the poster.

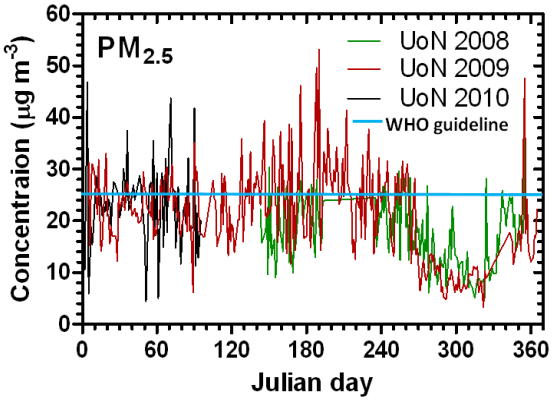

Figure 1: Seasonal variation of $PM_{2.5}$ sampled in Nairobi, Kenya.

In conclusion, it is worth noting that seasonal variation is evident in Nairobi city despite the unpredictability of the weather as experienced in 2009 when rainfall pattern became erratic. This observed variation can be exploited for modelling purposes as a way of planning for mitigation strategies to counteract the effects of aerosols on human health and local climate.

This work was funded by the Swedish International Development Cooperation Agency (SIDA) and the International Programme in the Physical Sciences (IPPS), Uppsala University, Sweden. We recognise the participation of Mr. Kagai at the UNEP site and support by the UNEP Environment Unit.

Stable carbon isotopic values ($\delta^{13}C$) of biofuel in Lithuania

A. Garbaras[1], A. Lipovec[1,2], A. Masalaite[1] and V. Remeikis[1]

[1]Center for Physical Sciences and Technology, Vilnius, LT-02300, Lithuania
[2]Faculty of Physics, Vilnius University, Vilnius, LT- 10222, Lithuania
Keywords: $\delta^{13}C$, aerosol particles, biofuel.
Presenting author email: garbaras@ar.fi.lt

Introduction

Research on the origin of aerosol particles is important for understanding the climate change, environmental pollution and environmental self-cleaning processes. Atmospheric aerosol absorbs and reflects radiation from the Sun and heat radiation from the Earth, thus changing thermal balance of the planet. Aerosol absorbs gases, chemical elements and compounds, influences water condensation processes, stimulates photocathalytical reactions and has influence on the global chemical processes in the atmosphere [Ceburnis et al., 2005].

Stable carbon isotope method is one of the methods which are more and more implemented in the source apportionment studies [Ceburnis et al., 2011]. Due to the ability to preserve source isotopic ratio this method can be used as source fingerprint and allows distinguish an aerosol sources if they differ in the isotopic ratios. Because of that, the need to have the database of the possible aerosol sources arises. The $\delta^{13}C$ values of main aerosol source pools are known, but there is a lack of data on more precise spatial distribution of isotopic ratios, as these ratios are varying depending on the geographical region.

As biofuel is becoming more popular comparing to the fossil fuel, the demand to know the isotopic ratios of different types of biofuel arises, and usage of these isotopic ratios to assess the part of aerosol particles which is coming from the biofuel. Carbon isotopic ratio of the emitted aerosol particle depends not only on the burning conditions but also on the plants used. Therefore, the knowledge of the plants carbon isotopic ratio is highly needed

The aim of this work is to measure the carbon isotopic ratio of the main plants, which can be used as biofuel in the regional scale. In the future this database will be used in source apportionment studies.

Methods

In this work $\delta^{13}C$ values of the 24 different plants are presented. Wood, leafs, bark, grain, seeds were measured, 77 positions in total. The samples were collected in the Ignalina region (East Lithuania) during August 2012.

Samples were dried and measured with the elemental analyzer connected to the stable isotope ratio mass spectrometer (*Thermo Flash EA 1112 – Delta V Advantage*).

Results

One C_4 plant was found (maize, $\delta^{13}C$ = -13 ‰). The stable carbon isotopic ratios for the rest of the plants (C_3 type) varied from the -25 ‰ to the -33 ‰. In the Fig. 1 are presented some measurements of the wood $^{13}C/^{12}C$ ratios In order to assess the net aerosol input from the biofuel, the data on the composition of burned biofuel is needed because the biofuel isotopic ratio interfere with the fossil fuel isotopic ratio [Masalaite et al., 2012].

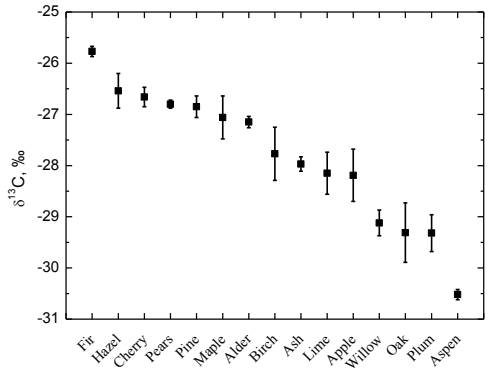

Figure 1. The carbon isotopic ratio of trees which grow in Lithuania and can be used as biofuel. (Wood part isotopic ratio is presented).

Integrated isotopic data from different sources (transportation, domestic heating, fires etc) can be used to perform source apportionment studies of the atmospheric aerosol particles.

Atmospheric aerosol episodes over Lithuania after the May 2011 volcano eruption at Grimsvötn, Iceland

K. Kvietkus, J. Šakalys, J. Didžbalis, I. Garbarienė, N. Špirkauskaitė, V. Remeikis

State Research Institute Center of Physical Science and Technology, Savanorių Ave. 231, LT-02300 Vilnius, Lithuania
Keywords: PM_1, volcanic sulfate, Grimsvötn.
Presenting author email: ingar@ar.fi.lt

Volcanic eruptions emit large amounts of gaseous and particulate material into the atmosphere. In particular, SO_2 is abundant in volcanic gases (Hobs et al. 1991). SO_2 emitted from volcano could act as a precursor of the formation of sulfuric acid particles. Information of the composition and size distribution of volcanic aerosol particles in the troposphere is important to evaluate their effects on atmospheric radiation and cloud formation.

We present measurements of PM_1 components concentration and size distribution in the vicinity of Vilnius at the Institute of Physics (54°38'N; 24°11'E) on 24-29 May 2011 after the eruption of the volcano at Grimsvötn in Iceland. An Aerodyne Quadrupole Aerosol Mass Spectrometer (Q-AMS) has been used to provide on-line measurement of size dependent chemical composition of non-refractory components (ammonium, nitrate, nss-sulfate, organics) in submicron aerosol particles (PM_1). In order to determine air mass transport routes to Vilnius, forward and backward trajectories were calculated every 1-3 h with a total of 120 h duration for the sites (Grimsvötn and Vilnius) using the National Oceanic and Atmospheric Administration (NOAA) Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) model (Draxler and Rolph, 2003).

To distinguish volcanic and non-volcanic origin of PM_1 components four concentration episodes at Vilnius during 24-29 May 2011 have been selected for analysis. Episode 1 (0700-1400 UTC 25 May) and 2 (0400-1100 UTC 26 May) were selected according to trajectories of air masses which travelled from Iceland over North Atlantic Ocean before the arrival to Vilnius. Episode 3 (1200-2300 UTC 26 May) was selected as transitional one when the air masses originated from Iceland travelled over North Atlantic Ocean, and over Scandinavia and partly passed over polluted industrial regions (Great Britain, Germany). During Episode 4 (from 0600 UTC 27 May to 0000 UTC 28 May) air masses were mainly passing over Central Europe.

This study shows that the sulfate emissions from the volcano at Grimsvötn in Iceland reached distances farther than 3000 km, and they can have an influence on the local concentration and size distribution spectra of PM_1 chemical components. Over the period of the volcanic eruption (Episode 1) the sulfate concentrations increased by a factor of 3 and reached 90% of PM_1, while the nitrate and organic levels remained low and unchanged (Fig.1). Air mass trajectory analysis indicates that the volcanic aerosol from Iceland was carried to Vilnius by air masses at the height of 3000–4500 m. The ammonium to sulfate molar ratio (ASR) during Episodes 1 and 2 is 0.81, suggesting that sulfate particles were partially neutralized by ammonium and determined by volcanic eruptions. However, during Episodes 3 and 4 the ASR was higher (1.0) and determined by both volcanic and non-volcanic origin components.

Combining air mass transport analysis as well as investigations of aerosol chemical composition and size distribution parameters, allowed us to explain possible sources of atmospheric submicron aerosol particles.

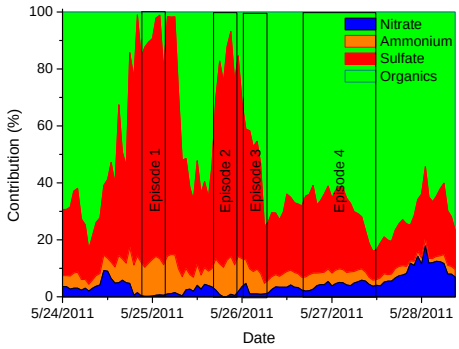

Figure 1. Relative contribution of chemical components of PM_1 measured at Vilnius from 24-29 May 2011.

Presenting author email: ageor@auth.gr

Satellite observations from MODIS have been extensively used in combination with observations from other satellite sensors or model simulations to quantify the optical properties of different aerosol types at a global as well as regional scale. Based on the pioneer results of Kaufman *et al* (2005) and a number of other studies that used a similar approach, Bellouin *et al* (2008) presented an algorithm that combines aerosol optical depth (AOD) and fine-mode ratio (FMR) at 550 nm from MODIS, Aerosol Index from TOMS and surface wind speed over oceans from SSM/I. This algorithm is capable of distinguishing the anthropogenic (fossil fuel and biomass burning) AOD from the corresponding sea salt and dust AOD on a daily basis. However, this is possible over oceans only, since, the FMR retrieval is not considered reliable over land. Over land they used regional anthropogenic fractions as derived from five global models that participated in the AEROCOM project (Bellouin *et al*, 2005). A similar approach was also used in a recent paper by Bellouin *et al* (2012) with data from MACC aerosol reanalysis. The fraction of different aerosol types to the total AOD is crucial for the calculation of the radiative forcing of each type separately (Quaas *et al*, 2008; Jones *et al*, 2009).

A common characteristic is that all the studies referenced above are focused on global observations using daily 1^ox1^o gridded level-3 MODIS data. Since the methodologies are now well established, we have to go a step further and investigate the relative contribution of different types of aerosols at a regional scale taking into account the special characteristics of each region. Here, we focus on Eastern Mediterranean [30^oN-$45N^o$, 17.5^oE-37.5^oE], a region subject to aerosol contributions from a variety of sources. Human activities, like industry and transport (anthropogenic aerosols), occasional Saharan dust intrusions (dust particles), sea spray (marine aerosols) and agricultural fires in Southeastern and Eastern Europe as well as occasional fire events in the region (biomass burning aerosols) contribute to the total aerosol burden. Hatzianastassiou et al (2009) used 1^ox1^o MODIS and TOMS monthly data to investigate the existence of anthropogenic and natural aerosols over Eastern Mediterranean but at a qualitative way rather than a quantitative one. In this work, the relative contribution of different aerosol types over the region is presented at a high resolution of 0.1^ox0.1^o on a daily basis along with the corresponding uncertainties. MODIS TERRA and AQUA level-2 datasets (10 km resolution at nadir) that span from 3/2000 and 7/2002 respectively are used for the compilation of two 0.1x0.1 degree gridded datasets that consist of 30000 grid cells each (see Georgoulias and Kourtidis, 2012 for more details). The use of these datasets in conjunction with Aerosol Index data from Earth Probe TOMS and OMI satellite sensors and wind field data from ERA-interim reanalysis within an algorithm similar to Bellouin *et al* (2008) allows for the calculation of the aerosol type fraction per grid and day. The seasonal and interannual variability of the relative contribution of each aerosol type is discussed while a Fourier-based method is used for the calculation of the trend (and its statistical significance) of AOD_{550} for each aerosol type.

This work was funded by QUADIEEMS project which is co-financed by the European Social Fund (ESF) and national resources under the operational programme Education and Lifelong Learning (EdLL) within the framework of the Action "Supporting Postdoctoral Researchers".

Keywords: ice nucleation, mixed-phase clouds, CLACE 2013
Presenting author: piotr.kupiszewski@psi.ch

Much of the uncertainty in climate projections is due to an insufficient understanding of aerosol-cloud interactions. In particular, the formation of mixed-phase clouds via heterogeneous nucleation, their temporal and spatial evolution and the physico-chemical characteristics of ice nuclei (IN), the aerosol sub-population facilitating formation of ice crystals, is not well known. Meanwhile, cloud glaciation enhances precipitation formation, decreasing cloud cover and lifetime, and affects cloud radiative properties. Analysis of ice residuals (IR) in mixed-phase clouds is a difficult task: small, freshly formed ice crystals (where the IR contained within can be considered representative of the original IN) must be separated from super-cooled droplets with similar aerodynamic sizes, as well as the orders of magnitude more abundant interstitial particles.

A new Ice Selective Inlet (ISI) has been designed to extract small ice crystals from mixed-phase clouds, simultaneously counting, sizing and imaging the hydrometeors contained in the cloud with the use of Welas optical particle counters (OPC) and a Particle Phase Discriminator (PPD). The core of the ISI is an evaporation unit with ice-covered inner walls, removing droplets using the Wegener-Bergeron-Findeisen process, while transmitting a relatively high fraction of ice crystals (Fig. 1).

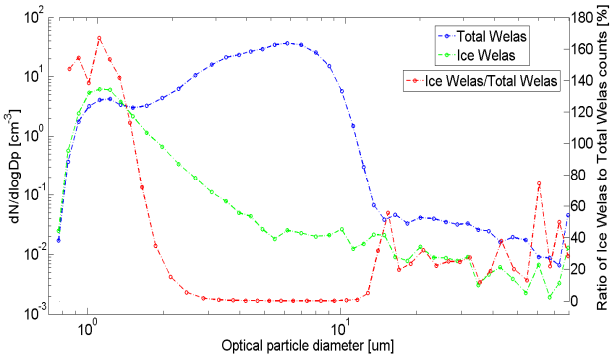

Figure 1. Particle and hydrometeor number size distributions measured by Welas OPCs upstream (blue) and downstream (green) of the droplet evaporation unit during a mixed-phase cloud event.

The ISI was deployed in winter 2013 at the high alpine Jungfraujoch site (3580 m.a.s.l) during the intensive CLACE 2013 field campaign. The measurements obtained shed light on both the microphysics of mixed-phase clouds and the physico-chemical characteristics of IR. Droplet and ice crystal size distributions measured with the optical spectrometers in the ISI are compared with those measured in situ by the Small Ice Detector (SID-3). A number of online instrumentation was deployed downstream of the inlet, including a scanning mobility particle sizer (SMPS) and a Grimm OPC for number size distribution measurements, as well as a single particle mass spectrometer (ALABAMA), single particle soot photometers (SP2) and a Waveband Integrated Bioaerosol Sensor (WIBS-4) for analysis of the chemical composition, with particular focus on the content of black carbon and biological particles in IR. Simultaneously, similar instruments were deployed downstream of a total inlet, which samples the bulk aerosol. A comparison of measurements from the total inlet and the ISI provides information on the characteristics of ice residuals relative to the total aerosol. First results show that the measured IR are generally larger than the bulk aerosol (Fig. 2).

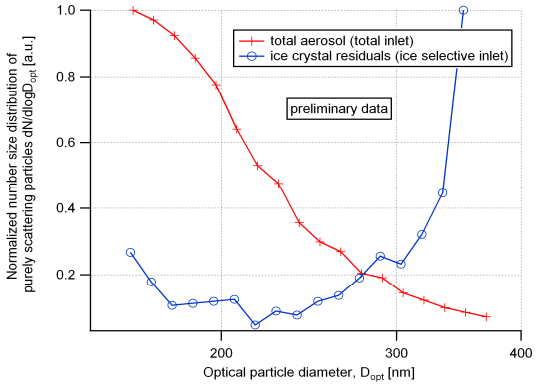

Figure 2. Normalized dry size distributions of the total aerosol (red) and ice residuals (blue)

The UPUPA project: Ultrafine Particles in the Urban Piacenza Area, Italy

M. Giugliano, G. Lonati, S. Ozgen and G. Ripamonti

Civil and Environmental Engineering Department, Politecnico di Milano, P.za L. da Vinci 32 – 20133 Milano, Italy
Energy and Environment Laboratory Piacenza, Politecnico di Milano, Via Nino Bixio, 27C – 29121 Piacenza, Italy
Keywords: ultrafine particles, particle number concentration, size distribution, urban areas, Po valley.
Presenting author email: michele.giugliano@polimi.it

Emerging epidemiological and toxicological evidence indicates particle toxicity to be dependent on particle size. Ultrafine particles (UFP, d_p<0.1 µm) are believed to be more toxic than larger particles because of their higher number and surface area per given mass, and higher deposition probability in the deep lung region (Chio & Liao, 2008; Hoek et al., 2010). Nevertheless, regularly monitoring are scarce and the available knowledge on urban UFP appears still lacking compared with the complexity and variability of the phenomenon. For instance, scarce evidence exists on UFP levels in areas like the Po Valley, Northern Italy, a well-known European hot-spot for air pollution due to the particular local orography and to the high density of emission sources.

In 2011-2012 the UPUPA project took place in Piacenza (45.03 °N, 9.41 °E, 67 m a.s.l), a mid-sized city (about 100.000 inhabitants) located in the centre of the Po Valley, aiming to provide information on UFP levels in the urban area, on the diurnal and seasonal variation of particle number concentration (PNC) and particle number size distribution (PNSD). For the urban area of Piacenza about 60-120 events per year of PM10 daily limit exceedances have been reported in 2007-2011, with PM10 and PM2.5 annual averages in the 34-45 µg m^{-3} and 24-27 µg m^{-3} range, respectively.

Measurements of PNC and PNSD were performed at three different sites: a traffic exposed site (TR), about 20 meters from a highway flyover; an urban background (UB) site, in a park in a residential area at the outskirts of the city; a rural site (RU) located at about 20 km South-West of the urban area on the first hills of Apennine mountains. At each site measurements were performed either during cold period (October-March) and warm period (April-September). PNC in the 7 nm-10 µm ($PNC_{7\text{-}10000}$) and related PNSD in 12 size bins were measured by an ELPI™ (Electrical Low Pressure Impactor, - Dekati Ltd., Finland) that was displaced between sites.

Hierarchical cluster analysis applied to PNSD from ELPI data identified 4 size intervals with peculiar time patterns: $PNC_{7\text{-}29}$ (7<d_p<29 nm), $PNC_{29\text{-}95}$ (29<d_p< 95nm), $PNC_{95\text{-}264}$ (95<d_p<264nm), and $PNC_{264\text{-}10000}$ (264<d_p<10000nm). $PNC_{7\text{-}10000}$ levels were higher at TR site compared to UB site and RU site, with the latter site displaying the lowest average levels in any season and day of the week considered (Figure 1). Daily average $PNC_{7\text{-}10000}$ at TR site were in the 8.7-17.2·10^3 cm^{-3} range (lowest levels on warm Sundays, highest on cold workdays). Workdays' to Sundays' ratio for $PNC_{7\text{-}10000}$ varied from 1.6 during cold period to 1.3 during warm period, as reported for other urban areas (Jeong et al., 2006; Wang et al., 2011).

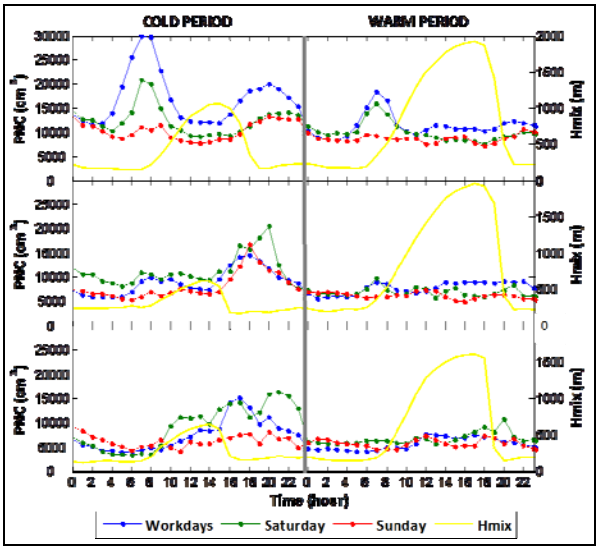

Figure 1. Average diurnal patterns of $PNC_{7\text{-}10000}$ on workdays, Saturdays and Sundays and of the atmospheric mixing height (Hmix)

UFP contribution to $PNC_{7\text{-}10000}$ was between 65-78% at TR site, 58-75% at UB and 56-78% at RU site, somewhat smaller than the European mean ratio (76%) reported by Putaud et al., 2010. At urban sites, all size fractions generally followed the same daily cycle of $PNC_{7\text{-}10000}$ but $PNC_{7\text{-}29}$ and $PNC_{29\text{-}95}$ levels increased on traffic rush hours (especially on cold season mornings). At TR site on warm workdays a third peak for $PNC_{7\text{-}29}$ was observed in the early afternoon (12.00-14:00); not correlated with traffic markers, this peak was likely of secondary origin, via photochemical nucleation of gaseous precursors.

DIAPASON: an user-oriented EC-LIFE+ Project to quantify the role of Saharan dust on European PM10 levels

G.P. Gobbi[1], F. Barnaba[1], F. Costabile[1], L. Di Liberto[1], C. Tirelli[1], R. Sozzi[2], A. Bolignano[2] and M. Morelli[2]

Presenting author email: g.gobbi@isac.cnr.it

PM10 is a widely-employed to assess air quality. The current European Union Air Quality Directive 2008/50/EC allows no more than 35 exceedances per year of the daily-average threshold of 50 µg/m^3 while the PM10 yearly average should not exceed 40 µg/m^3. Considering the high levels of PM10 observed over a large part of Europe, these limits might result as rather stringent. The Directive 2008/50/EC also allows for subtraction of the natural contributions to the PM10 concentrations, after assessing the natural origin and relevant amount. In Mediterranean Europe the natural phenomenon which mostly affects PM10 concentrations is the transport of mineral dust from the nearby Sahara desert. In the central and western Mediterranean, such outflow of mineral dust reaches its maximum between Spring and Autumn, while minimizing in winter.

Under the Directive 2008/50/EC, the European Commission has recently released specific 'Guidelines' to quantify the contribution of natural sources to PM10 (EC, 2011). For Saharan dust, these Guidelines rely on back-trajectories, dust model forecasts and satellite observations coupled to ground PM10 concentration monitoring. The EC LIFE+2010 DIAPASON Project (*Desert dust Impact on Air quality through model-Predictions and Advanced Sensors ObservatioNs*, 2011-2015), intends to build on the capabilities of the current 'Guidelines' and explore possible improvements from the use of remote sensing devices. In this respect, at the core of DIAPASON is the prototyping of affordable Polarization Lidar-Ceilometers (PLCs) able to 'observe' the presence of dust plumes and thus 'certify' their loading in the lowermost atmosphere. Within DIAPASON PLC measurements will be used to define and validate an upgraded Saharan dust detection Methodology. The Project is implemented in the Pilot Region of Rome, in Central Italy, where three networked PLCs will monitor the altitude-resolved advections of Saharan dust for one year.

As the observational phase of DIAPASON has not started yet, an initial phase of the Project was devoted to the development of an effective, user-oriented tool to implement the current EC-Guidelines. To this purpose, DIAPASON has implemented a Graphic User Interface (GUI) (Fig.1) to allow an easy evaluation of the Saharan dust contribution to the PM10 records in a given area. This tool, adaptable to any European site/region/area and freely available upon request, is currently routinely used by the Italian Regional Agency in charge of Air Quality monitoring in the Lazio region (ARPA-Lazio).

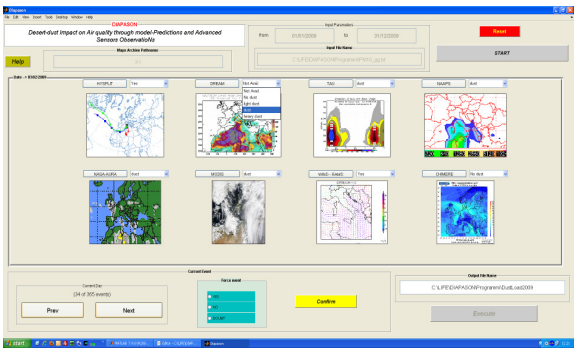

Figure 1. DIAPASON GUI to apply the EC Guidelines

Potential improvements of the current EC-Guidelines are also under evaluation. These include overcoming the selection of a Regional Background site (RB), as prescribed by the EC Guidelines. In fact, in Italy, PM10 monitoring sites "purely" representative of rural background conditions are difficult to find and the choice of the RB was found to be critical in the EC-Methodology outcome. DIAPASON is therefore investigating the use of the out-of-dust record in each single PM10 monitoring site as a 'background reference' for the evaluation of a Saharan dust load at the same site (self-calibration method, Gobbi et al. 2013). An example of the outcome of such a modified approach is given in Fig. 2. Major pro and cons of the new approaches under investigations will be discussed.

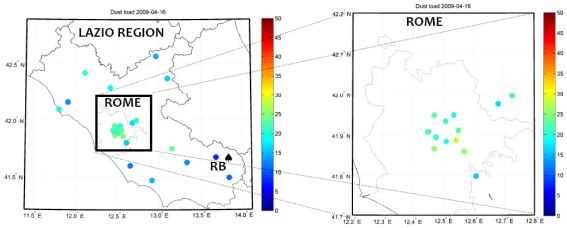

Figure 2. Example of dust load (µg/m^3) derived from a modified version of the EC Guidelines.

Testing of aerosols in Barentsburg area (Spitsbergen)

L.P. Golobokova[1], D.G. Chernov[2], U.S. Turchinovicn[2], V.V. Pol'kin[2]

[1]Limnological Institute SB RAS, Irkutsk, 664033, Russia
[2] V.E. Zuev Institute of Atmospheric Optics SB RAS, Tomsk, 634021, Russia
Keywords: aerosols, correlation, share factors, the sum of ions
L.P. Golobokova: lg@lin.irk.ru

In Spring to Summer periods of 2001-2012 (table 1) testing of aerosols air characteristics were conducted on the territory of the Spitsbergen archipelago (western Artic section) in the area of Zonal Hydrometeorological Observatory (ZHO), in Barentsburg (78.1°N 14.2°E, eastern part of the Grenfjord bay of the Greenland sea). Aerosols samples were taken on PTFE filters with 0.8 μm pore size. Chemical composition of aerosols water soluble fraction was done on ion chromatographer ICS-3000 (Dionex, USA).

During testing periods in the area of Barentsburg northern and western (Greenland island side) air mass transports were observed. During Summer seasons higher temperatures and lower wind speeds were observed. In summer it was often that foggy and thick weather was observed. Atmospheric pressure and relative air humidity varied within short ranges.

Mean concentration of ions within aerosols soluble fraction in April-May 2011 was twice higher as compared to their concentration in August. Maximum concentration of ions (5.6 $\mu g \cdot m^{-3}$) was recorded on May 16, and the minimum (0.48 $\mu g \cdot m^{-3}$) was recorded on August 02, 2011. In spring there was significant correlative interrelation of concentrations between the ion pairs NH_4^+–SO_4^{2-}, Na^+–Cl^-, Mg^{2+}–Cl^-, Ca^{2+}–NO_3^- with correlation ratios equal to 0.79, 0.97, 0.96 и 0.90 accordingly. In summer period this interrelation went down (0.68, 0.63, 0.61, 0.58) while higher positive correlation between the other pairs especially cations and nitrate- and chloride ions was indicated.

Mean cumulative ratio of ions in 2012 as compared to the previous testing was one and a half times higher during summer season. Exceeding of concentrations was due to ions of marine origin - Na^+ and Cl^- that together with ions NH_4^+ and SO_4^{2-} prevailed in aerosols composition. To this effect, during summer season higher correlative interrelation of concentrations between ion pairs Cl^- and Na^+, NH_4^+, Mg^{2+}, Ca^{2+} (r = 0,93-0,98) was observed. Comparison of aerosols compositions sampled in Barentsburg in 2011-2012 was indicative of its identity. Although similarity of qualitative composition there were differences in quantitative relation. During spring season number of soluble substances in aerosols composition during both testing years was more or less similar, however, in summer 2012 amount of ions rose three times as compared to 2011. Concentrations of Na^+ were 8.5 times higher, Mg^{2+}- - 3.7 times higher, K^+ and NO_3^- - 2.9 times higher, Cl^- and NH_4^+ - 1.8 times higher, and SO_4^{2-} - 1.6 times higher. During the same period increase of mass concentration of smock black within Barentsburg atmosphere was 1.5 times higher as compared to spring time. Similar increase of smoke black ratio was observed in 2011 when mean values in summer seasons were 3 times higher.

For identifying input of different sources into building chemical composition of aerosols FM_{cont} and FM_{ocean} share factors were used [1]. Relations of K^+, Mg^{2+}, Na^+, Ca^{2+}, Cl^-, SO_4^{2-} concentrations being the main ones both in sea water, and in aerosols. It was found out that prevailing factor of impact on building chemical composition of aerosols is continental. However, in summer season 2012 increase of sea factor input reaches up to 30 %.

The Spanish network on environmental DMAs (Red Española de DMAs Ambientales, REDMAAS) is currently formed by six groups involved in the measurement of atmospheric particle size distributions by means of Differential Mobility Analyzers (DMAs). These groups are: IUMA-UDC, IDÆA-CSIC, INTA, IARC-AEMET, University of Granada and CIEMAT. The network has been working during the period 2010-2012 (Gómez-Moreno et al., 2011 & 2012). The REDMAAS has as main objective the cooperation between the groups to solve common problems and to optimize their facilities and protocols. The main activities developed in the network include: DMA calibration; CPC, SMPS and UFP intercomparison; measurement quality control program; losses in sampling lines; support for the radioactive facility license; webpage; and new DMA applications. In this work, the main results obtained during the 2012 SMPS+UFP intercomparison campaign, including the DMA calibrations and a study on particle losses in dryers are shown.

The field intercomparison exercise was performed during November 2012 in the INTA facilities (El Arenosillo, Huelva). There were 5 complete SMPS systems, an UFP and two additional CPCs. After calibrating all the flow rates, a CPC intercomparison was performed obtaining good results. The results for the DMA calibration was better than the previous campaigns, with a maximum deviation of 2% for 80 nm latex particles and only one SMPS above 5% for 190 nm latex particles. The SMPS intercomparison showed similar results to those obtained in the previous years (Gómez-Moreno et al., 2011 & 2012). The UFP showed good results when the adequate correction matrix was used.

One of the problems to study was the particle losses in the lines, especially in the dryers because of the few results published. The setup was as followed: the sampled air went through a dryer after which there was a flow splitter. Two SMPSs in parallel measured the particle size distribution, the first of them had the testing dryer and the second didn't have any. These two SMPSs were selected because they previously had shown to measure the same distributions. The pipes lengths from the splitter to the SMPS were the same for both of them, so the differences in the measurements were caused by the particle deposition in the dryer. Six dryers (5 Permapure Nafion dryers SS12" and 1 dryer SS24") were tested. An example of the results can be found in figure 1

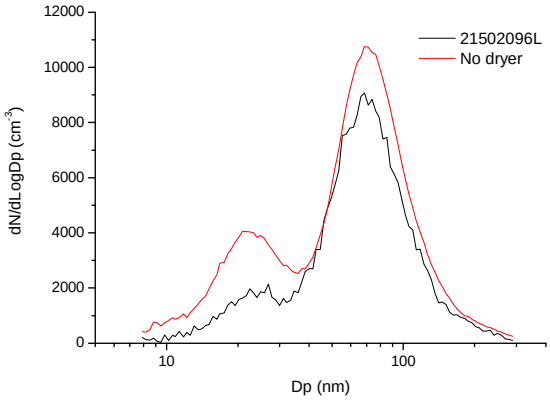

Figure 1. Comparison of a dry aerosol (flow rate: 1 lpm) measured with and without dryer (Nafion SS24"). The difference between the two measurements is the particle deposition in the dryer.

A comparison with theoretical deposition has been done. To calculate diffusional particle losses in the dryers, Wiedensohler et al (2012) recommended to consider the Permapure Nafion dryers SS12" and SS24" as pipes with equivalent lengths of 1.25 and 2.5 m respectively. These same equivalent lengths have been used to consider other different mechanisms for deposition.

This network is financed by the Ministry of Science and Innovation (CGL2011-15008-E & CGL2011-27020).

The potential role of ion-induced nucleation at a coniferous forest site in north eastern Bavaria

S. G. Gonser[1], F. Klein[1,2], W. Birmili[3], J. Größ[3] and A. Held[1]

[1] Junior Professorship in Atmospheric Chemistry, University of Bayreuth, 95440 Bayreuth, Germany
[2] Now at: Gasphase and Aerosol Chemistry Group, Paul Scherrer Institute, 5232 Villigen, Switzerland
[3]Leibniz-Institute for Tropospheric Research, 04318 Leipzig, Germany
Keywords: Ion-induced nucleation, Nucleation, Growth, Ions.
Presenting author email: stefan.gonser@uni-bayreuth.de

Mechanisms governing the nucleation process of secondary aerosol formation are widely discussed. In particular, there is no general consensus on the relevance of ion-induced nucleation. Over the last decade a set of new instruments has become available capable of measuring the number size distribution of neutral and charged clusters in size ranges relevant for nucleation. One of these instruments is the neutral cluster and air ion spectrometer (NAIS) which measures neutral clusters down to 2 nm diameter and ions down to diameters of 0.9 nm. Field based measurements in the lower troposphere using the NAIS indicate a minor impact of ions on nucleation (~10% or less, see e.g. Manninen *et al*, 2010), whereas modelling results as well as different approaches towards interpretation of the field data point at a major role of ion induced nucleation (Yu and Turco, 2011).

During an eight-week measurement campaign we applied a NAIS as well as a scanning mobility particle sizer (SMPS) to study new particle formation events at the "Waldstein" ecosystem research site in the Fichtelgebirge mountain range, NE Bavaria, Germany. The measurements were performed from mid of June to mid of August 2012. In the summer season, new particle formation is a frequently observed phenomenon at this site (e.g. Held *et al*, 2004).

The Fichtelgebirge mountains are well known for their elevated background radiation levels. The radiation originates from the bedrock, containing an increased concentration of uranium and thorium. Additionally, the fissured granitic bedrock promotes the molecular diffusion of gaseous radon. The radioactive background shows a diurnal variation with highest values during the night and decreasing radiation during day time. Thus, ion concentrations may be elevated at times and may play a role in particle nucleation.

During the campaign a total of 18 clear nucleation event days were observed with nucleation rates J_{2nm} between 1-38 cm^{-3} s^{-1} and growth rates in the range of 0.5-5 nm h^{-1}. In Fig. 1 the evolution of a new particle formation event is shown. The lower panel shows the ion fraction of the total particle number in the diameter range 2-3 nm. An increase in the ion fraction was observed shortly prior to the onset of the nucleation event, indicating the potential role of ions on nucleation.

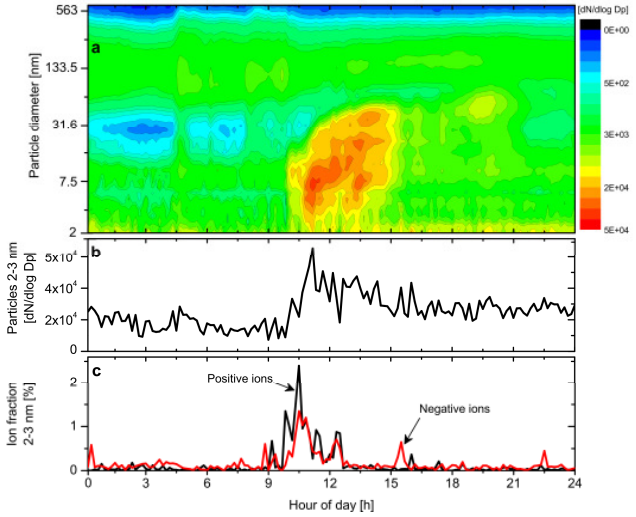

Figure 1. Time evolution of a new particle formation event on 4th July 2012. **a**) total particle number size distribution, **b**) total particle sum in the diameter range 2-3 nm, **c**) fraction of positive and negative ions of total particle number between 2-3 nm.

Daily mean small ion (< 2 nm mobility diameter) concentrations were found to be in the range from 90 cm^{-3} to more than 400 cm^{-3}. Further detailed analysis of the role of ion-induced new particle formation at this forest site will be presented.

Aerosol particles are a key component in the atmosphere regarding its contribution to climate change. They can affect the Earth-Atmosphere energy budget by means of direct and indirect effects. An improved knowledge about the effects of the size increase of the aerosol particles due to water uptake (hygroscopic growth) is necessary for better understanding these effects. It directly affects the scattering of radiation and also the indirect effect. There are already many in-situ studies about the hygroscopicity effects on the aerosol properties. Under ambient conditions, analysis have usually been performed using humidified nephelometers or humidified tandem differential mobility analyzers. These instruments present mainly two limitations: firstly, they are unable to provide accurate results above 85% relative humidity (RH); secondly, they modify the ambient conditions by drying the air sample and then re-exposing it to varying RH. Remote sensing systems can overcome these difficulties, e.g, by sampling the atmosphere without modifying ambient conditions. Moreover, they can also detect RH close to saturation, which is of great importance since the region between 85 and 100% RH is where particles are more affected by hygroscopic growth. The combination of aerosol backscatter (or extinction) and relative humidity profiles retrieved from remote sensing systems are the needed information to perform hygroscopic studies. For this purpose, it is necessary to detect an aerosol layer with a RH increase large enough to observe the variations in the growth factor while the same type of aerosol is present in the corresponding portion of the layer. In that sense, the detected increase in the backscatter (or extinction) would be associated with the change in aerosol size due to the water uptake but not to changes in aerosol composition.

In this study, a combination of Raman lidar, radiosounding (RS) and microwave radiometer (MWR) data over the city of Granada (37.16ºN, 3.60ºW and 680 m asl) has been used to analyse aerosol hygroscopic growth with increasing RH in the vertical profile. In order to guarantee that the same type of aerosol was present along the profile, only situations with a good mixing in the boundary layer were analysed. As a first step, a backtrajectory analysis was performed using the HYSPLIT model. Only when the origin of the air masses was independent of the altitude in the range of interest, the same type of aerosol might be present along the profile (Veselovskii et al., 2009). To confirm good mixing within the boundary layer, potential temperature (θ) and water vapour mixing ratio (*r)* profiles were obtained. Constant profiles of θ and *r* are considered as indicators of well mixed conditions within the boundary layer. Usually RH profiles are obtained from RS, however, in this analysis also a combination of lidar *r* profiles with MWR temperature profiles was used to obtain RH. The accuracy of these RH profiles was checked against RH from RS, thus the analysis of aerosol hygroscopic properties can be extended to cases when radiosoundings are not available. The hygroscopic growth factor is defined as

$$f(RH) = \frac{X_\lambda(RH)}{X_\lambda(RH_{dry})}$$

where X_λ represents whether the backscatter or the extinction coefficient. To obtain *f*(RH) it is necessary to combine the backscatter or extinction coefficient profiles provided by the lidar with the RH profiles. The reference RH_{dry} is usually chosen as the lowest value of the RH in the profile.

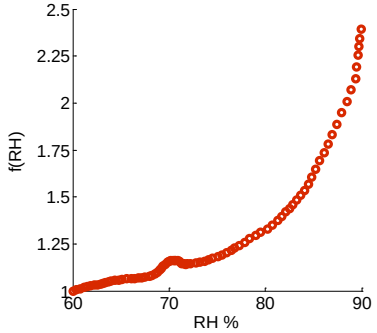

Figure 1. Hygroscopic growth factor for 22 July 2011 between 20:30 and 21:00 corresponding to a layer between 1200 and 2500 m asl. RH_{dry} = 60%.

Hygroscopic growth parameterization of aerosol particles based on high humidity measurements in the Po-Valley, Italy

J. Größ[1], I. Pap[1], W. Birmili[1], A. Hamed[1, 2] and A. Wiedensohler[1]

Keywords: Hygroscopic growth, Hygroscopicity parameter
Presenting author email: johannes.groess@tropos.de

The hygroscopic behaviour of atmospheric aerosol particles was determined during the PEGASOS measurement campaign in 2012. The measurements were performed at the regional site in San Pietro Capofiume (SPC) in the PO-Valley, Italy, from June 9 to July 12, 2012. A High Humidity Tandem Differential Mobility Analyzer (HH-TDMA) was used for the hygroscopicity measurements. The HH-TDMA was developed to quantify the hygroscopic growth factor (HGF) and the mixing state of the aerosol particles for relative humidities (RH) ≥ 90 % under highly temperature-stabilized conditions (Hennig, T. et al., 2005). The HH-TDMA was applied to measure the hygroscopic properties at 90, 93 and 95 % RH for the particle size with 75, 100, 200 and 300 nm. Based on the measured HGFs and under use of the single-parameter κ-Köhler model, the hygroscopic growth behaviour was analysed. κ is the so called hygroscopicity parameter and enables the comparison between measurements at different RHs at a certain dry diameter (Liu et al., 2011). According to Petters, M. D. et al. (2007), κ can be estimated by the following equation:

$$\kappa = \left(HGF^3 - 1\right)\left[\frac{1}{S}\exp\left(\frac{4\sigma_{s/a}M_W}{RT\rho_W D_P HGF}\right) - 1\right] \quad (1)$$

where S is the saturation ratio, $\sigma_{s/a}$ the surface tension of the interface solution/air, M_W the molecular weight of water, R the universal gas constant, T the absolute temperature, ρ_W the density of water, and D_P the particle dry diameter. In order to obtain a parameterized κ, some analysis steps are required. First, for each D_P and S the measured HGF was averaged over the whole measurement period. In a second step the Köhler equation (1) was aligned to the point quantity (S, HGF) with κ as variable fitting parameter. The results are shown in Fig. 1. To get a parameterized κ in dependence on D_P a sigmoid curve (Fig. 2) approach was used:

$$\kappa\left(D_P\right) = A_2 + \frac{A_1 - A_2}{1 + \exp\left(\frac{D_P - D_0}{\Delta D}\right)} \quad (2)$$

with the fitting parameter A_1, A_2, D_0 and ΔD.

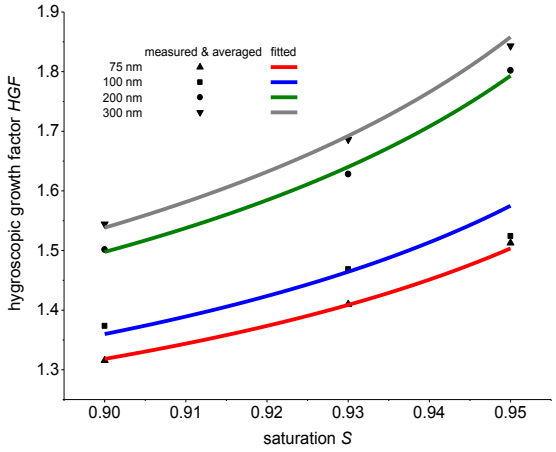

Fig. 1: The hygroscopic growth of different particles sizes (75, 100, 200 and 300 nm). The HGFs are the mean values of the measured HGF corrected to their target RHs (90, 93, 95 %). The red, blue, green and grey lines represent the fitted κ-Köhler curves.

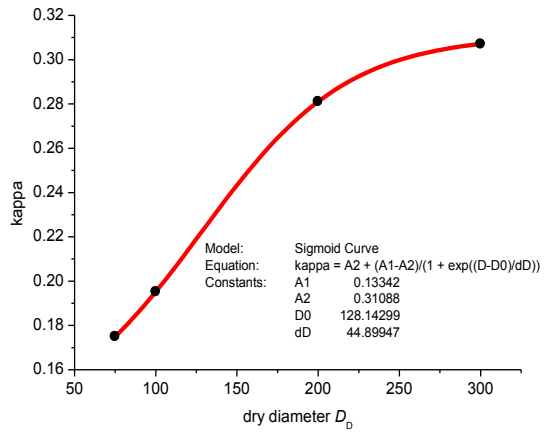

Fig. 2: The hygroscopicity parameter κ for four different particle sizes (75, 100, 200 and 300 nm). The black points are the fitted κs from the Köhler equation (1). The κ sigmoid curve (eq. 2) is displayed as red line.

Keyword: aerosols, biomass, AERONET, lidar,
Presenting author email: sgurlui@uaic.ro

Iasi is a municipality from North-Eastern part of Romania and one of the largest cities in the country. Being a city in continuous development, several urban projects were started in the spring of 2012, with the purpose of improving the city's infrastructure and restoration of some cultural buildings and parks.

Urban and industrial aerosols type is a major component of the tropospheric aerosol load over IASI LOA-SL site monitoring station (47N, 27E). This study presents the results from optical properties analysis (from May 2012 to February 2013 period) on biomass-burning and urban aerosols mixtures by means of lidar and sun-photometer measurements.

In order to both identify and categorize the biomass burning types influences, Aerosol Robotic Network (AERONET) Version 2 data criteria (Level 1.5, solar zenith angle larger than 50^o and retrieval error less than 5%) have been used to compute parameters such as: optical thickness, spectral dependence of Ångström exponent (α), spectral dependence of Single Scattering Albedo and the dominating size mode. Both biomass burning and urban-industrial aerosols are characterized by very small particles, so that fine mode is predominating in the particle size distribution.

The decreasing of Single Scattering Albedo's total average with the increasing of the wavelength (440, 675, 870, 1020 nm) from 0.95 (± 0.1) to 0.81 (± 0.1) agree on dominant aerosol type (Fig. 1).

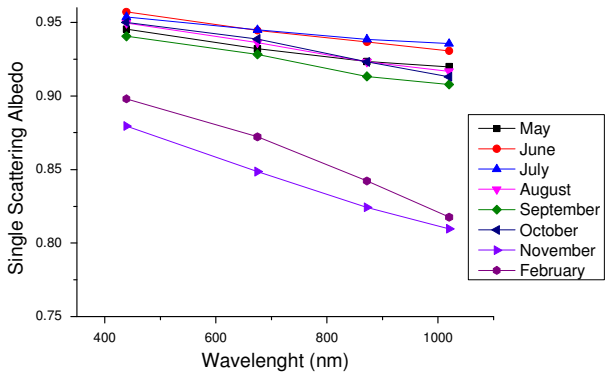

Fig. 1 Spectral single scattering albedo, monthly averages.

The lidar ratio has been calculated from both AERONET inversion and Fernald – Klett inversion (Nicolae et al., 2008). Single Scattering Albedo, Phase Function and Aerosol Optical Thickness were used to determine the lidar ratio and the extinction coefficient. An event on 5 July, 2012 shows that the AERONET lidar ratio calculated at 532 nm (S_{532aer}) is between 55~75 sr with an Ångström exponent between 1.3~1.7 for urban/industrial aerosol and 1.6~1.9 for biomass burning. The lidar measurements were performed by a mini-lidar system described in details in previous papers (Cazacu et al, 2012), developed in the framework of ROmanian LIdar NETwork (ROLINET) and RADO (Romanian Atmospheric Research 3D Observatory) research projects. The values of lidar-lidar ratio (S532) were in the range of 41 ~ 70 sr.

Furthermore, a good method to determine the dominating aerosol type is a/the correlation between the Absorption Ångström exponent (440 – 870 nm) and the Extinction Ångström exponent (440 – 870 nm). Aerosol absorption provides uncertainties in determining the dominance of aerosol types, while applying an aerosol particle size parameter (e.g., Extinction Ångström exponent at 440 – 870 nm) to separate larger particles, improves this method. (Giles et al., 2012; Russell et al., 2010).

The atmospheric aerosols, especially fine particles, are known to have adverse health effects on human populations. Understanding the composition of fine particles is necessary to identify their sources and to predict their effect on various atmospheric processes. Although organic aerosols are major components of the fine particles in urban atmospheres, the composition, formation mechanisms, and seasonal variation of concentrations of organic aerosols (OA) are not well understood. To study the organic aerosol source apportionment, the AMS data has been used to chemically characterise the sources and evolution of OA at many worldwide (Zhang *et al*., 2007).

The Aerodyne AMS were operated at Saitama University (C-ToF-AMS), Center for Environmental Science in Saitama (Q-AMS), Gunma Prefectural Institute of Public Health and Environmental Sciences in Maebashi (H-ToF-AMS), Japan, from 23 to 30 July 2011, except for occasional periods of maintenance and calibration (Figure 1). PMF (PMF2 ver4.2 ; Paatero (2000)) and PET (Ulbrich *et al*., 2009) were used to analyze datasets for each organic aerosol mass spectra from three differnt site.

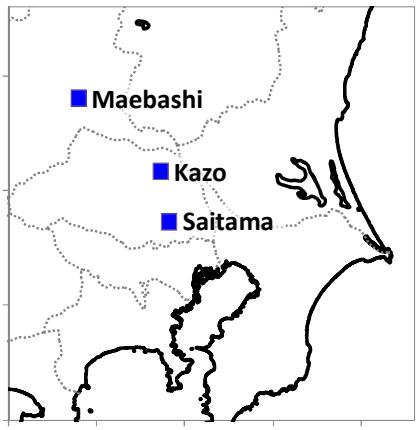

Figure 1. Sampling Sites

Organic aerosol (OA) was detected as major component in this sampling campaign. The organic aerosol mass spectra was divided into two types of OA components, oxygenated organic aerosol (OOA) and hydrocarbon-like organic aerosol (HOA), using positive matrix factorization (PMF) (Figure 2). The OOA was ubiquitous in various atmospheric environments, on average accounting for 44%, 49% and 55% of the total OA in Saitama (urban), Kazo (rural), and Maebashi (rural), respectively.

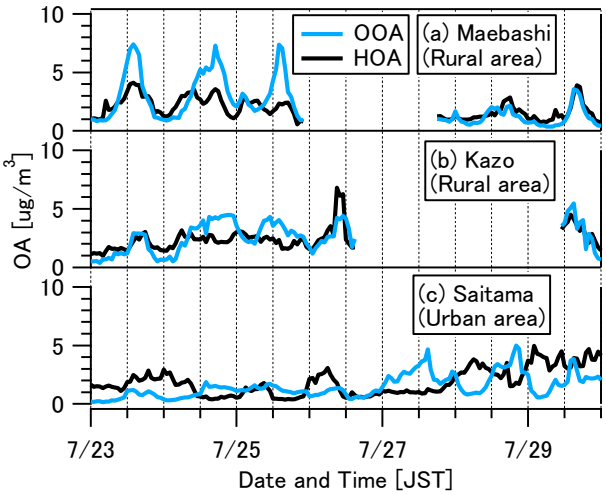

Figure 2. Variations of OOA (Oxygenated Organic Aerosol) and HOA (Hydrocarbon-like Organic Aerosol) concentration at Saitama, Kazo, and Maebashi, as 1 hour averages.

This research was supported by the Environment Research and Technology Development Fund (C-1001) of the Ministry of the Environment, Japan.

Hygroscopicity of Sub-6 nm Sodium Chloride Particles

J. Hakala[1], J. Kangasluoma[1] and T. Petäjä[1]

[1]Division of Atmospheric Sciences, Department of Physics, University of Helsinki, Helsinki, 00560, Finland
Presenting author email: jani.hakala@helsinki.fi

Some studies suggest that the hygroscopic growth of water soluble salt particles may not follow the Köhler theory with particles below the diameter of 8 nm (Biskos et al., 2006a; Hakala et al., 2013). So far the hygroscopic growth of sodium chloride (NaCl) particles has not been studied below the mobility diameter of 6 nm (Biskos et al., 2006a, 2006b). In this study we present our investigations in hygroscopic growth of NaCl measured with a specially made nano Hygroscopicity Tandem Differential Mobility Analyzer (nHTDMA) from mobility diameter of 2.5 nm to 6 nm and in relative humidities from 10% to 95%.

Methods

The nHTDMA is consisted of a high resolution Herrmann Differential Mobility Analyzer (HDMA) for selecting the initial mobility diameter, a humidifier, and a TSI nano Differential Mobility Analyzer (nDMA, TSI DMA 3085) for measuring the mobility diameter after the humidifying. The nDMA was used in a closed loop arrangement. This way the humidifying is easy to achieve and keep stable with just one humidifier. The particles were produced in a tube furnace by vaporization-condensation method in ultrapure nitrogen carrier gas flow (Kangasluoma et al., 2013). To convert the agglomerates produced by this method (Krämer et al., 2000) into cubical crystals, the sample aerosol flow was humidified with an additional humidifier and cooled to 2°C. The aerosol experienced supersaturated conditions inside the cooling unit undergoing a phase transition into solute droplets. After drying in a silica gel diffusion dryer the NaCl particles were assumed to be cubical crystals.

Results

The Hygroscopic Growth Factors (HGF=diameter of humidified particle/diameter of dry particle) in different RH conditions were measured for NaCl particles with mobility diameters of 2.5 nm, 3 nm, 4 nm, 5 nm and 6 nm. The results showed clearly that the HGFs were lower for smaller particles due the Kelvin effect. Also the Deliquescence Relative Humidities (DRH) were determined for 4 nm, 5 nm and 6 nm NaCl particles. The DRH was higher the smaller the particle was. Particles below the mobility diameter of 4 nm had higher DRH than 95%. In Fig. 1. are the HGF distributions for 2.5 nm and 6 nm NaCl particles at different RHs. 2.5 nm particles have significantly lower HGF in same RH than 6 nm particles. The DRH is between 85% and 90% for 6 nm particles. This is marked by disappearance of the mode near HGF 1.1. The bimodal nature of the distribution for 2.5 nm particles is not as clear as for 6 nm particles at high RHs, but the widening of the distribution at RH of 95% shows that the DRH is not yet reached. The bimodal distribution near DRH is caused by different RH histories the particles have experienced before the size classification in nDMA.

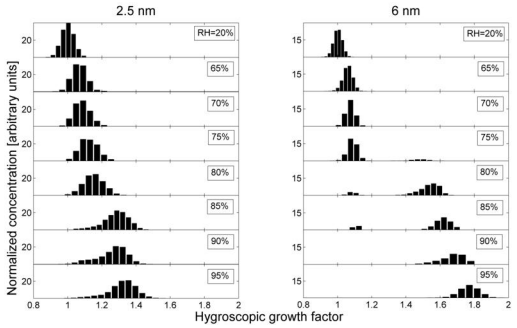

Figure 1. The hygroscopic growth factor distributions for 2.5 nm and 6 nm (mobility diameters) NaCl particles.

New particle formation occurs frequently in the atmosphere (Kulmala *et al*, 2004). According to global model estimations these newly formed particles contribute significantly to global CCN (cloud condensation nuclei) concentrations after growing large enough (Spracklen *et al*, 2008).

It has been observed that sub-20 nm particle growth is size-dependent (Manninen *et al*, 2010; Yli-Juuti *et al*, 2011) and has in some environments seasonal pattern comparable to that of atmospheric biogenic organics, e.g. monoterpenes (Yli-Juuti *et al*, 2011). These results among others suggest that atmospheric nanoparticles are growing mainly by condensation of low-volatile organic vapors and that different fractions of these condensable organics are condensing onto different sized particles due to Kelvin effect.

The challenge in current atmospheric models is to accurately yet efficiently represent atmospheric nanoparticle growth by biogenic and anthropogenic organics. In this work we introduce a simple semi-empirical parameterization for sub-20 nm particle growth that distributes secondary organics to the nanoparticles according to their size (1.5-3 nm, 3-7 nm, 7-20 nm) and this way captures particle growth rates observed in the atmosphere. The parameterization includes particle condensational growth by sulfuric acid, by secondary organics from monoterpene oxidation ($SORG_{MT}$) and by additional condensable non-monoterpene organics ("background") (Eq. 1).

$$I_{tot}(d_p)=I_{SA}(d_p)+k(d_p)I_{SORG,MT}(d_p)+k_{bg}(d_p)I_{SORG,bg}(d_p), \quad (1)$$

where I_{tot} is the total mass flux onto particles with a diameter of d_p, I_{SA} is the mass flux of sulfuric acid, $I_{SORG,MT}$ and $I_{SORG,bg}$ are the mass fluxes of the $SORG_{MT}$ and the background organics, respectively. $k(d_p)$ and $k_{bg}(d_p)$ are factors for distributing the $SORG_{MT}$ and the background organics to particles with diameter of d_p. I_{tot}, I_{SA} and $I_{SORG,MT}$ were obtained from ambient data. $I_{SORG,bg}$, k and k_{bg} values for the three particle sizes were obtained with a least-square method by fitting Eq. 1 to the ambient data. Ambient growth rate data was acquired from particle number size distribution measurements at six continental sites over Europe. The longest time series of 7 years (2003 to 2009) was obtained from a boreal forest site in Hyytiälä, Finland.

The parameterization was able to reproduce observed particle growth rates and their seasonal cycles with good accuracy (see Figure 1 for Hyytiälä as an example). The weighting factors (k) for distributing the $SORG_{MT}$ were 0 for 1.5-3 nm, 0.7 for 3-7 nm and 1 for 7-20 nm. The concentration of the background organics was comparable to the concentrations of the $SORG_{MT}$ and sulfuric acid, around $6 \cdot 10^7$ cm^{-3}. The weighing factors (k_{bg}) for distributing the background organics were 0.3 for 1.5-3 nm, 0.8 for 3-7 nm and 1 for 7-20 nm. Simulations with a global model, GEOS-Chem-TOMAS (Pierce *et al*, 2012), suggest that the "background" can be linked to biogenic organics that are oxidized in the presence of anthropogenic pollution (Spracklen *et al*, 2011).

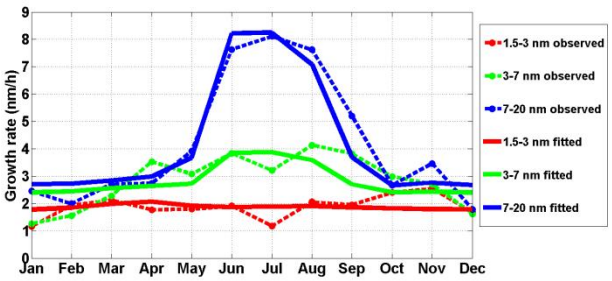

Figure 1. Comparison between particle growth rates (1.5-3, 3-7 and 7-20 nm sizes) obtained from ambient observations and from the parameterization in Hyytiälä.

New particle formation (NPF) events occur frequently in the atmosphere in both clean and polluted environments. It is not, however, yet possible to predict, a priori, rates at which particles are formed and grow, or even to know with certainty which chemical species are involved. To improve the understanding of atmospheric NPF, numerous field measurements, laboratory experiments and models studies are devoted to monitor the gas-phase nucleating vapors and chemical compositions of NPFs. Advanced field measurements are crucial to provide information about the spatial distribution of the rate coefficient in the nucleation parameterizations to assess the impacts of aerosols on climate, weather, air quality, and human health.

Recently, an intensive field campaign (a joint campaign between the Supersito project and the PEGASOS FP7-project) was conducted at San Pietro Capofiume (SPC) (44° 39' N, 11° 37' E; 11 m a.s.l; polluted rural site); and Mt.Cimone (MTC) (44°12' N, 10°42' E; 2165 m a.s.l.; mountain site) measurement stations in the Po Valley region from June 9th to July 10th 2012. Simultaneous measurements of NPF at different parts of the Po Valley give us a good opportunity to study the driving factors of NPF at different sectors of the PoValley region. Particle size distribution (PSD) measurements in diameter range from 3 to 600 nm were measured by a twin Differential Mobility Particle Sizer (DMPS) at the SPC site since March 2002 (Hamed et al., 2007). In November 2005, similar DMPS system but with diameter range from 10-500 nm was established at MTC site in the frame of EUSAAR and ACTRIS projects.

Here, we are presenting the NPF analysis for the first time at MTC station, in addition to SPC site, during the joint PEGASOS/Supersito campaign period. As a summary, 28 NPF event days were identified at SPC site while 9 NPF event days at MTC site. Figure 1 shows surface plots of PSD data as measured with a DMPS system from July 1st to July 7th at both SPC and MTC stations. It is clearly seen that NPF events at SPC are more frequent and more intense (in terms of clear formation and growth for several hours) than NPF events at Mt.Cimone site.

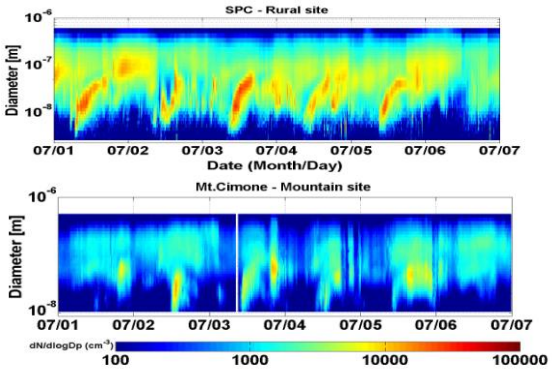

Figure1. Example of one week particle formation bursts observed at SPC (upper panel) and at Mt.Cimone (lower panel), in frame of PEGASOS/Supersito campaign.

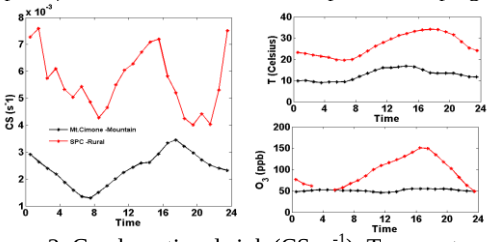

Figure 2. Condensational sink (CS; s^{-1}); Temperature (T; Celsius) and O_3 concentrations (ppb) at Mt.Cimone (black) and SPC (red) on the NPF day of July 3rd.

Our preliminarily results show that CS and T were both lower in MTC than SPC (Fig. 2), which could be possible driving factors of NPF occurrence at MTC site. These two combinations of conditions (low T and low CS), were also shown to favour NPF occurrences at the Finnish boreal station, Hyytiälä (Boy and Kulmala 2002). On the other hand, in SPC both T and O_3 were higher (Fig.2), therefore it is possible that volatile organic compounds (VOCs) and their oxidation products were at higher level in SPC. If VOC oxidation products participate in NPF events at SPC, then that favors NPF events more in SPC than in MTC. The above differences in NPF events hint that different processes are controlling the particle formation events at different parts of Po Valley. More details on characterization of NPF events at PoValley will be discussed in our presentation.

Secondary New Particle Formation in Central Europe: Eight years of Aerosol Particle Size distribution data from Melpitz Site, Germany

A.Hamed[1,2], Z.Wang[1], W.Birmili[1], G.Spindler[1], A.Wiedensohler[1]

[1]Institute for Tropospheric Research (TROPOS), Leipzig, Germany
[2]Department of Applied Physics, University of Eastern Finland, P. O. Box 70211, Finland
Keywords: New particle formation, DMPS, Particle growth.
Presenting author email: Amar.Hamed@uef.fi

New particle formation (NPF) in the atmosphere is a global phenomenon that has been shown to take place in a wide variety of environments (Kulmala et al., 2004). However, the formation mechanisms and the participating substances have not been resolved yet. Long-term data continuous measurements are valuable as they are expected to reveal useful information that enable studies into the dynamics of the NPFs and present control data for climate modelers to predict with more accurately the future climatic conditions.

Here, we present eight years data set (2003-2011) of NPF conducted at the atmospheric research station Melpitz in Eastern Germany (51°32´ N; 12°54´ E; 87 m a.s.l.).The Melpitz station is part of the observation net works German Ultrafine Aerosol Network (GUAN; Birmili et al., 2009) and ACTRIS (Aerosols, clouds, and trace gases research Infrastructure network). Particle size distribution measurements were carried out using dual DMPS systems (Differential Mobility Particle Sizers) with particle size ranges of 3-800 nm.

The particle formation events were identified and classified into two categories i.e., NPF events and non-events. Figure 1a illustrates the total number of NPF events and non events over the period of eight years; while figure 1b shows the monthly frequency of NPF events and non-events for the same period. Earlier study shows that particle formation event days are observed at Melpitz measurement station on 60–100 days in a year (Birmili and Wiedensohler, 2000; Hamed et al., 2010).

Interestingly, for this long-data set, we have observed that number of intensive NPF events shows clear declination, more pronounced, after year 2006. In our earlier study, Hamed et al. (2010) showed that decreasing anthropogenic SO_2 emissions from years 1996/1997 to years 2003/2006 decreased the intensity of new particle formation and thus their frequency and formation rate in Melpitz rural site. Figure 1b shows that the event frequency (the event frequency has been calculated by dividing the total number of days with new particle formation by the total number when the DMPS was working efficiently -we excluded the days when the DMPS system malfunctioned-) was higher during spring and summer months with maximum values in April and May while the minimum was in winter and autumn months. Such high seasonal event frequency in spring has been observed quite often in clean and polluted areas as well. However, the high event frequency in summer contrasts with the observations performed in other rural German site, Hohenpeissenberg (Birmili et al., 2003), which shows a pronounced minimum in the summer (0.075 events per day at Hohenpeissenberg) but at the same time agreed with the observation at the SPC rural site in Italy (Hamed et al., 2007).

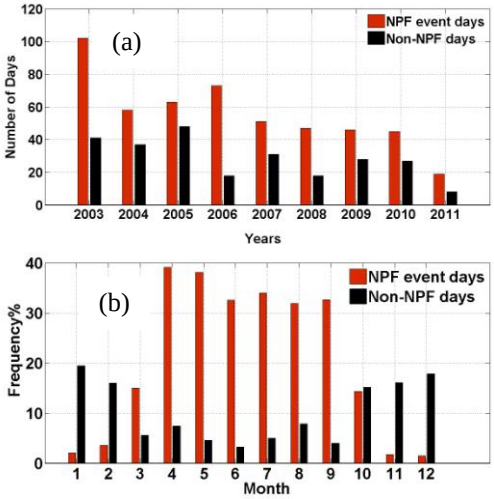

Figure 1: (a) the total numbers of New Particle formation days (NPF-event days; red bar) and non-event days (Non-NPF days; black bar) during each year; (b) monthly frequency of NPF events in Melpitz station, Germany during 2003-2011.

We will show a comprehensive statistical comparison of Melpitz data sets with respect to meteorological and trace gases of NPF events to elucidate the process govern particle formation at Melpitz station. Moreover, comparison of NPF events between Melpitz and other GUAN stations will be discussed in our future presentation.

Presenting author email: hao.liqing@uef.fi

Boreal forests emit large amounts of biogenic volatile organic compounds (VOCs), primarily in the form of mono- and sesquiterpenes, which react with anthropogenic oxidant nitrate radical (NO_3) or undergo photochemical chemistry in the daytime to produce large, multifunctional organic nitrate with vapor pressures low enough to contribute new particle formation and growth. The organic nitrate aerosols, as a significant contribution to the global aerosol burden, can grow to cloud condensation nuclei (CCN) size and be activated into cloud droplets. However, the knowledge of organic nitrate aerosol-cloud interaction is poorly understood.

Observation of cloud events was carried out in a cloud observation station in Kuopio, Finland in 2010 (Hao et al., 2003, Leskinen et al., 2009). Samples from the cloud are introduced into the instruments through twin sampling lines. The first one is the total inlet line to collect the mixed information of cloud residual (RES) and interstitial particles (INT). The other is PM1.0 line to measure the cloud interstitial particles. The difference of both allows the estimation of composition of cloud residual. An Aerodyne high resolution aerosol time-of-flight mass spectrometer (TOF-AMS) was used to measure the chemical composition of cloud particles. We also applied positive matrix factorization (PMF) analysis to track the aerosol origin (Ulbrich et al., 2009). NO^+ and NO_2^+ ions were also integrated into the organic matrix for PMF analysis to separate the organic and inorganic nitrate components.

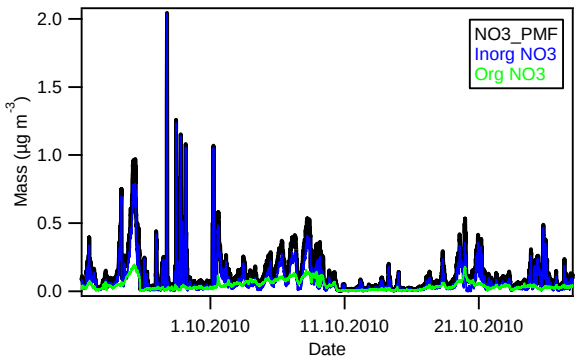

Figure 1. The time series of organic nitrate and inorganic nitrate mass concentrations from PMF fitting.

PMF analysis of the high resolution mass spectra of organics together with NO^+ and NO_2^+ ions allows for the separation of organic and inorganic species. Figure 1 shows the time series of organic nitrate and inorganic nitrate from PMF fitting results. Organic nitrates accounts for 34.7% of total nitrates and contributed to 1.9% of total aerosol masses, suggesting the significance as one of the global aerosol sources.

The investigation of chemical composition in cloud has showed in Table 1. The organic nitrates account for 51±7 % of total nitrate signals in the cloud interstitial particles, whereas its portion in the cloud residual particles was 26%. The difference between two can be explained by the cloud processing and particle size effects. However, the observations in this study highlight the potential important role of organic nitrates compounds playing in the cloud formation.

Table 1 Distribution of organic and inorganic nitrates compounds in cloud.

Ultrafine particle concentrations: importance of local sources and new particle formation in two central European cities

A. Wonaschuetz[1], R. Wagner[1], I. Aschauer[1], R. Haindl[1], W. Ludwig[1], G. Zecha[1], J. Ondráček[2], P. Vodička[2], N. Zíková[2], V. Ždímal[2], J. Schwarz[2], R. Hitzenberger[1]

Presenting author email: anna.wonaschuetz@univie.ac.at

Ultrafine particle concentrations in urban areas are a major concern regarding air quality and public health. Local direct emissions of small, often carbonaceous, particles as well as new particle formation events are sources of fine and ultrafine particles, but meteorological conditions and the properties of the background aerosol moderate both the production and the fate of freshly produced particles. Concentrations of ultrafine particles from local sources are governed by human activity patterns and meteorology (Borsos *et al*, 2012, Kalafut-Pettibone *et al*, 2011, Salma *et al*, 2011), in particular boundary layer characteristics (Olofson *et al*, 2009). The timing and extent of new particle formation in urban areas is linked to precursor gas concentrations, solar radiation and condensational sink strength (Cheung *et al*, 2012, Stanier *et al*, 2004, Zhang *et al*, 2004), and often shows a strong seasonal dependence (Borsos *et al*, 2012, Salma *et al*, 2011, Stanier *et al*, 2004).

In this study, the importance of local primary sources and new particle formation as sources of fine and ultrafine particles is investigated for winter and summer in two central European cities. Particular attention is given to the impact of local meteorological characteristics: air mass origins play a large role in the characteristics of the background aerosol and the concentrations of trace gases associated with new particle formation and growth, and precipitation and thus the condensational sink.

The measurements were conducted in Prague (June 25 - July 9, 2012 and Jan. 14 - 30, 2013) and Vienna (July 16 - 30, 2012 and Feb. 4 - 16, 2013). Particle size distributions were measured continuously with an SMPS (Prague: TSI 3034 ,Vienna: DMA with CPC 3760A, TSI, Inc.). Black, brown, elemental and organic carbon concentrations were measured using a variety of methods (Hitzenberger *et al*, 2013). These measurements of carbonaceous aerosol concentration served as an indicator of human activity patterns and local anthropogenic emissions. Size-resolved chemical information was obtained from impactor data (ion chromatography). Meteorological data (temperature, relative humidity, precipitation, wind speed and direction) as well as solar radiation and concentrations of O_3, SO_2 and NH_3 were obtained from measurement networks. Air mass origin trajectories were calculated using the HYSPLIT model.

First results show that new particle formation events, which occurred mainly in summer, were often, but not always, linked to diurnal peaks in solar irradiation, and contributed substantially to fine particle concentrations. New particle formation events were absent in winter, due to both higher background aerosol concentrations and lower solar radiation in winter. Correspondingly, the contribution of fine and ultrafine particles to total number concentrations in winter was dominated by local anthropogenic sources.

Absorbing aerosol long-term trend at Mukteshwar, a pristine location in Central Himalayas foothills

Rakesh K. Hooda[1, 2], A.-P. Hyvärinen[1], V.P. Sharma[2], M. Komppula[1,3], E. Asmi[1], Y. Viisanen [1] and H. Lihavainen[1]

Presenting author email: rakesh.hooda@fmi.fi

Only recently have we become aware that anthropogenic absorbing aerosols, particularly BC (black carbon), can potentially play a major role in the global scale changes in hydrological cycle (Ramanathan et al., 2001; Liepert et al., 2004). Thus, the Finnish Meteorological Institute together with The Energy and Resources Institute have conducted continuous measurements of aerosol physical and optical properties in Mukteshwar, about 350 km northeast of New Delhi in India since 2006. The site is located at 2180 m above the sea level at the Himalayan Mountains. This is a background location in the foothills of Central Himalayas, and absorbing aerosol measurements with such a time span are unique from the area. Long-term trends in absorbing aerosol concentrations can be observed to emerge from the data set.

The black carbon concentrations were measured with a Magee AE 31 Aethalometer. The PM_{10} and $PM_{2.5}$ measurements were carried out using real-time beta attenuation particulate monitors (FH 62 I-R) manufactured by Thermo Scientific. In addition, other measurements included the particle number size distribution from 10nm to 800nm, aerosol scattering coefficient, and meteorological parameters including temperature, pressure, relative humidity and wind speed/direction (Hyvärinen et al., 2009). The black carbon concentrations were sampled from a $PM_{2.5}$ inlet.

The black carbon and $PM_{2.5}$ concentrations for the 7-year measurement period show high seasonal variability (Fig. 1). The maximum concentrations are observed in April, before the annual monsoon season. The average value of $PM_{2.5}$ fraction of PM_{10} was about 66%, indicating dominance of fine particles. The annual $PM_{2.5}$ concentrations during last 7-year measurements have not shown a clear increasing trend. In contrast, long-term trend of BC in $PM_{2.5}$ has shown a clear increase (Fig. 2). This reveals that anthropogenic activities which emit black carbon have increased during the time.

The highest concentrations of black carbon observed during the warm summer could be due to air lofted from the Indo-Gangetic plains below, when the boundary layer height is at its yearly maximum. It was noted that the $PM_{2.5}/PM_{10}$ ratios between 0.50 and 0.75 and the monthly mean ratio of BC to $PM_{2.5}$ mass lies between 3.0 and 7.5 % (Panwar et al., 2012). Furthermore, it is also observed that the winter months have a higher ratio of BC to $PM_{2.5}$ since the biomass burning is increased due to heating requirements. Therefore, it is not well evident which is the most vital factor for BC variations at this remote location: far emitting sources or changes in meteorological conditions.

In near future, our expanded study in the region would enhance knowledge of absorbing aerosols (brown and black carbon) horizontal variation, ageing processes and influence on climate. India has recently launched an ambitious program NCAP (National Carbonaceous Aerosol Program). The main focus of NCAP is on elemental carbon (EC) while our main aim is to chemically as well as optically characterize both brown and black carbon.

Vertical profiles of aerosol optical properties and wavelength dependent absorption at Maldives Climate Observatory Hanimaadhoo

F. Höpner[1], F. Bender[1], P. S. Praveen[2], V. Ramanathan[2]

[1]Department of Meteorology, Stockholm University, Stockholm, 10691, Sweden
[2]Scripps Institution of Oceanography, University of California San Diego, La Jolla, California, 92093, USA
Keywords: absorbing aerosol, aerosol profiling, radiative forcing.
Presenting author email: friederike@misu.su.se

Aerosol radiative forcing is strongly dependent on the vertical distribution of aerosol. Especially, aerosol particle number and size distribution, particle optical properties and chemical composition are important features for calculating the radiative forcing (Kinne et al., 2006). Satellite based as well as surface based remote sensing instruments like Aeronet sun photometers can provide information about amongst other things columnar aerosol optical depth (AOD) and single scattering albedo (SSA). In addition, surface based as well as space borne lidar measurements can provide profiles of atmospheric backscatter and extinction. Meanwhile vertical in situ aerosol measurements are rare but also necessary to obtain actual particle concentrations and particle size information.

One focus of contemporary in situ aerosol measurements is the quantification of surface as well as vertically resolved carbonaceous aerosol (CA). CA consists mainly of black carbon (BC) and organic material (OM). BC, a product of incomplete combustion processes, is a main absorber of solar radiation and hence plays an important role in the climate system (Bond et al., 2012). Hence, it is important to incorporate BC properly in models. A good parameterization based on actual aerosol data leads to reducing uncertainty in model estimations of aerosol radiative forcing.

We will here present data from Cloud Aerosol Radiative Forcing Dynamics EXperiement (CARDEX) at Maldives Climate Observatory in Hanimaadhoo (Maldive Islands) in February and March 2012. This time of year is part of the dry monsoon season with arriving polluted air masses from the Asian continent. Thus air with high BC loading can be investigated. During CARDEX, aerosol profile measurements with lightweight unmanned aerial vehicles (UAVs) were performed. Amongst other instruments, a condensation particle counter (CPC), aethalometer and optical particle counter (OPC) were installed on board. Furthermore, surface instrumentation included a ground based lidar, nepholometer, aethalometer, CPC and an Aeronet sun photometer were in use.

Surface and vertical measurements from the CARDEX field campaign are used to calculate particle scattering, absorption as well as extinction profiles as functions of total particle concentration and relative humidity. A comparison between calculated profiles and measured absorption values from the on board aethalometer as well as from the lidar results will be presented. Reasons for potential discrepancies will be discussed. Figure 1 shows an example of calculated and measured vertical profiles of scattering, extinction and absorption on a day with an elevated aerosol layer present above the boundary layer.

Determined AOD and absorption AOD (AAOD) from vertically integrated extinction and absorption profiles respectively will also be compared to sun photometer based AOD results. Furthermore wavelength dependent AOD and AAOD will be analysed to separate the influence of dust, biomass and fossil fuel burning products (Chung et al, 2012).

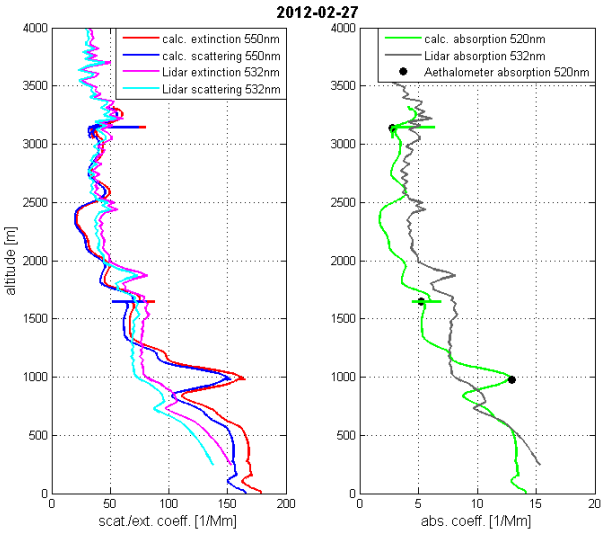

Figure 1: Calculated and measured vertical profiles of scattering, extinction and absorption. The calculated profiles (red, blue, green) and the measured absorption from an on board aethalometer (black) are results from a downward flight on Feb.27th 2012 between 10:00 and 11:00 local time. The lidar profiles (magenta, cyan, grey) are determined the same day at 10:00 local time.

Spatial variations and source apportionment of the marine organic aerosol over the Atlantic Ocean

S. Huang, L. Poulain, Z. J. Wu, H. Herrmann, A. Wiedensohler

Leibniz Institute for Tropospheric Research, Leipzig, 04318, Germany
Keywords: marine aerosol, organic compounds, methane sulfonic acid, source apportionment.
Presenting author email: huang@tropos.de

The marine aerosol plays an important role in global climate regulation and marine biogenic system. The organic compounds are found in both primary and secondary marine aerosol and related to the number size distribution, hygroscopic growth and optical properties of particles. However, the contribution and formation mechanisms of marine organic aerosol are still poorly understood (O'Dowd and De Leeuw, 2007). In this study, physicochemical properties of the marine boundary layer aerosol were measured by a comprehensive suite of on-line instrumentation on the research vessel Polarstern during 4 cruises over the Atlantic Ocean. The cruises details are shown in Table 1.

Table 1. The starting/terminal ports and duration of 4 cruises

Expedition	Port	Duration
Cruise I (ANT-XXVII/4)	Cape Town - Bremerhaven	20.04.2011 - 20.05.2011
Cruise II (ANT-XXVIII/1)	Bremerhaven - Cape Town	28.10.2011 - 01.12.2011
Cruise III (ANT-XXVIII/5)	Punta Arenas - Bremerhaven	10.04.2012 - 15.05.2012
Cruise IV (ANT-XXIX/1)	Bremerhaven - Cape Town	27.10.2012 - 27.11.2012

Table 2. Mass fraction of the main species for 3 cruises

Species	Cruise I	Cruise II	Cruise III
Organics	24%	29%	30%
Sulfate*	58%	56%	54%
Ammonium	13%	10%	11%
Nitrate	4%	3%	4%
Chloride*	1%	2%	1%

*non-sea salt sulphate and non-sea salt chloride

The chemical composition of non-refractory submicrometer particles was derived from High Resolution Time of Flight Aerosol Mass Spectrometer (HR-ToF-AMS) measurements from the first 3 Polarstern cruises. Table 2 provides the mass fraction of each main species measured by AMS. Sulfate is the dominant component, accounting for more than 50% of the total measured particle mass concentration. Organics are the second important species, taking 24-30% of total particle mass concentration. Ammonium contributes 10-13% to the total particle mass concentration. Nitrate and non-sea salt chloride showed very low concentrations during the cruises.

As an example, the spatial variations of organic component mass concentration for cruise I-III are given by Figure 1. High concentrations are observed when the ship is close to the continent, possibly influenced by both the air mass transport from the continents and the phytoplankton blooming depending on the season.

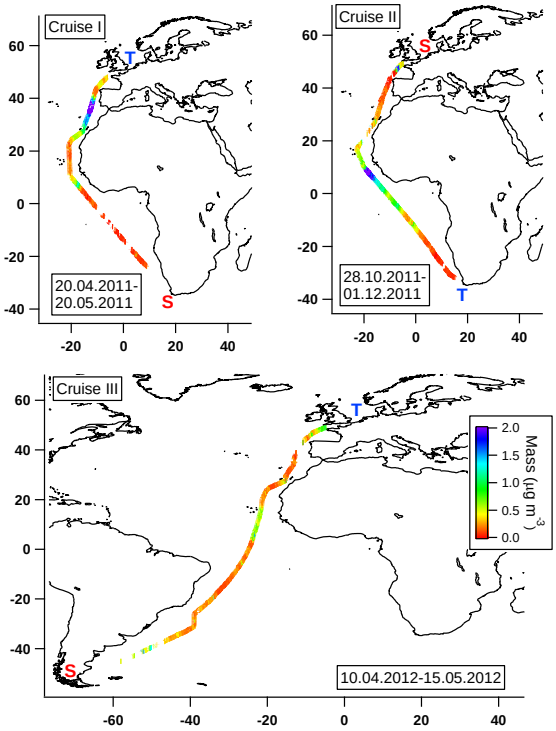

Figure 1. Organics mass concentration along the ship track for the first 3 cruises (S: starting port, T: terminal port)

Based on the high resolution mass spectra of HR-ToF-AMS, methane sulfonic acid (MSA) and sodium chloride (NaCl) are extracted from the original signals, providing clues of the secondary marine aerosol and the primary marine aerosol, respectively. They are being validated by filter sample results and being used to improve the source apportionment by Positive Matrix Factorization (PMF) method. The AMS-PMF analysis is on-going and more detailed results will be shown in the presentation.

Chemical composition, concentration, size distribution and diurnal variation of atmospheric submicron aerosol particles at the background and urban sites in Lithuania

K. Kvietkus, J. Šakalys, J. Didžbalis, E. Meinorė

State Research Institute Center for Physical Science and Technology, Savanoriu 231, LT-02300 Vilnius, Lithuania

Keywords: PM_1 chemical composition, concentration, size distribution, diurnal variation
Presenting author email: ernesta.pesliakaite@gmail.com

The aim of this study is to analyze PM_1 chemical composition, concentration, size distribution and diurnal variation of submicron aerosols particles at the background and urban sites in Lithuania. The quantitative size and chemical composition measurements of PM_1 are essentially important in determining aerosol particles effect on global climate as the major part of all aerosols volume is occupied by PM_1. PM_1 concentration and size-resolved chemical composition were measured with an *Aerodyne* Quadrupole Aerosol Mass Spectrometer (Q-AMS) during campaign in 2011. The detailed description of instrument performance is available in Jayne *et al.* (2000). The measurements of non-refractory particles were performed with a time resolution of 5 min in every sampling site, thus during campaign there were evaluated over 21 million values of measurements.

Rūgšteliškis sampling site is located in a forested area (55º27´48´´N, 26º03´60´´E) at national park of Aukštaitija with the highest point of 188,6 m a.s.l. and with mean average air temperature of 5,8 °C. Preila station is located nearby the Baltic Sea (55º22´24,4´´N, 21º4´4,5´´E) 5 m a.s.l. Rūgšteliškis and Preila sites are considered to be rural/background sites. Urban sampling site is located in the vicinity of Vilnius city, which is industrial centre with a population over 550 000 and residential area of about 400 km^2.

The average concentrations of non-refractory PM_1 chemical components (ammonium NH_4^+, nitrate NO_3^-, sulfate SO_4^{2-}, chloride Cl^- and organics) are presented in Table 1. The concentration of nitrates at polluted site in Vilnius was about twice as high as at Rūgšteliškis and Preila sites. According to O'Dowd *et al.* (2011) the source of nitrate at polluted areas is nitrate oxides from exhaust gases.

Clear diurnal variation of organics and nitrates components was indicated in Vilnius site, whereas in Preila site clear diurnal variation was observed only for chloride component. Clear diurnal variation was observed only at the presence of Northeast wind in Vilnius site.

PM_1 size distribution spectra at Preila site for ammonium and nitrates particles were shifted towards coarse particle size. Possible reason of the spectra shift is conditioned of hydrophilic aerosol particles in Preila station.

Table 1. Average concentration of PM_1 chemical components ($\mu g/m^{-3}$).

Keywords: aerosols, climate change, air quality, Saudi Arabia
Presenting author email: antti.hyvarinen@fmi.fi

The Arabian Peninsula has one of the largest aerosol particle burdens in the world because of the frequent presence of dust storms, smoke advection from South Asia, and its own pollution emissions from road traffic, the petroleum industry and local construction. In addition, the Arabian Peninsula exhibits extremely complicated meteorology with variable sea surface temperatures, enormous latent heat fluxes, abrupt topography, and strong mesoscale circulation, making both modeling and remote sensing of aerosols extremely difficult in this region.

The object of this study is to establish an aerosol measurement station in the Western Saudi Arabia to evaluate the quantities and properties of both natural and anthropogenic aerosols in the area, and their effect on climate change and air quality. The measurements were begun October 2012 with a projected length of three years.

The Hada Al Sham site (21.802° North, 39.729° East, 254 m a.s.l.) is situated about 60 km east of the coastal city of Jeddah. The surroundings represent a rural area. The following in situ measurements are conducted at the station: $PM_{2.5}$ and PM_{10} mass concentrations, total particle number concentration, particle number size distribution from 7 nm to 10 µm, aerosol black carbon concentration (absorption coefficient) and aerosol scattering coefficient. Cimel sunphotometer is used for measuring the columnar properties of the atmosphere. In addition, weather parameters are measured.

The early results from Hada Al Sham show a wide diversity of different aerosol sources. In December 2012, 85 % of the recorded days exhibited a new particle formation event (Fig 1.). This can be related to sulphate emissions from heavy oil combustion occurring in the Western Saudi Arabia, such as oil refining (Khodeir et al. 2012).

The scattering and absorption coefficients measured during December 2012 showed a clear diurnal variation (Fig 2.). While the scattering coefficient showed two daily maxima, occurring at 7 am and 5 pm, the absorption coefficient was elevated from 12 am to 7 am. This illustrates that the absorbing aerosols related to anthropogenic activities have different sources than scattering aerosols, which also have natural sources, such as mineral dust.

In the future, the seasonal variation of aerosols in Hada Al Sham, together with their spatial sources will be investigated.

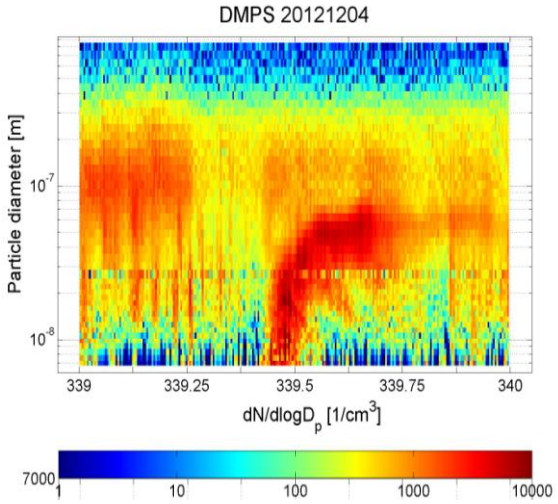

Figure 1. Example particle size distribution as a function of time on 4.12.2012.

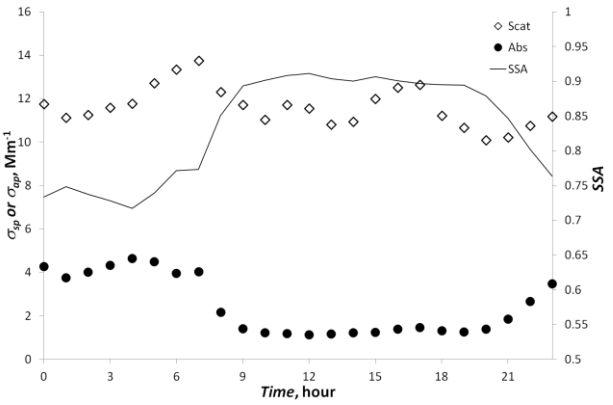

Figure 2. Diurnal variation of scattering coefficient (σ_{sp}), absorption coefficient (σ_{ap}), and single scattering albedo (*SSA*) at 525 nm on December 2012.

This study was funded by King Abdulaziz University (KAU), Jeddah, Saudi Arabia (under grant No. 1220/430). The authors acknowledge the technical support of KAU.

Presenting author email: xuguang.chi@mpic.de

Atmospheric aerosols are currently a subject of high scientific and political interest mainly due to their role in climate and their effects on human health (Andreae and Crutzen 1997). Aerosols are a complex mixture of many different chemical species originating from a variety of natural and anthropogenic sources. Their chemical composition is determined by their sources and subsequent transformation while airborne, and is temporally and spatially highly variable. The major aerosol components (aerosol types) normally include organic matter (OM), elemental carbon (EC) or Black carbon (BC), sulfate, nitrate, ammonium, crustal matter, and sea salt. Data on aerosols chemical composition are necessary for source identification and apportionment, and also needed for the testing and validation of numerical aerosol models, which are becoming tools to extrapolate monitoring data. During the last decades, a growing number of scientific studies have been investigating the chemical composition of aerosols at various sites around world. However, the data for chemical aerosols composition in Siberia, a vast region in Central Eurasia, are still lacking. This is highly contradictory to the global relevance of the Siberian landmass as a source and sink for aerosol particles, and their role in the global radiation budget.

In order to characterize the Siberia aerosols, filter sampling were started at Zotto site (60.80°N and 89.35°E, 114 m a.s.l.), Russia in April 2010. Nuclepore polycarbonate and quartz fibre filter samples were taken in parallel with real time aerosols optical properties measurements and some tracer gas measurements. Up to March 2011, 66 samples were taken for each samplers. The quartz fibre filters were analysed for the particulate mass by weighing, and analysed for organic carbon (OC) and elemental carbon (EC) by sunset OC/EC analyser. The Nuclepore filters were analysed for major anions and cations by ion chromatography (Dionex, ics-1100), and for water soluble organic carbon (WSOC) with a Shimadzu TOC analyzer. With help from high time resolution CO and light absorption results and Hysplit back trajectories calculations, the filter samples were separate to episode samples and non-episode samples. The aerosols chemical compositions were clearly different between episode and non-episode samples, and between winter and other three seasons. The winter episodes associated with elevated concentrations for most of species, and were usually related to anthropogenic pollution, the air masses during such episodes had passed over the central Siberian region around Omsk and Novosibirsk – a heavily industrialized area. During spring and fall, a number of samples exhibited high K^+, and oxalate levels, indicating an impact from biomass burning. In addition a notable episode with extreme high Na^+, Cl^-, and Mg^{2+} were observed for the samples collected between 20 to 24 December 2010, which may result from long range transport of sea salt from North. More than 80% of OC are found to be Water soluble in summer non-episode period, which may due to the enhancement of secondary organic aerosols formation.

In the aerosol chemical mass closure calculations, six aerosol types were considered. Organic matter (OM) contributed by far the most to the PM mass; it accounted for about 40-70% of the average PM mass. Followed by Secondary Inorganic Aerosols species (SO4, NH4, and NO3), more than 30% of PM mass. OM contribution to PM mass was lower in winter than that in the other three seasons, while EC, Ammonium and Nitrite show higher contribution in winter. The mean PM mass attribution to the different aerosol types for April to November 2010 at Zotto during non-episodes periods were similar to those for the 2007 campaign at the forested site of Hyytiälä, Finland. EC and Nitrate were more important and Ammonium was clearly less important at Zotto, though.

Estimation of emission rates of resuspended road dust using a mobile monitoring system

Sehyun Han and Yongwon Jung

Department of Environmental Engineering, Inha University, 253 Yonghyun-Dong, 402-751, Incheon, Korea
Keywords: PM10, PM2.5, resuspended road dust, emission factor
Presenting author email: jungyw@inha.ac.kr

Resuspended road dust has been one of the main PM10 emission sources in Western United States and some of European countries including Norway during winter. According to the previous study based on CAPSS(Clean Air Policy Support System) developed by Korean Ministry of Environment, resuspended road dust is likely to contribute with significant amount to PM10 emission not only in road transport sector but also in entire PM10 emission inventory in Seoul metropolitan area including the city of Incheon. One of the main problems in estimating PM10 emission rate of resuspended road dust using the emission estimation equation in AP-42 of US EPA is that there are very large uncertainties in estimated values, which often result in overestimation of the PM10 emission rate of resuspended road dust. This study focuses on reducing uncertainties in estimating PM10 and PM2.5 emission rate of resuspended road dust.

To estimate PM10 emission rate of resuspended road dust, a mobile monitoring system was developed in this study, which is similar to the SCAMPER(System for the Continuous Aerosol Monitoring of Particle Emission Rates from Roads, Fitz and Bumiller, 2005) in principle. Originally, the mobile system was designed in 2005 using the principle of the TRAKER(Testing Re-Entrained Kinetic Emissions from Roads, Kuhns *et al*, 2001) and has been employed to measure silt loading on paved roads in Seoul metropolitan area(Han and Jung, 2012). Therefore, our system employs principles of both TRAKER and SCAMPER and thereby the silt loading data and emission rate of resuspended road dust can be estimated on a test road simultaneously. A schematic of a hybrid type mobile monitoring system is shown in Figure 1.

PM10 emission factors of resuspended road dust on a test road section can also be estimated using the emission estimation equation in AP-42 of US EPA, which uses silt loading and vehicle weight as parameters in the equation. Therefore, if one compares the emission factors (*i.e.* g/km) obtained using the emission estimation equation in AP-42 of US EPA with those obtained using SCAMPER principle, one can correct the predicted emission factors from the emission estimation equation in AP-42 of US EPA. By doing so, uncertainties in the emission estimation equation in AP-42 of US EPA can be reduced and possibility of modification of the equation, for example, by adding a vehicle speed dependency term to the equation as an additional parameter can also be verified. For this, we attempted to correlate the correction factors (or scaling factors hereafter) obtained at different test conditions with vehicle speed and silt loading as parameters.

It was found that the resulting correlation for the scaling factor is approximately proportional to the square of vehicle speed, whereas it has relatively weak dependency of silt loading. Detailed results will be presented in the conference.

Presenting author email: Ariane.Kahnt@ua.ac.be

Biomass burning aerosol (BBA) contains a significant fraction of nitro-aromatic compounds and recent studies identified nitrocatechols ($C_6H_5NO_4$, MW 155) and methyl-nitrocatechols ($C_7H_7NO_4$, MW 169) as main constituents. These compounds were proposed as tracer compounds for processed (secondary) BBA (Iinuma *et al.*, 2010). Higher homologues of methyl-nitrocatechols ($C_8H_9NO_4$, MW 183) were described also recently as abundant compounds in ambient filter samples (Kitanovski *et al*., 2012a, b). Furthermore, nitrocatechols and their methyl homologues were shown to correspond to the abundant yellow-coloured compounds of humic-like substances that were isolated from BBA (Claeys *et al.*, 2012). Taking into account the abundance of nitro-aromatic compounds in atmospheric aerosol samples and their potential effects on health and climate, the aim of the present study was to examine their time series over a whole year and their relationships with other known tracers for BBA and biogenic secondary organic aerosol.

PM_{10} filter samples were collected from a rural station in Hamme, Belgium, which was recently shown to be largely impacted by biomass burning (Maenhaut *et al.*, 2012). The extracted filter samples were further investigated in terms of liquid chromatography combined with negative ion electrospray ionisation mass spectrometry and different compounds were quantified. The targeted compounds included four nitro-aromatic compounds (MWs 139, 155, 169, and 183), nitrooxy organosulfates (MW 295) originating from α-pinene and the resin acid dehydroabietic acid, DHAA (MW 300) (Figure 1).

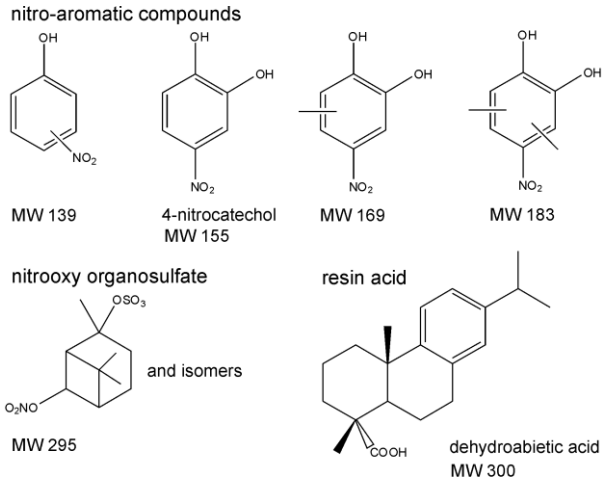

Figure 1. Targeted compounds in the present study.

A strong seasonal variation was observed for the nitro-compounds with highest concentrations during the winter months (Figure 2), followed by the autumn, spring and summer periods. In agreement with a previous study (Kitanovski *et al.*, 2012b), high correlations between the nitrocatechols and methyl-nitrocatechols were observed, with r-values up to 0.97. There were also substantial correlations (r-values up to 0.68) between these BBA tracers and the primary BBA tracer levoglucosan.

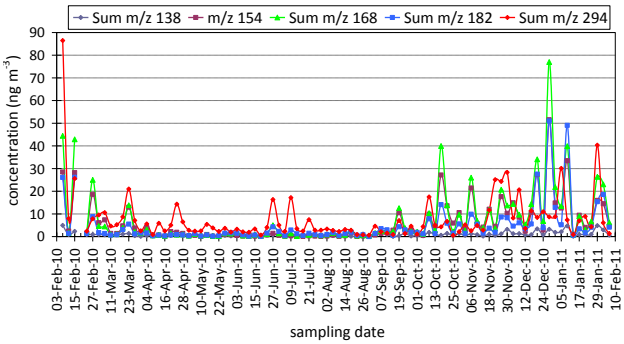

Figure 2. Time series for PM_{10} nitro-aromatic compounds in Hamme, Belgium.

Based on the DHAA measurements and the correlation analysis, the burning of softwood and foliage of coniferous trees is likely an important source for the formation of all of the targeted species.

Presenting author email: nkalivitis@chemistry.uoc.gr

Quantifying the contribution of atmospheric nucleation processes as source of cloud condensation nuclei (CCN) is an important step towards the understanding of the interactions between aerosols and clouds, and subsequently the radiative forcing of the atmosphere (Kerminen et al., 2012).

During the FRONT (Formation and growth of atmospheric nanoparticles) project both nucleation and growth of atmospheric aerosols are studied, with special emphasis given to the precursor gases driving these processes. Continuous measurements of aerosol and ion size distributions and real time aerosol chemical composition are performed at Finokalia station, Greece.

In Fig. 1 an event of consecutive nucleation days observed at Finokalia is presented. Aerosol size distributions were measured with an SMPS in the size range 10-900nm and real time chemical composition of fine particles was monitored with an ACSM (Aerosol Chemical Speciation Monitor). The onset of new particle formation sequence took place when the origin of the air masses changed from west to north. Back trajectories analysis showed that air mass penetration from higher altitudes resulted to a drastic drop of condensation sink (CS). For the days presented the air mass origin remained the same. There were 4 events of atmospheric nucleation observed. The chemical composition of aerosols showed that the change of air masses origin, except of the drop of CS resulted additionally to a cations/anions (C/A) ratio well above 1. As has been shown in the past (Pikridas et al., 2012) under these conditions nucleation is favored, high C/A ratio is an indication of NH_3 excess in a sulfate rich environment as Finokalia.

Number concentration for particles with D_p<20nm (N_{nuc}) and D_p>100nm (N_{acc}) were calculated, N_{nuc} to demonstrate the nucleation and N_{acc} as representative for CCN number. In previous experiments during summer at Finokalia it was observed that N_{acc} is well correlated to CCN number for supersaturation of 0.2% (not shown). As can be seen in Fig. 1, the variation of N_{acc} follows closely that of sulfate indicating that sulfate is the major species that result to growth to CCN sizes. On the other hand, organic compounds present a weaker correlation to N_{acc}, playing important role though in the determination of CCN number. However, it is expected that the contribution of different species in the growth process changes on annual basis as a subject of the abundance of each species. Future work will provide supplementary information on VOCs and their potential role in the formation and growth processes.

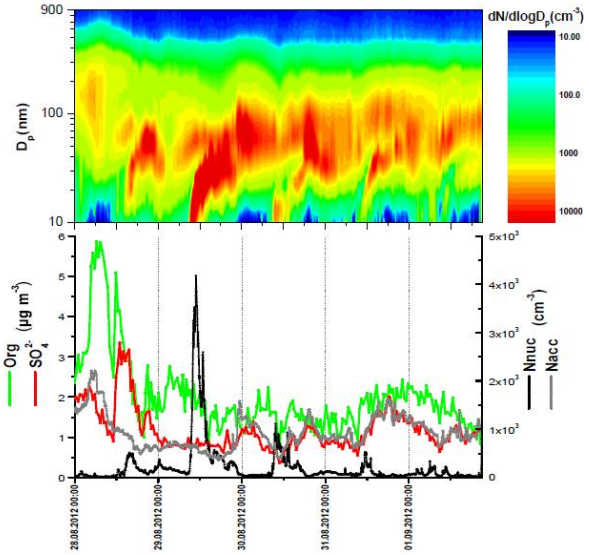

Figure 1. Nucleation events observed at the Finokalia station during the period 28/8-1/9/2012. Upper panel, number size distributions of atmospheric aerosols (D_p 10-900 nm). Lower panel, time series of aerosol chemical composition (major components) and number concentration of nucleation and accumulation mode particles.

The research project is implemented within the framework of the Action «Supporting Postdoctoral Researchers» of the Operational Program "Education and Lifelong Learning" (Action's Beneficiary: General Secretariat for Research and Technology), and is co-financed by the European Social Fund (ESF) and the Greek State. This research is supported by the Academy of Finland Center of Excellence program (project number 1118615).

Nitration and oxidation of bioaerosols and allergenic proteins

C. J. Kampf[1], K. Selzle[1], and U. Pöschl[1]

[1]Multiphase Chemistry Department, Max Planck Institute for Chemistry, Mainz, 55128, Germany
Keywords: nitro-protein, reactive oxygen intermediates (ROI), bioaerosol
c.kampf@mpic.de

Primary biological aerosol particles, e.g. pollen, fungal spores, bacteria, etc., significantly contribute to the coarse mode particulate matter in urban, rural, and pristine environments (Elbert et al., 2007; Després et al., 2012). Up to ~5% of the total urban particulate matter are proteins. These proteins influence the physico-chemical properties of atmospheric particles and play a major role as airborne allergens (Franze et al., 2003)

Protein nitration was found to occur at the tyrosine residues, and to proceed at timescales and NO_2 and O_3 concentrations relevant to the ambient atmosphere (Franze et al., 2005). Moreover, recent studies suggest that nitration affects the allergenicity of proteins (Gruijthuijsen et al., 2006; Untersmayr et al., 2010).

For this study, the reaction products and pathways of protein nitration were investigated using 3 different nitration agents. Nitration of the investigated proteins was carried out in solution using 1) tetranitromethane (TNM), 2) peroxynitrite, and by passing gaseous nitrogen dioxide and ozone (NO_2+O_3) over protein spiked filters as illustrated in Fig 1. The nitration degrees of individual tyrosine residues (ND_Y) were determined by site-specific quantification using HPLC-MS/MS (Zhang et al., 2011) and compared to the total protein nitration degrees (ND) determined by photometric detection with HPLC-DAD (modified Yang et al., 2010).

The observed nitration patterns revealed that the site selectivity of the reaction depends on 1) the nitrating agent, 2) reaction conditions, and 3) molecular structure of the protein. Therefore, different nitration mechanisms in endogenous and exogenous processes lead to specific post-translational modifications of proteins under summer smog conditions in the atmosphere (NO_2 and O_3), or during inflammatory processes in the human body (peroxynitrite). Further, a correlation of ND and relative humidity (RH) was observed for protein nitration by gaseous NO_2 and O_3. Meteorological conditions therefore seem to play an important role in the ambient protein nitration. Atmospheric aerosol samples will be analyzed to investigate the extent of protein nitration and oxidation under ambient conditions.

The chemical mechanisms and molecular processes responsible for the adverse health effects of NO_2 and O_3 are still not well understood. We suggest that protein nitration by air pollutants plays a major role in the increase of allergies in the western countries besides nutrition effects and excessive hygiene practices.

Effects of mineral dust and sea salt on global nitrate concentration field

V.A. Karydis[1], A.P. Tsimpidi[1], and J. Lelieveld[1,2]

[1]Max Planck Institute for Chemistry, Mainz, 55128, Germany
[2]Energy, environment and water research center, Cyprus Institute, Nicosia, 1645, Cyprus

Keywords: Nitrate Aerosols, Aerosol Thermodynamics, Mineral Dust, Sea Salt.
Presenting author email: v.karydis@mpic.de

Inorganic particulate nitrate constituents contribute significantly to the total aerosol mass; i.e. over Europe particulate nitrate accounts for about 10–20% of the total dry aerosol mass (Putaud et al., 2004). While nitrate is predominantly present in the submicron mode, coarse mode aerosol nitrate can also be produced by adsorption of nitric acid onto sea salt particles and soil particles. Naturally emitted particles affect the phase partitioning of nitrate and ammonium, especially in areas where dust or sea salt comprises a significant portion of total particulate matter, and the simulation of these effects can considerably improve model predictions. However, most thermodynamic models used in global studies lack a realistic treatment of crustal species. Furthermore, assuming thermodynamic equilibrium between the gas and aerosol phases may not be appropriate for coarse mode aerosols in global models.

The project aims to improve the representation of nitrate aerosols in a global chemistry climate model, the ECHAM/MESSy Atmospheric Chemistry (EMAC) model (Jöckel et al., 2006), and address the shortcomings of previous models. EMAC calculates the aerosol microphysics and gas/aerosol partitioning by using the Global Modal-aerosol eXtension (GMXe) aerosol module (Pringle et al., 2010). Aerosol microphysics are treated using an extended version of the M7 modal aerosol scheme (Vignati et al., 2004), which describes the aerosol size distribution by 7 interacting lognormal modes (4 hydrophilic and 3 hydrophobic modes). An advanced dust emission module also accounts for the soil particle size distribution of different deserts worldwide (Astitha et al., 2012). Gas/aerosol partitioning is simulated using the EQSAM (Metzger and Lelieveld, 2007) and ISORROPIA-II (Fountoukis and Nenes, 2007) thermodynamic equilibrium models. The EQSAM model is a simplified, non-iterative, treatment of gas/aerosol partitioning that uses analytical expressions based on the species solubility. EQSAM can be run in a range of complexities; in this work we consider the interaction of K^+-Ca^{2+}-Mg^{2+}-NH_4^+-Na^+-SO_4^{2-}-NO_3^--Cl^--H_2O aerosol components. ISORROPIA-II uses the same suit of components and solves for the equilibrium state by considering the chemical potential of the species.

Simulation of the effects of mineral dust and sea salt on nitrate aerosol partitioning and size distribution requires an accurate description of the aerosol dynamics in the coarse mode, while it is desirable for the model to remain computationally efficient. In this project we use the hybrid method for aerosol dynamics developed by Capaldo et al. (2000) in which only the aerosol particles in the fine (nucleation, aitken, and accumulation) mode are simulated assuming equilibrium by applying EQSAM or ISORROPIA-II. For coarse particles the mass transfer differential equations are solved using the gas-phase concentrations calculated by the equilibrium step.

The proposed modeling framework combines the accuracy of the dynamic approach with the speed and simplicity of the equilibrium approach, which makes it ideal for the accurate prediction of the nitrate global concentration fields. The new model is tested in long-term simulations covering the years 2005-2008. Model predictions are compared with data from the European Monitoring and Evaluation Programme (EMEP), the Clean Air Status and Trends Network (CASTNet), the Acid Deposition Monitoring Network in East Asia (EANET)

Keywords: bioaerosols, bacteria, fungi, particle size distribution, indoor working place
Presenting author email: katsivela@chania.teicrete.gr

The aim of the present work was to determine the size distribution of the viable, cultivable, airborne bacteria and fungi, as well as of the inhalable particulate matter emitted from the coarse bubble aerated grit chambers (indoors) as well as from the primary settling tanks (outdoors, partially covered) of a Municipal Wastewater Treatment Plant. Measurements were conducted at a Mediterranean site (Chania) from March to July 2008.

Air samples were taken with an Andersen six stage viable particle impactor (Thermo Electron Corporation, USA). The heterotrophic bacteria were grown in Tryptone Soy Agar at 37°C for 48 h, whereas the mesophilic fungi were cultivated in Malt Extract Agar at 20°C for 72 h. The total coliforms were grown in Membrane Lauryl Sulphate Agar at 37°C for 48 h. Mass and number concentrations of particulate matter (PM) were determined using portable aerosol monitors (Dust-Trak and P-Trak instruments, TSI, Germany). Hydrogen sulfide measurements were performed using a Jerome 631-X sampler (Arizona Instruments, USA).

Table 1 summarizes the arithmetic mean concentrations of all measured parameters in the two stages of the wastewater treatment plant as well as of the control at a background site.

Table 1. Arithmetic mean values of parameters measured.

Parameter	Aerated Grit Chambers	Primary Settling Tank	Urban Background (control)
Sum Heterotrophic bacteria	3,145 cfu/m^3	36 cfu/m^3	89 cfu/m^3
Sum Mesophylic fungi	204 cfu/m^3	70 cfu/m^3	318 cfu/m^3
Sum Total coliforms	29 cfu/m^3	0 cfu/m^3	0 cfu/m^3-
PM_{10}	136 μg/m^3	38 μg/m^3	39 μg/m^3
$PM_{2.5}$	76 μg/m^3	28 μg/m^3	26 μg/m^3
PM_1	62 μg/m^3	23 μg/m^3	20 μg/m^3
PM_1	160,668 pt/cm^3	5,250 pt/cm^3	4,312 pt/cm^3
H_2S	8,121 ppb	195 ppb	4 ppb
T		23.6 °C	
RH		51 %	
υ		8.7 m/s	

A gradual decrease of bioaerosol concentrations was observed during the advanced wastewater treatment from the pretreatment to the primary treatment in agreement with a previous study (Karra and Katsivela, 2007). It is observed that the mean concentration of the airborne heterotrophic bacteria at the aerated grit chambers was 87 times higher than those at the primary settling tanks, and 35 times higher to the values measured at an urban background site. Similarly, the highest concentrations of the total coliforms as well as the mass and particle number concentrations of the inhalable particulate matter (PM_{10}, $PM_{2.5}$, PM_1) as well as the concentration of hydrogen sulfide were observed at the aerated grit chambers of the wastewater pretreatment. Only the mean concentration of mesophilic fungi at the aerated grit chambers had similar values to the background site.

Although, the size distribution profile of the mean concentrations of the airborne heterotrophic bacteria at the primary settling tanks and the urban background site was typical for this taxonomic group (Raisi *et al*, 2012), their profile at the aerated grit chambers was different and showed a maximum aerodynamic diameter concentration at the 3.3-4.7 μm size range (Figure 1).

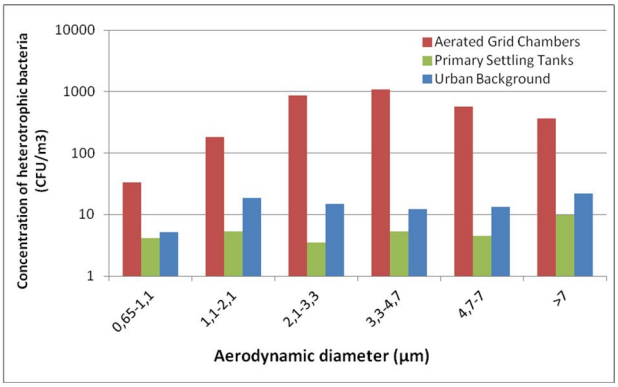

Figure 1. Mean concentration size distribution of viable, cultivable, airborne heterotrophic bacteria during the whole measurement period.

The current study concludes that the advanced wastewater treatment leads to the diminution of health risks associated emissions of potentially pathogenic microbes (heterochthonous heterotrophic bacteria and total coliforms), inhalable particles and hydrogen sulfide.

The research leading to these results has received funding from the European Union Seventh Framework Programme HEXACOMM *FP7/2007-2013* under *grant agreement* n° *315760*.

Comprehensive studies of chemical composition of atmospheric aerosol above Lake Baikal surface area, Russia

T.V. Khodzher

Limnological Institute SB RAS, Irkutsk, 664033, Russia
Keywords: aerosols, Baikal, elements, n-alkanes, PAH
T.V. Khodzher: khodzher@lin.irk.ru

Long-term studies of the chemical composition of aerosols above the surface area of Lake Baikal (53º30' N, 108º0' E) were performed. This lake is one of the world's deepest lakes (1,637 m) which contain 20% of the world's surface fresh water.

Natural aerosol was sampled from the forebody of the research vessel at a height of 6 m above the water surface. Two types of sampling equipment were used – a standard high-volume pump and a six-phase high-volume slit cascade impactor TE-236 (Tisch Environmental Inc.) for particle sampling of the following size fractions – <10.2 μm and 10.2-4.2; 4,2-2.1; 2.1-1.3; 1.3-0.69; 0.69-0.39. "Whatman 41" served as a substrate for mineral particles. Persistent organic pollutants (POPs) were collected onto a fibrous glass filter.

Mean annual total concentration of ions amounted to 1.0-1.3 $\mu m/m^3$ in aerosol particles above the central areas of the lake water surface, which made up 25-30% of the total aerosol.

The majority of aerosols above Lake Baikal were represented by fractions of less than 1 μm, 60% of them being within the range less than 0.7 μm. Bicarbonates, sulphates, calcium and ammonium dominated in their composition. Differences in chemical composition of aerosol particles were mainly attributed to local sources of their origin which were located on the lake shore. Elevated concentrations of components were recorded in aerosol above the southern basin of Lake Baikal in the vicinity of settlements where total ions increased up to 2.0-4.0 $\mu m/m^3$. In the coastal area near the town of Baikalsk, the contribution of sodium and chloride ions was higher due to Baikalsk Pulp and Paper Plant located on the lake shore.

Distribution of microelements was also studied in aerosol particles of different sizes. Coarse-dispersion fraction (over 2 μm) was dominated by typical terrigenous elements (Ca, Mg K, Ti, Fe, Al, and Si). Such elements as Br, Zn and Pb prevailed in the fractions less than 0.7 μm. Some elements (V, Ni and Cu) had two peaks of maximal distribution in coarse (2.1-1.3 μm) and fine (0.69-039 μm) particles. To study remote and regional transfer of components to Lake Baikal (at tens and hundreds of kilometres), element composition of aerosol particles of 0.39-0.69 μm was analysed. Among 20 elements analysed by XRFA-SR, Mn, Ni, Cu, Zn, Ga, Sr, Br, and Pb were the most informative elements.

The concentration of the majority of microelements in aerosol particles above the Baikal surface area corresponded to the clarkes of the Earth's crust. The enrichment factor for such elements as Mn, Ni, Cu, Zn, Ga, Sr, Br, and Pb was by 1-2 orders higher compared to that of the soil. Therefore, there were some other sources for these elements besides terrigenous ones.

Electron microscopic analysis (X-ray spectral microanalysis) showed a high diversity of aerosol particles above the lake. Faceted particles were the most common in Northern Baikal. Particles >1 μm of oval or spherical shapes were registered above all three basins of the lake. The composition of rounded particles together with organic material (~ 80 %) consisted of inclusions of Al, Si, K, Ca, and Mg of terrigenous origin. Faceted particles and aggregations of particles like conglomerates contained C, O, Al, Ca, Si, and Mg. A more diverse range of elements (O, C, Si, K, Fe, Al, S, Ca, Na, and Mg) was recorded in particles of other shapes.

Twelve polycyclic aromatic hydrocarbons (PAH) and n-alkanes were analysed in Baikal aerosol. Maximal PAH concentration was detected in the size fraction less than 0.7 μm. The atmosphere above Southern Baikal contained benz(a)pyrene and chrysene – dominant components of forest fires, and benz(g,h,i)perylene and indeno(1,2,3-c,d)pyrene, indicators of atmospheric pollution by automobile transport. The ratio between PAH concentrations showed that the submicron fraction was represented by "aged" particles existing in the atmosphere for a long time and by aerosol of local origin in the coarse-dispersion fraction. The highest content of n-alkanes was registered in aerosol of Central Baikal where there are natural oil seepages. The dominance of odd homologues from n-C_{23} to n-C_{33} was observed in the fraction of higher homologues which is evident of their natural origin.

The results obtained allow us to conclude that the atmosphere above Lake Baikal remains relatively pure, and the components in it are mainly of natural origin. The southern part of the lake experiences some anthropogenic impact. However, the concentration of contaminants here is rather low.

Airborne Measurements of Emissions from Oil and Gas Exploration and Production Activities in the Norwegian Sea

J. Kim[1], A. Roiger[1] , B. Weinzierl[1], M. Rose[1], A. Reiter[1], J. Thomas[2], L. Marelle[2], K. Law[2], and H. Schlager[1]

Keywords: Arctic pollution, Emissions, Combustion aerosols, In-situ measurements.
Presenting author email: Jin.Kim@dlr.de

Over the past few decades, a rapid decline in Arctic sea ice has been observed. Unlocking of the Arctic Ocean is expected to promote hydrocarbon extraction in the Arctic, which in turn will increase emissions of climate-relevant pollutants such as black carbon (Ødemark *et al*, 2012). Despite the anticipated impact, there are still insufficient in-situ measurements of emissions from oil and gas activities.

In July 2012, an aircraft campaign based in northern Norway was conducted, as a part of the EU ACCESS (Arctic Climate Change Economy and Society) project, to investigate impacts of different pollution sources on the Arctic atmosphere. Among 13 flights performed, the flight on 19 July focused on measuring emissions from various oil/gas platforms, drilling rigs and tankers in the Norwegian Sea.

The DLR research aircraft Falcon was extensively equipped with aerosol instrumentations: Condensation Particle Counters to measure total, non-volatile and nucleation mode particle number concentrations, Optical Particle Counters, Ultra-High Sensitivity Aerosol Spectrometer, Passive Cavity Aerosol Spectrometer Probe and Forward Scattering Spectrometer Probe to measure particle size distributions across a wide range of particle sizes, Particle Soot Absorption Photometer to measure absorption coefficient and Single Particle Soot Photometer to measure black carbon concentrations. Aerosol measurements were complemented by measurements of trace gas (NO_x, SO_2, O_3 and CO) concentrations and meteorological parameters.

Particle size distributions measured within exhaust plumes from all facilities showed large enhancement in the number concentrations for particles < ~150 nm, which is characteristic of combustion emissions. However, different types of facilities emitted plumes with distinct chemical compositions as can be seen in Fig 1 as an example. Plumes from shuttle tanker and condensate storage tanker (*e.g.* Åsgard C in Fig 1) operating on fuel oil were characterised by high SO_2 concentration and high fraction of non-volatile particles (> 45%). Drilling rigs (*e.g.* Deepsea Bergen in Fig 1) were also high emitters of non-volatile particles.

On the other hand, oil/gas platforms (*e.g.* Heidrun in Fig 1), which combust large amounts of fuel gas, emitted low levels of SO_2 and mostly volatile particles with non-volatile particle fractions < 10%. Also, a significant increase in the nucleation mode particle concentration (up to 50% of total particle concentration) was observed which suggests new particle formation in the plumes, possibly due to high levels of co-emitted VOC. Especially high particle concentrations (> 20,000 cm^{-3} but < 2% non-volatile fraction) were measured for a platform which was flaring at the time of the measurement.

In addition to the freshly emitted plumes, relatively aged (1.5 – 2.5 hour old) pollution plumes were also sampled. Even in the aged plumes, total particle concentrations were more than 6 times higher than the background concentration. Therefore, emissions from oil and gas activities are expected to have a significant impact on the local air quality.

The results from this study will be used to improve current emission inventories and to validate regional and global chemical transport models. This will ultimately allow better prediction of future Arctic air pollution and associated warming.

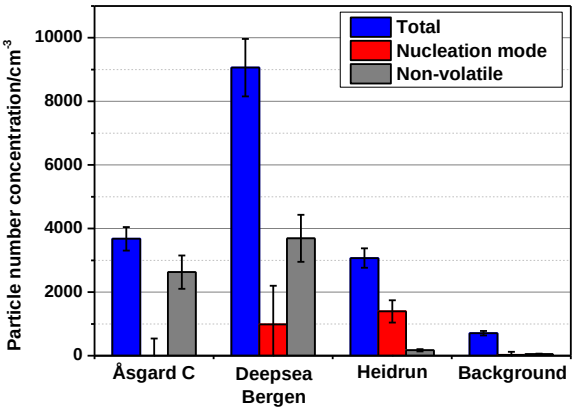

Figure 1. Maximum particle number concentrations measured in the pollution plumes from different oil/gas facilities (*n.b.* plume dilutions have not been taken into account yet). Average background concentrations measured in the marine boundary layer are also shown.

Research flights were funded by the EU project, ACCESS (Arctic Climate Change Economy and Society). The authors would like to thank the DLR flight department, Statoil, scientists and engineers from DLR and LATMOS for their valuable support during the campaign.

Development of Reference Film for Quality Control and Assurance for Beta Attenuation Particulate Matter Measurement

H.H. Kim[1], J.Y. Lee[1] and S. Lee[2]

[1]Center for Analytical Measurement Service, Korea Research Institute of Standards and Science, Daejeon, 305-340, Republic of Korea
[2]Center for Gas Analysis, Korea Research Institute of Standards and Science, Daejeon, 305-340, Republic of Korea
Keywords: particulate matter, beta attenuation, air quality, reference film.
Presenting author email: hhkim@kriss.re.rk

Beta attenuation method is widely used to determine particulate matter mass concentration for air quality monitoring. Results from the beta attenuation method are used to determine whether air quality standards for particulate matter are attained.

Particulate matter mass concentration by the beta attenuation is determined by the equation

$$I = I_0 e^{-\mu x} \quad (1)$$

where I is the measured beta ray intensity with particulate matter, I_0 is the measured beta ray intensity without particulate mater, μ is the mass absorption coefficient (cm^2/mg), x is the areal density of the sampled particulate matter (mg/cm^2).

A reference beta attenuation instrument and film were developed to establish a harmonized method for the quality control and assurance of the beta attenuation method. Multiple particulate matter samples were prepared to measure I, I_0, x and then μ (0.291 ± 0.001 cm^2/mg) was determined by using the equation 1 and linear regression. The estimated mass absorption coefficient was applied to the reference beta attenuation instrument to determine the areal density of reference films. The masses of the reference films were determined by the reference beta attenuation instrument and gravimetric method. Results show that the estimated masses by two independent methods agree well, indicating that the developed reference films are valid. The results from this study illustrate that the reference film can be an effective tool for the quality control and assurance of the beta attenuation for particulate matter mass determination.

This work was supported by Project Measurement Standards and Technology Services from Korea Research Institute of Standards and Science.

Keywords: Soot particles, Absorption, Aerosol impacts, Climate effect.
Presenting author email: niku.kivekas@fmi.fi

Soot consists mainly of light absorbing carbon. When deposited on snow, it decreases the snow albedo, increases the absorption of radiation in snow and thereby enhances melting. This process has been studied for decades (e.g. Clarke and Noone, 1985) and it has been recognized to be one of the major sources of warming in the Arctic regions (Flanner et al., 2007). The link between soot, snow albedo, and climate change is still not known in enough detail for quantitative analysis (Hansen and Nazarenko, 2004). To provide more insight into these connections, the Finnish Meteorological Institute and Helsinki University have started a series of Soot on Snow (SoS) measurement campaigns during years 2011-2013. In these campaigns soot is deposited on snow in the beginning of the melting season and then the properties of the snow pack are measured throughout the whole melting season until the snow is gone (Kivekäs et al., 2012).

The first experiment, SoS-2011 was conducted on a farming field at Nurmijärvi, Southern Finland some 40 km outside Helsinki. The soot was produced by burning rubber and firewood in a portable stove. The smoke was led through a pipe, cooled by snow surrounding the pipe, and led into a garage tent that was built on top of the snow. The smoke drifted out from the other end of the garage tent that was left open. This method produced a clear gradient (in both concentration and particle size) of soot on the snow.

We measured albedo and melting of the snow at the area with most soot and at a reference area with no added soot. After the soot was deposited the albedo of the dirty snow was roughly 0.4 and that of the reference area roughly 0.8. After snowfall the albedos were equal, but 1-2 days the albedo of the dirty snow had decreased to about 0.1 lower than that of the clean snow. The dirty snow also melted earlier than the clean one and the melting rate was faster.

SoS-2012 was conducted on an agricultural field outside the meteorological observatory of Jokioinen in southern Finland, about 100 km from Helsinki. This time we used soot collected by chimney cleaners from residential fire places in eastern parts of Helsinki. The soot was deposited on the snow by blowing it through a cyclone removing particles larger than about 3 μm into a specially manufactured cylindrical tent. This method produced a more uniformly distributed soot layer on the surface of snow. Three spots with different amounts of soot and one reference spot were produced.

This time the results were not so clear. A snowfall with high winds covered the spots with 10 cm of new snow soon after the measurements were started. After that all spots had very similar albedos, and the melting time of the snow depended mostly on the amount of snow in each spot. In later snow sample analysis it was also found that the wind had possibly blown away the top layer of snow, containing the added soot.

SoS-2013 is planned to take place at the old airport of Sodankylä in Northern Finland north from the Arctic Circle. The conditions there represent better those on the Arctic. There is more snow, and the melting of the snow continues further to the spring, making solar radiation a more prominent forcer in melting the snow.

The soot will be deposited similarly to the method in 2012, but with some improvements to be able to produce more homogenous soot spots with better controlled concentrations of soot. This time we will also make some spots with volcanic dust. Our planned time window for depositing the soot is two weeks, allowing us to time the experiment better related to weather. The snow albedo will be measured continuously, and the snow depth daily. Also snow samples will be taken weekly throughout the melting season to understand better how the soot is penetrating through the snow. Results from this experiment are to be analysed before the EAC conference in September 2013.

This work was supported by the Tor and Maj Nessling Foundation and by the Academy of Finland through project A4 (Arctic Absorbing Aerosols and Albedo of Snow, project number 3162). The work is also a part of the Finnish Centre of Excellence in Physics, Chemistry, Biology and Meteorology of Atmospheric Composition and Climate Change (program number 1118615) as well as the Nordic research and innovation initiative CRAICC (Cryosphere-atmosphere interactions in a changing Arctic climate). We also thank Consti Talotekniikka for providing us the soot.

Characterization of particle formation in a spruce forest in north east Bavaria

F. Klein[1,2], A. Held[1]

[1]Atmospheric Chemistry research group, University of Bayreuth, Bayreuth, 95445, Germany
[2]Laboratory of Atmospheric Chemistry, Paul Scherrer Institute, 5232 Villigen, Switzerland
Keywords: NAIS, nucleation, H2SO4, spruce
Presenting author email: felix.klein@psi.ch

Particle formation is happening all over the world (Kulmala et al., 2007) and influences human health and the global climate. However the processes leading to particle formation are not sufficiently understood until today. The formation and growth rate are essential parameters for the characterization of particle formation events (Kulmala et al., 2012). We tried to characterize particle formation and searched for connections between meteorological parameters and particle formation events.

We conducted particle and meteorological measurements during the summer 2012 in a spruce forest in north east Bavaria to increase the knowledge of particle formation events. For the particle measurements we used a scanning mobility particle spectrometer and a neutral cluster and air ion spectrometer which allows to measure particles down to a diameter of about 2 nm. The data of both instruments was used to generate a combined particle distribution for the calculation of nucleation and growth rates. We estimated the condensation and coagulation sink and parametrized sulphuric acid concentrations from measured sulphur dioxide concentrations and parametrized hydroxide radical concentrations.

We identified 18 event days which could be divided into three classes by their nucleation and growth behaviour. We also used 8 non event days without a rise in ultra fine particle concentration for comparison with the meteorological parameters. The overall growth rates were between 0 and 5.5 nmh^{-1}, the nucleation rates mostly under 10 $cm^{-3}s^{-1}$. We observed the highest relative humidity on non event days which is in good agreement with observations made by Boy and Kulmala (2002) who proposed that low water concentrations in the atmosphere favour nucleation events. Drops of the precursor sulphur dioxide concentration often during changes of wind direction or a decrease of radiation due to clouds often led to an interruption of the particle formation events. Correlations between air temperature and growth indicate an influence of oxidation products of volatile organic compounds (VOC) on particle growth. Particle formation occurred mainly on days with easterly winds. One reason for this finding could be wast forested areas in the east of the research area providing large amounts of precursor VOCs needed for the growth of the particles. Furthermore, rise of sulphur dioxide concentrations, a precursor for sulphuric acid, was often connected to easterly winds. The results of the correlation between sulphuric acid concentrations and nucleation rates are consistent with the homogenous binary nucleation of two sulphuric acid molecules. There was a clear connection between the rise of sulphuric acid concentrations and the rise of ultra fine particle concentration with a time delay of about 1.5 hours (c.f. Fig.1). In contrast we observed that the influence of sulphuric acid on the growth is under 7 % (c.f. Tab.1).

In summary our study emphasizes the influence of sulphuric acid on the nucleation and hints at the importance of VOC for the further growth of the newly formed clusters.

Table 1: Growth [nm/h] calculated from the geometric mean (observed growth), explained by the condensation of sulphuric acid (explained growth), in per cent on 5 event days

Day	Observed growth	Explained growth	[%]
24.07.	1.5	0.05	3
12.08.	4.6	0.06	1
13.08.	1.2	0.09	7
14.08.	1.8	0.11	6
15.08.	3.4	0.08	2

Keywords: Aerosol formation, Barbeque, Fuel, Grillables
Presenting author email: sebastian.schmitt@uni-bayreuth.de

Barbecueing is conducted in different styles as a recreational activity in many countries around the world even though early studies (Elmenhorst and Dontenwill 1967; Dyremark and Westholm 1994) had shown severe health risks due to particle formation from hazardous substances. Following studies mainly dealt with indoor cooking activities because of the more controllable experimental conditions. This study was conducted outside under realistic winter time conditions in order to test for influences of fuel and grillables on particle formation and their potential health risk.

The experiment was conducted in two separate runs. First, wood, charcoal (loose and briquettes), gas and pine cones have been used as fuel and a mixed beef-pork burger as grillable in order to test for the influence of different fuels. Second, gas was used as a low emission fuel and the grillables were vegetables (with and without oil), pork (lean and fatty), turkey, pork sausages and a mixed beef-pork burger in order to test the influence of different grillables. Temperature was tracked in order to take into account differences caused by different fuels.

Particles in the range of 10 – 750 nm were measured using a stationary Scanning Mobility Particle Sizer (SMPS) with an inlet installed one meter above the grill. Additionally, the grill master was equipped with a portable optical particle spectrometer (OPC; diameter range 0.3 µm to 10 µm, 6 channels) with an inlet of a 30 cm PTFE-tube placed at his breast. During the first run of the experiment particles were additionally collected on a quartz-filter placed next to the SMPS inlet. These filters and samples of the solid fuels and of the meat have been analyzed via temperature-programmed-pyrolysis mass-spectrometry (TPP-MS) to gain information about the composition of the pyrolysed material.

SMPS measurements show the highest particle emissions for pine cones in comparison to the other solid fuels (Fig. 1). Charcoal and briquettes have lower emissions than wood. As gas exhibits the lowest total aerosol emissions it was used as standard fuel for the comparison of various grillables. As indicated by mean PM1/PM10 ratios derived from OPC measurements, gas has the highest fraction of small particles which is supported by SMPS data.

The amount of fat in grillables does not only influence the total emitted aerosol concentration but also impacts the size distribution of the emitted particles. As a general result, our hypothesis that more fatty grillables tend to emit larger particles was confirmed. Nevertheless, most particles have diameters below 200 nm, which cannot be neglected for discussing health risks.

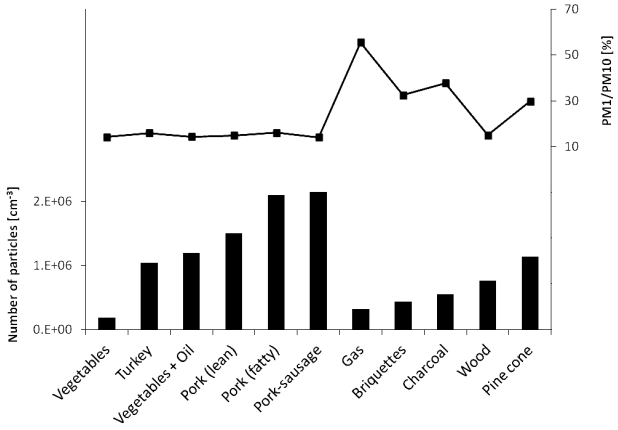

Figure 1. Numbers of emitted particles per cm³ during the main grill process (SMPS), and PM1/PM10 ratio (OPC)

TPP-MS results show that emitted organic aerosols are mainly oxidized, especially for larger molecules in both charcoal and briquettes. Within single measurements the most larger molecules were emitted at a pyrolysis – temperature of 550-600 °C for the solid fuels. The pyrolysed meat did not show this unique pattern. In consequence, aerosol samples are considered a mixture of meat- and fuel-derived particles.

Altogether the described experiments show that total number, size resolution and composition in chemistry differ significantly as a function of both grill fuel and grillables. Fat seems to be a major control for total particle number and dominant particle size.

Photophoretic effects for the black carbon aerosols at stratospheric altitudes

L.B. Kochneva, S.A. Beresnev, V.I. Gryazin, M.V. Vasiljeva, K.G. Gribanov and V.I. Zakharov

Ural Federal University, Ekaterinburg, 620083, Russia
Keywords: fundamental aerosol physics, stratospheric aerosols, photophoresis, soot aerosol
Presenting author email: Louisa.Letfulova@usu.ru

This report continues and summarizes analysis and estimations of the photophoretic effects for soot aerosols in stratosphere. One of possible mechanisms of aerosol transport in the thermally and mechanically stable stratosphere can be radiometric photophoresis as the regular factor of aerosol vertical motion on the synoptic and global temporal scales. It can lead, for example, to the uncontrollable accumulation of soot particles at the certain altitudes in stratosphere from aircraft engines and biomass burning.

At the first stage of studies the estimations of transport opportunities of negative "solar" (motion of particles in the field of short-wave solar radiation against gravity) and positive "thermal" (motion in the field of thermal outgoing radiation) photophoresis of soot particles have been given at the assumptions of the highest possible intensities of atmospheric radiation fluxes. In this report we present updated and expanded calculations of the photophoretic motion characteristics according to the advanced radiation block of the model. Firstly, the results for “solar” photophoretic motion are calculated in the framework of advanced model for short-wave solar radiation (Beresnev *et al*, 2012a). Secondly, the characteristics for “thermal” photophoresis are specified taking into account the downward flux of the long-wave thermal radiation (Beresnev *et al*, 2011).

The results of theoretical analysis of photophoretic motion of soot particles in the short-wave solar radiation field for stationary atmosphere are presented. The integrated fluxes of solar radiation were calculated by the Monte Carlo method with approximation of a plane-parallel, horizontal-homogeneous molecular-aerosol atmosphere. The analysis confirms again an opportunity essential photophoretic effects for soot aerosol particles in stratosphere: the "sun" photophoresis can be considered as the effective mechanism of vertical transport of well-absorbing sub-micrometer particles up to heights of the middle stratosphere. The forces of "sun" photophoresis can compete to gravities up to heights 30-35 km for particles of sub-micrometer and micrometer sizes. On other hand, the estimations have shown again the small efficiency of radiometric photophoresis for weakly-absorbing, dense and high-conducting particles of atmospheric aerosol. The results for photophoretic motion of soot particles in the field of the Earth’ thermal radiation in a stationary atmosphere are also presented. In calculations the up- and down-fluxes of thermal radiation are taken into account. It is shown that positive "thermal" photophoresis potentially can be the effective mechanism of vertical transport for micron-sized soot particles at stratospheric altitudes.

Besides, in this report the theoretical and experimental estimations for so-called “accommodation” (gravito-photophoretic) forces which can compete partly with radiometric photophoretic forces are presented. We discuss, first, the independent development of the consecutive and rigorous gas-kinetic theory of the phenomenon for the free-molecular regime with detailed consideration of gas-surface interaction features and, second, an attempt of the measurement of predicted forces using an experimental technique with model macroparticles for quantitative comparison with the theoretical predictions (Beresnev *et al*, 2012b).

The theoretical estimations show that in the upper troposphere and in the middle stratosphere the “accommodation” (gravito-photophoretic) forces can be comparable with the radiometric photophoretic forces, but do not exceed the gravity force. These conclusions both qualitatively and quantitatively differ from the conclusions of the semi- empirical theory of gravito-photophoresis by Rohatschek (1984).

The measurements with the appropriate model macroparticles in vacuum chamber have confirmed the existence of “accommodation” forces affecting a particle with artificial asymmetry of surface characteristics together with the forces of radiometric photophoresis. The experimental values for the system “steel particle–helium” are in good agreement with theoretical predictions, and the ratio of the “accommodation” force to the photophoretic force does not exceed 3%.

Thus, the action of "accommodation" (gravito-photophoretic) forces, in our opinion, is not capable to provide effective vertical transport of aerosol particles against gravity at stratospheric altitudes.

Particle collection properties of high vegetation elements

R. D. Kouznetsov[1,2], M. A. Sofiev[1]

[1]Finnish Meteorological Institute, PL 503, 00101 Helsinki, Finland
[2]A. M. Obukhov Institute of Atmospheric Physics, Moscow, Russia
Keywords: aerosols, dry deposition, air pollution, mechanistic models, high vegetation
Presenting author email: rostislav.kouznetsov@fmi.fi

A new scheme for dry deposition of atmospheric aerosols onto surfaces is developed by the authors (2012, hereafter KS2012). For rough surfaces it utilizes a similarity between deposition processes for momentum and matter. The scheme considers deposition via three main processes: inertial impaction, interception and Brownian diffusion, controlled by three basic particle properties: inertial relaxation time τ_p, physical size d_p, and Brownian diffusivity D. It was found that there is a parameter a, called "collection scale" that, together with aerodynamic roughness, fully describes surface properties with respect to the deposition processes. The values of this parameter for few surface types including low vegetation were found from published wind-tunnel data. Current study attempts to evaluate the collection scales for high vegetation from three wind-tunnel experiments with vegetation elements.

In the experiments by Beckett et al. (2000), Freer-Smith et al. (2004) and Reinap et al. (2009), branches or small trees were exposed to a flow of particles NaCl particles of size $d_p \sim 1$ μm. The wind speeds U in these experiments were within 1-10 m/s, which is higher than normally observed in natural canopies, but provides some dynamic range to evaluate collection scales. The deposition rates were evaluated as mass fluxes per unit of projected leaf area whereas the concentrations were measured as number densities.

Simple calculations with KS2012 scheme show that main deposition mechanism in the experiments is interception, i.e. capture of particles due to their finite size. The deposition velocity to a rough surface surface due to interception v_{int} is proportional to square of particle size:

$$v_{int} = u_* \cdot 80\,(d_p/a)^2\,\mathrm{Re}_*^{1/2}, \qquad (1)$$

where $\mathrm{Re}_* = u_* a/\nu$ is a collector Reynolds number, ν is the kinematic viscosity of the air, $a = d_c u_*/U_{top}$ is the collection scale, that fully describes the deposition within the canopy layer for diffusion and interception, d_c is a collector size (leaf width or needle diameter) and U_{top} is the wind speed at the canopy top. In the context of KS2012, the scale a can be considered as a surface parameter without its actual connection with actual collector geometry.

To match the experimental data with KS2012 few assumptions have to be made. Firstly, the drag coefficient of canopy elements $C_d = 1$ is assumed, which means that they have poor aerodynamics and shadowing is neglected. Secondly, the ratio $U_{top}/u* = 3$ is assumed. Then a single-element collection efficiency for a canopy element:

$$\eta = \frac{9}{2} \cdot 80\,(d_p/d_c)^2\,\mathrm{Re}^{1/2}, \qquad (2)$$

where $\mathrm{Re}_* = u_* d_c/\nu$. The collector size d_c can be obtained from best fit for each of the plant species (Fig. 1).

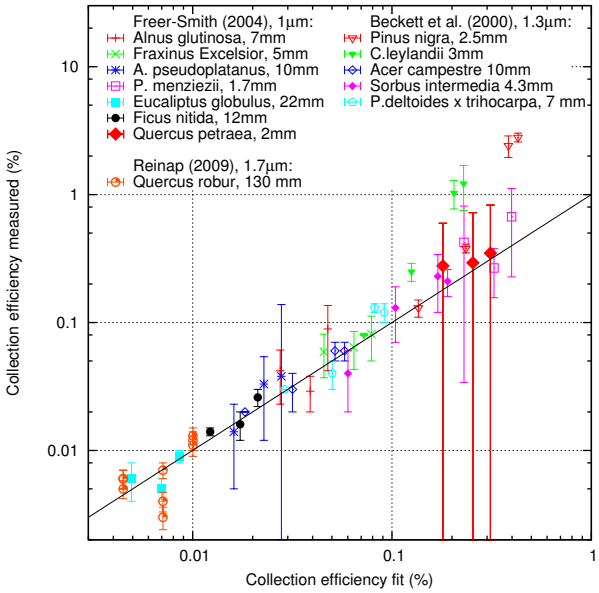

Figure 1: The fitted collection efficiencies for best-fit values of collector size d_c of each species

In general the relation $V_d \propto U^{3/2}$ (1:1 line in the plot) holds well for each species, except for the coniferous species (*Pinus nigra* and *Cupressus leylandii*) at high wind speeds when inertial impaction becomes significant. The collection scales obtained in different experiments appear incomparable for two oak species (*Q. robur* and *Q. petraea*), most probably due to significant effect of coarse tail in particle size distribution. The missing information on actual aerodynamic drag and uncertain coarse tails in particle-size distributions in the experiments prevented more accurate evaluation.

A scheme for particle deposition from turbulent flows above surfaces

R. D. Kouznetsov[1,2], M. A. Sofiev[1]

[1]Finnish Meteorological Institute, PL 503, 00101 Helsinki, Finland
[2]A. M. Obukhov Institute of Atmospheric Physics, Moscow, Russia
Keywords: aerosols, dry deposition, air pollution, mechanistic models
Presenting author email: rostislav.kouznetsov@fmi.fi

A new scheme for dry deposition of atmospheric aerosols is developed by the authors (2012, hereafter KS2012 scheme). Unlike earlier schemes, it is based on physical considerations and contains minimum of empirical parameters. This makes the scheme applicable in atmospheric transport models at various scales. The scheme provides simple relationships that can be tested both in laboratory and in outdoor experiments.

The scheme expresses the deposition velocity V_d – steady-state deposition flux per unit concentration at given height – through the physical properties of a species, flow, and surface. Particles are given by three basic properties: inertial relaxation time τ_p, physical size d_p, and Brownian diffusivity D. These properties can be related to diameter of a spherical particle of a given density at particular air temperature and pressure, however arbitrary particles can be handled as long as their basic properties can be expressed. This approach allows in particular to account for non-spherical particles, particle size growth with humidity, *etc*. The flow is characterized by the turbulent velocity scale at the surface. In case of thermally homogeneous flow this scale is a friction velocity u_*.

The surface properties are given only with two parameters that have clear physical meaning and can be derived from basic surface properties. One of them – aerodynamic roughness length z_0 is used to distinguish between smooth and rough flow regimes. This distinction is based on the roughness Reynolds number $u_* z_0/\nu$, where ν is air viscosity. The expression for the deposition rate onto smooth surface results from the solution of the steady-flux equation with turbophoresis term and has no tuning parameters.

Rough surfaces are characterized by z_0 and newly-introduced "collection scale" which accounts for the effective size of collectors and ratio of the velocity at the roughness top to the friction velocity. The collection scale was found to characterize the deposition with three main processes: inertial impaction, interception and Brownian diffusion, corresponding to the basic particle properties. The expressions for deposition rates are found and verified against the data of wind tunnel measurements and numerical simulations.

The results of the scheme agree well to the available experimental data on particle deposition onto solid and water surfaces at least up to 20 m/s wind speeds. The scheme agrees well with the data of wind tunnel studies of deposition onto low-vegetated and gravel surfaces. The scheme also agrees with wind-tunnel experiments on the deposition to vegetation elements, but no quantitative conclusion can be made due to the experimental uncertainties. The data of outdoor experiments have too much scattering to judge on the performance of the parameterization.

The resulting scheme for chemical transport models is shown in Fig. 1. The deposition fluxes are evaluated at height z_1. Each model grid cell is assumed to have "smooth" and "rough" tiles with corresponding velocity scales. The resulting flux is a weighted sum of fluxes onto tiles. The fluxes for "smooth" tiles are evaluated directly from height z_1. For "rough" tiles the deposition pathway is split into above-canopy- and in-canopy layer. The latter is assumed to start at z_0. $V_d(z_0)$ is calculated as a sum of deposition velocities due to different mechanisms and then the above-canopy layer is accounted with standard Monin-Obukhov profiles for eddy diffusivity and exponential scheme that treats diffusion and regular velocity (settling) consistently, and unlike earlier resistance-based schemes, allows for the concentration evaluation at particular height z_{obz}.

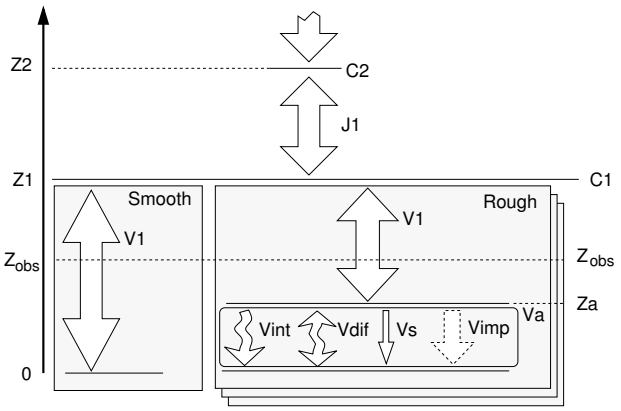

Figure 1: The outline of KS2012 dry deposition scheme

The scheme in a reduced form is implemented into SILAM chemical transport model (http://silam.fmi.fi). The full implementation requires a knowledge of collection scales for various land-use types. Few of them were found from available data of experiments with calibrated aerosols. Unfortunately, such experiments are very few in literature so more experiments for various surfaces are needed (see our poster).

Intermodal fraction of aerosol from indoor and outdoor microenvironments

J. Kozáková[1] and M. Braniš[1]

[1] Institute for Environmental Studies, Faculty of Science, Charles University in Prague, Benátská 2, 128 01, Prague 2, Czech Republic
Keywords: cascade impactor, intermodal fraction, $PM_{2.5-1}$, indoor air quality
Presenting author email: jana.kozakova@gmail.com

Coarse and fine particles overlap in a particle size interval between 1 µm and 2.5 µm (aerodynamic diameter). Since this interval appears between the accumulation and coarse mode it is called intermodal fraction ($PM_{2.5-1}$). Sources of both coarse and fine aerosols contribute to intermodal fraction to a xcertain extent and the contributions of individual sources may vary under different meteorological and/or spatial conditions. According to several studies, intermodal fraction correlates more with coarse aerosol during higher wind velocities and windstorms in arid regions (*Kegler et al., 2010, Claiborn et al., 2011*). In contrast, other studies have shown ambiguous or different results (*Jalava et al., 2006, Geller et al., 2012*). Intermodal fraction has not been so far investigated sufficiently.

Concentrations of size-resolved PM were monitored indoors and outdoors by a low volume (9 litres per minute) Personal Cascade Impactor Sampler (PCIS) with 5 stages A to F (A: 2.5-10 µm; B: 1.0-2.5 µm; C: 0.5-1.0 µm; D: 0.25-0.5 µm; and F-backup <0.25 µm) during various seasons in three different urban and rural locations. Basic meteorological parameters (temperature, relative humidity, wind velocity) were monitored as well. Presence of persons in the buildings was recorded in a diary.

Generally, outdoor and indoor concentrations of $PM_{2.5-1}$ correlated strongly with coarse aerosol.

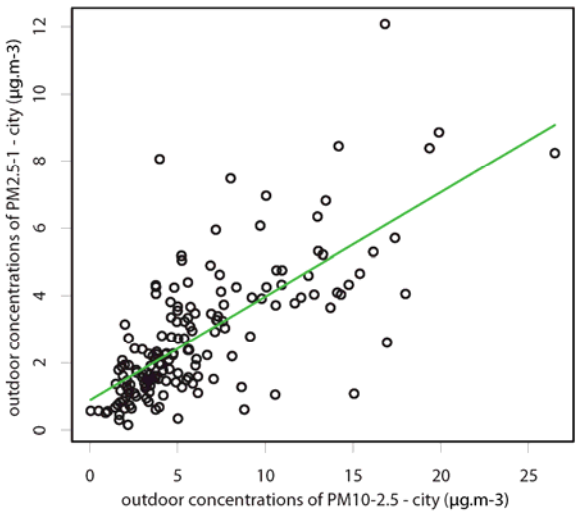

Figure 1. The association between outdoor concentrations of coarse aerosol and PM2.5-1 in Prague.

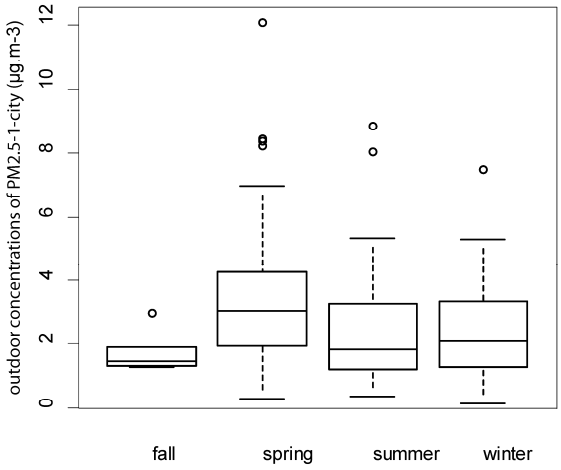

Figure 2. Comparison of outdoor concentrations in different seasons in Prague.

Correlation between the intermodal and fine fraction (PM_1) was also documented, however, it was much lower than the above mentioned coarse-intermodal association. In the indoor environment, the intermodal fraction was also associated with the number of persons present indoors.

ACIDIC REACTION PRODUCTS OF MONO- AND SESQUITERPENES IN ATMOSPHERIC FINE PARTICLES IN BOREAL FOREST IN HYYTIÄLÄ, FINLAND

M.Vestenius[1], H.Hellen[1], J.Levula[2], P.Kuronen[1] and H.Hakola[1]

[1]Finnish Meteorological Institute, P.O.Box 503, 00101 Helsinki, Finland

Keywords: biogenic acids, boreal forest
Presenting author email: mika.vestenius@fmi.fi

A large amount of biogenic VOCs (monoterpenes and sesquiterpenes) is emitted to the atmosphere by vegetation, especially in the densely forested boreal regions (Hakola et al., 2006). In the atmosphere, these compounds are oxidized producing reaction products, which may take part in the formation and growth of new particles (Tunved et al., 2006). Even though organic compounds account for 20-90 % of the total fine particle mass concentration in a wide variety of atmospheric environments (Kanakidou et al., 2005), only little is known about their detailed composition.

For many sesquiterpenes atmospheric lifetimes are so short that their concentrations in the air cannot even be measured. Therefore knowledge about real atmospheric concentrations of the reaction products of terpenes is essential for different kind of aerosol studies. In this study, acidic reaction products of biogenic VOCs, which affect the formation and growth of fine particles, were analyzed from PM 2.5 aerosol samples taken at Hyytiälä, Finland.

Highest concentrations for all studied compounds were measured in summer, except pinonic acid in 2010. (Table 1). Concentrations peaking in summer are most clear for caryophyllic acid. It is known to be emitted from typical boreal trees only in July and August (Hakola et al. 2006). Limonic acid concentrations increased already in spring. Pinonic acid is showing relatively high concentrations also in winter. Pinonic acid is more volatile compared to other acids measured here so that cold winter temperatures may have more effect on it's gas-particle distribution. In summer 2010 concentrations of pinonic and pinic acids were clearly lower than in 2011.

Concentrations of pinonic and pinic acids had relatively good correlation during summer months. This was expected since they have same precursors i.e. they are both reaction products of a- and b-pinene. Average concentrations for pinonic acid were 40% higher than for pinic acid. Ambient monoterpenes pinic and caric acids show clearly the highest concentrations during summer months concomitant with their precursors (Hakola et al., 2012). β-caryophyllinic acid also has highest concentrations in summer, but it's precursor β-caryophyllene cannot be found in ambient air due to it's high reactivity. Limonic acid concentrations increase already in spring even though limonene concentrations are still low.

Table 1. Average concentrations of bio acids during different seasons (summer 2010 - summer 2011).

		Average concentrations (ng m^{-3})					
Bio acid	Precursor	Sum 10	Aut 10	Win 10/11	Spr 11	Sum 11	Aut 11
Pinonic acid	α-pinene	5.7	7.4	9.5	5.8	14.8	8.8
Pinic acid	α-pinene	2.6	4.4	1.5	0.8	10.1	2.0
Caric acid	3-carene	7.0	2.1	2.5	3.5	7.3	4.0
Limonic acid	limonene	1.0	0.9	0.5	1.8	1.7	1.2
β-caryophyllinic acid	β-caryophyllene	3.3	0.8	0.5	0.6	2.8	1.2

Bioacids and their precurosors show a similar trend, α-pinene and its reaction products (pinic acid+pinonic acid) having the highest concentrations and limonene and its reaction product limonic acid the lowest.

Presenting author email: krassovan@gmail.com

The role of the atmosphere in the biogeochemical cycle of phosphorus is generally associated with the emission of soil dust, sea-salt particles, bioaerosols and industrial aerosols Mahowald *et al* (2008). Quite independently, a reduced gaseous phosphorus compound (phosphine, PH_3) was measured over various sources such as marshes and sewage plants Dévai *et al* (1988) and also in the global troposphere. Given that phosphine is a reactive gas that rapidly yields low-volatility phosphoric acid in the atmosphere Frank and Rippen (1987), secondary aerosol formation can be an important sink that has never been considered in the global phosphorus cycle.

In our study we present mass size-distribution measurements of phosphorus in aerosol samples collected at three locations in Hungary. The elemental compositions of the samples were determined by proton induced X-ray emission (PIXE). The evaluation of the X-ray spectra was performed with the PIXEKLM program code. The bimodal size distribution of phosphorus indicated two distinct formation mechanisms in the fine and coarse modes.

As expected, the mass concentration of phosphorus was dominated by the coarse particles (aerodynamic diameter >1 μm) Vicars *et al* (2010), the contribution of fine mode phosphorus was in the range of 10–27 % (median 19 %) of the total. The contribution of biomass burning to the fine mode phosphorus was inferred from measured K concentrations and P/K ratios reported for biomass smoke (Echalar, 1995).

It was found that biomass burning just partly accounted for fine mode phosphorus, the major part of which likely formed as secondary aerosol component from the photooxidation product of gaseous phosphine.

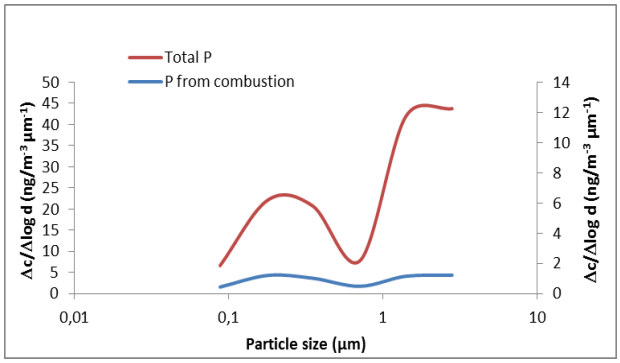

Figure 1. Measured size distribution of phosphorus in rural aerosol collected on 21st of July in 2003.

Secondary aerosol phosphorus can be even more important in providing this essential nutrient for remote ecosystems since it is associated with fine aerosol particles which have longer residence time and thus are more prone to long-range atmospheric transport than coarse primary particles.

Measurement of evaporation rates of atmospheric nanoparticles

N.K. Kumar[1, 2] and S.N. Pandis[1]

[1]Department of Chemical Engineering, Carnegie Mellon University, Pittsburgh, PA 15213, USA
[2]Laboratory of Atmosphric Chemistry, Paul Scherrer Institute (PSI), CH-5232 Villigen PSI, Switzerland
Keywords: organic aerosol, volatility
Presenting author email: niveditk@andrew.cmu.edu

Atmosphereic organic aerosol (OA) is a complex mixture of thousands of individual organic compounds (Hildemann et al., 1991; Fraser et al., 1997, 1998; Goldstein et al., 2008). Large fractions of OA consist of organic compounds that are difficult to separate by gas chromatography (Schauer et al., 1996), and the majority of the OA consists of highly oxidized organic molecules. A critical determinant of whether an organic compound is found in OA (as opposed to the gas phase) is its saturation vapor pressure (often referred to as volatility). An accurate understanding of OA volatility is therefore important to properly predict the chemistry and phase partitioning of both natural and anthropogenic OA species, and to properly interpret OA measurements.

The current study was undertaken to extend the existing database of vapor pressures of semivolatile organic compounds in the atmosphere. The Tandem Differential Mobility Analyzer (TDMA) technique using a long temperature-controlled laminar reactor between the two DMAs was evaluated. The vapor pressure and surface free energy of glutaric acid have been previously measured by Bilde and Pandis (2001). This system was therefore studied to evaluate our experimental system. The saturation mixing ratio of glutaric acid was found to be 9.5 ppb at 303 K using a surface free energy of 0.1 Jm^{-2} and an accomodation coefficient equal to 1. This is in close agreement to the results obtained by Bilde and Pandis (2001) of a saturation mixing ratio of 11.5 ppb.

The other pure component organic aerosols studied were squalane and docosane.The vapor pressure of squalane was measured after flash-vaporizing it in a smog chamber. The saturation mixing ratio of squalane was found to be 0.03 ppb at 323 K. Docosane 100 nm particles evaporated in less than 2 seconds (before reaching the first sampling port of the TDMA) at 306 K. This behavior is consistent with a saturation mixing ratio of more than 6 ppb at 306 K. However, the results obtained at 298 K are inconsistent with this behavior as the measured saturation mixing ratio was 0.2 ppb. A possible explanation is that docosane particles existed as liquid at higher temperatures and solid at lower temperatures in our experiments. When the docosane particles are injected into the chamber by flash vaporization they exist in the liquid state and do not form solid particles until they reach temperatures below their melting point. Therefore they could be present as supercooled drops at 306 K and solid particles at 298 K.

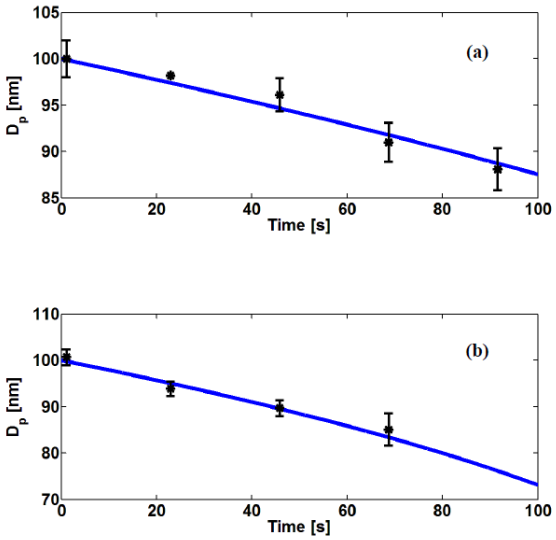

Figure 1. Measured (symbols) and predicted (line) diameters of squalane particles as a function of their evaporation time at (a) 313 K and (b) 323 K.

Organic compounds in PM2.5 aerosol in Ostrava (Czech Republic)

P. Mikuška, K. Křůmal and Z. Večeřa

Institute of Analytical Chemistry of the ASCR, v.v.i., Veveří 97, 602 00 Brno, Czech Republic
Keywords: organic tracer, urban aerosol.
Presenting author email: krumal@iach.cz

Atmospheric particulate matter (PM) is known to play an important role in many environmental problems. During last years much attention has been paid to the identification of emission sources of PM. To track the contributions of the main sources to composition of atmospheric aerosols, various source-specific organic and inorganic tracers are analysed in collected PM (Křůmal *et al.*, 2010; Křůmal *et al.*, 2013).

Atmospheric aerosols in the size fraction PM2.5 were sampled over 24-h periods using the high-volume sampler (DHA-80, Digitel, 30 m^3/h) on quartz filters during winter period of 2012 (26. 1. – 20. 2.) in industrial city Ostrava.

Collected aerosols were analysed for monosaccharide anhydrides (MAs), resin acids (RAs), methoxyphenols (MPs), monosaccharides (MSs), disaccharides (DSs), sugar alcohols (SAs), alkanes, hopanes/steranes (H/S) and polyaromatic hydrocarbons (PAHs). Analysis of MAs, RAs, MPs, MSs, DSs and SAs includes extraction of parts of filters with mixture dichloromethane/methanol (1:1 v/v) under ultrasonic agitation, derivatization of extracts with mixture of MSTFA/TMCS, dryness, redissolution in hexane and GC-MS analysis. Analysis of alkanes, H/S and PAHs includes extraction of parts of filters with mixture of dichlormethane/hexane (1:1 v/v), fractionation on column with silicagel, dryness to 1 mL and GC-MS analysis.

Analysed compounds include:

- MAs: levoglucosan, mannosan and galactosan.
- RAs: abietic and dehydroabietic acid.
- MPs: vanillic and syringic acid, vanillin and syringol
- MSs: xylose, fructose, galactose and glucose.
- DSs: sucrose and trehalose.
- SAs: arabitol, manitol, sorbitol and inositol.
- Alkanes: C8 – C40.
- H/S: 17*α*(H),21*β*(H)-hopane, 22*RS*-17α(H),21β (H)-homohopane, 17*α*(H),21*β*(H)-norhopane and *ααα* (20*R*)-cholestane.
- PAHs: fluorene, phenanthrene, anthracene, fluoranthene, pyrene, retene, benzo[*a*]anthracene, chrysene, benzo[*b*+*k*]fluoranthene, benzo[*e*]pyrene, benzo[*a*]pyrene, perylene, indeno[1,2,3-*c*,*d*]pyrene, dibenzo[*a*,*h*]anthracene benzo[*g*,*h*,*i*]perylene and picene.

Figure 1 compares the concentrations of PM2.5 aerosol and sum of analysed organic compounds in Ostrava. It is evident that course between the concentrations of PM2.5 and sum of organic compounds is similar. The atmosphere in industrial city Ostrava was very polluted by PM2.5 particles.

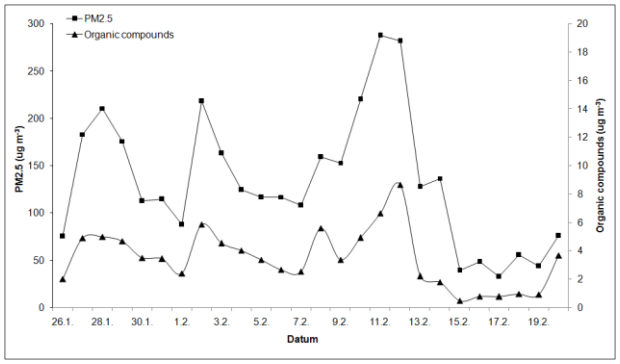

Figure 1. Mass concentrations of PM2.5 (μg.m^{-3}) and sum of analysed organic compounds (μg.m^{-3}) in Ostrava.

Detailed results including comparison of analysed organic compounds in winter in Ostrava will be presented.

Presenting author email: juha.kangasluoma@helsinki.fi

Atmospheric particle nucleation is an important environmental nano-scale process, with climate models indicating that nearly half of the global cloud condensation nuclei (CCN) may be formed from freshly nucleated particles. However, our understanding of atmospheric nucleation and its influence on climate is limited since few direct measurements have been made of either the nucleation rate or the chemical composition of the freshly formed clusters, both of which are necessary to constrain the mechanism and develop a nucleation model. In our study, we have developed an instrument to infer the size-resolved composition of freshly formed atmospheric particles, addressing a key knowledge gap in the composition of nucleated aerosol below 3 nm. This size-resolved condensation particle counter battery (SR-CPCb), is an extension of the CPCb concept [1] developed and used to infer the composition of nucleation mode particles between 2 and 9 nm [2]. In the SR-CPCb, the CPCb measurement principle has been extended down to 1 nm by combining a conventional nanoparticle mobility classifier with a CPCb composed of CPCs designed for the detection of sub 2 nm aerosol [3-7]. By sampling mobility-classified particles, the size resolved CPCb (SR-CPCb) eliminates the strong dependence of CPC response on particle size and charge below 2 nm [4-10]. Therefore, any measured differences in CPC response are then attributed solely to composition-specific interactions between the particle and the various working fluids.

The SR-CPCb is composed of a nanoparticle mobility spectrometer that has been optimized for the sampling and mobility classification of sub 3 nm particles [9]. The particle detector is composed of a CPCb containing the following CPCs with their accompanying working fluids: a Particle Size Magnifier [3] (diethylene glycol), a DEG-UCPC [5] (diethylene glycol), a TSI 3786 UCPC (water), a TSI 3025A UCPC [5] (butanol), and a pulse height UCPC [6] (butanol). The experimental schematic for determining the size, charge, and composition dependent particle detection efficiencies of the CPCb is described in [10]. The following methods were used to generate challenge aerosols for the characterization of the CPCb: (1) electrospray generation of molecular ion mobility standards, (2) evaporation of solid sodium chloride via tube furnace, (3) evaporation of ammonium sulfate via tube furnace, (4) tungsten oxide formation via a wire generator, and (5) candle aerosol generation. Presented results will include the particle composition dependent response of the SR-CPCb and size-dependent transmission efficiencies associated with the nanoparticle mobility spectrometer.

Presenting author email: kubelova@icpf.cas.cz

In this work we investigated rapid changes in chemical composition of fine particulate matter during the celebrations of New Year 2013. The measurements were carried out at the urban background site Prague-Suchdol. The compact time-of-flight aerosol mass spectrometer (c-ToF-AMS, Aerodyne), Drewnick *et al* (2005), was used to analyze highly time-resolved samples of non-refractory aerosol components. We focused on four episodes with significantly elevated total aerosol mass concentration. The scrutinized intervals are highlighted in Figure 1. We assume that the increased concentrations are due to: smoke plume from wood burning in Episode 1, fireworks in Episode 2, arrival of another air mass in Episode 3, and an uncategorized source of poly-aromatic hydrocarbons in Episode 4. The highest attention was given to the time interval between midnight and 3 a.m. on the New Year (marked in Figure 1 as Episode 2) as the aerosol composition was significantly affected by the occurring annual celebrations. In this period, the most significant increase in mass concentration was observed by sulfate, chlorides, and potassium (involved in the mass spectra for fragment 39). At the same time, nitrate and ammonium were unaffected. Those trends were compared to other measurements with c-ToF-AMS during annual celebrations, Drewnick *et al* (2006).

Available meteorological data from a nearby measuring site were taken into account for explanation of the observed trends.

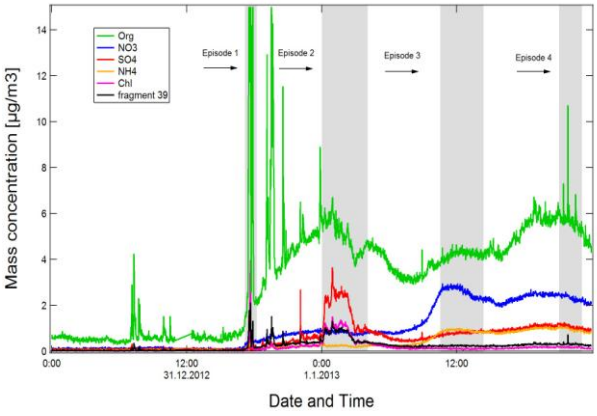

Figure 1. Time course of mass concentrations for various species determined by the c-ToF-AMS. Values over 15 µg are not shown.

Figure 2 shows mass size distributions for the whole period investigated and for the four selected episodes. Similar analyses were carried on for particular species. It is clearly seen that during the first event the particle size distribution was markedly shifted towards smaller sizes. It can be hypothesized that the source of these particles was in close vicinity to the measurement site.

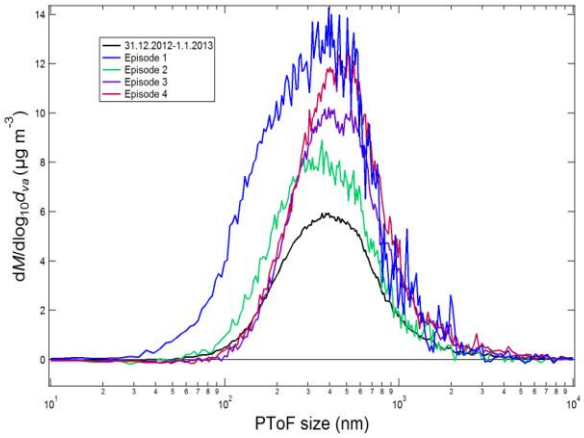

Figure 2. Average mass size distributions measured by c-ToF-AMS for the whole measurement period and for the selected episodes.

Generally, the analysis illustrates the possibilities and advantages of such highly time- and size-resolved measurement of the aerosol chemical composition. It is possible to characterize the individual events thoroughly when a shorter time period is taken into account. Nevertheless, it is necessary to pay attention to correct evaluation of such short events during data analysis.

Presenting author email: agnieszka.kupc@univie.ac.at

Knowledge of the mechanisms leading to atmospheric new particle formation and growth is of significant importance to the understanding of climate relevant aerosol radiative forcing. New particle formation (NPF) can be characterized by means of formation and growth rates (Kulmala, 2003). These parameters are usually determined using condensation particle counters (CPC) for measuring particle number concentration and scanning mobility particle sizers (SMPS) for measuring the size distribution.

At the moment, however, the main obstacles in aerosol research are related to detection limits and time-resolution of instrumentation for characterizing nanometer-sized particles (nanoparticles). Since nanoparticles may grow fast, high time-resolution instruments are required to precisely follow these processes.

A new measurement technique proposed by Winkler *et al.*, (2013), the DMA Train, provides precise and rapid measurements of the size distribution of growing nanoparticles. The DMA Train (Figure 1) consists of a set of differential mobility analysers (DMAs), each set to select particles of a specific mobility diameter. Size-selected particles from each DMA are subsequently counted by a dedicated CPC placed downstream. The DMA Train provides an alternative way of studying the dynamics of NPF by offering measurements of particle size distributions at high time-resolution (1 sec.).

In recent chamber experiments (Winkler *et al.*, 2013), the DMA Train was shown to provide definite growth rates even at low size-selected particle number concentrations. While the laboratory experiments describe measurements in well-defined and controlled conditions, it is important to confirm whether (1) the same behaviour can be observed in real atmospheric conditions and (2) the DMA Train measurement technique is suitable to be used in field studies. Thus, the DMA Train was deployed at a field site in Lewes, Delaware in August 2012 to perform size-resolved measurements of growth and formation rates for a particle size range between 3 and 10 nm.

The DMA Train at the Lewes Field Campaign measurement site utilized a parallel arrangement of four CPCs: a di-ethylene-glycol-based CPC (DEG-CPC; Iida *et al.*, 2009) and three butanol-based ultrafine CPCs (UCPCs, TSI 3025; Stolzenburg and McMurry, 1991) each coupled to a nano-DMA (TSI 3085) and a Po^{210} radioactive source (Figure 1). Further, each DMA was set at a fixed voltage and sample flow (1.5 L/min) for measuring ambient particle number concentration in a narrow range of mobility diameters. For this study the sampled mobility diameters were 3, 6, 8 and 10 nm.

Results from the Lewes field study, obtained using the DMA Train, will be presented and compared to data provided by the Particle Size Distribution (PSD) instrument.

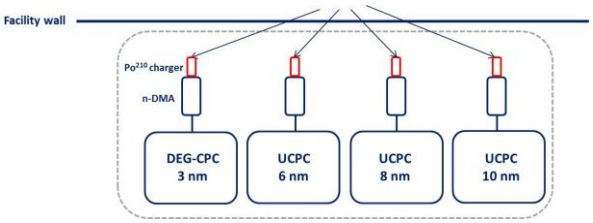

Figure 1. Schematic of experimental set-up includes DEG-CPC and three UCPC set to diameters of 3, 6, 8 and 10 nm respectively.

The Arctic aerosol has been studied since the early 1970s, but there are few available long-term datasets of the particulate chemical composition. There have been significant changes in the Arctic in the past half century. Long-term trends in aerosol chemical composition, specifically sulfate and black carbon, can provide a better understanding of the changes in these climatic forcing particles that have occurred. Changes in anthropogenic and natural sources can also be determined.

Week-long historical filter samples collected at Kevo, Finland from 1964 to 2010 have been analyzed for various chemical species. Major ions and methane sulfonate (MSA) have been analyzed by ion chromatography (IC), trace elements by inductively coupled plasma - mass spectrometry (ICP-MS), and BC by light transmission. Positive Matrix Factorization (PMF) and Potential Source Contribution Function (PSCF) analysis will be applied to the 47-year data set to determine possible source areas.

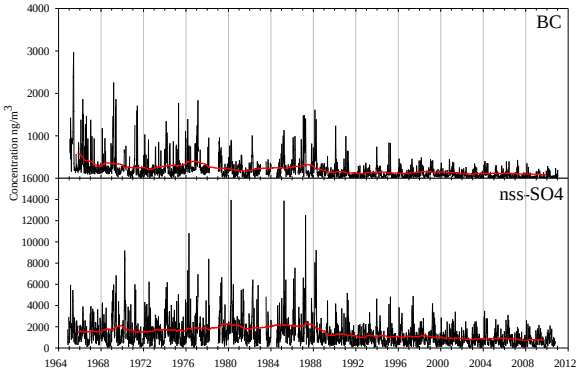

Figure 1. Black carbon and non-sea salt sulphate time series with 1-year moving average.

Time-series trend analysis will be performed to evaluate the evolution of sources over time. Black carbon and nss-SO_4 concentrations have decreased over the past five decades, most dramatically around 1990 coinciding with the fall of the Soviet Union (Figure 1). This decrease matches global inventories of anthropogenic emissions (Bond, 2007; Smith, 2011). Concentrations of lead have steadily decreased as a result of bans and regulations on the use of leaded gasoline.

Forest and agricultural fires have recently been shown to be a major source of Arctic BC during the spring/summer (Stohl, 2007; Warneke, 2010). It has been predicted that climate change has increased forest fires in central Canada and Russia (Stocks 1998). This prediction will be assessed and source areas of forest fires will be determined (Figure 2).

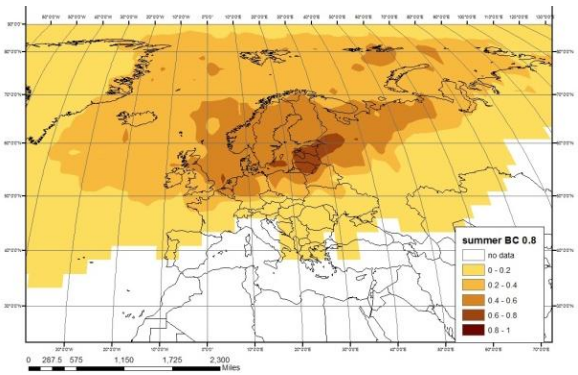

Figure 2. PSCF plot of BC during summer months.

In the northern hemisphere 7.5% of total sulfur emissions are from oceanic sources and for arctic regions (65° to 80°N) oceanic sulfur emissions constitute 42% of total emissions (Bates, 1992). MSA (Methane Sulfonate) is a unique sulfate that can be used as a marker for these biogenic oceanic sources. Marine planktonic algae excrete DMS (dimethylsulfide) which is transported to the air and oxidized to MSA (methane sulfonate) as well as nss-sulfate (Bates, 1992).

Week-long historical filter samples collected at Kevo, Finland from 1964-2010 have been analyzed for methane sulfonate (MSA) as well as various other species.

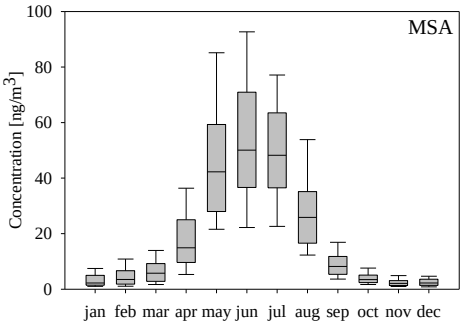

Figure 1. Seasonality of MSA concentrations.

MSA has a distinct summer maximum during the months of May, June and July associated with warmer waters and increased primary productivity in the surrounding oceans (Figure 1).

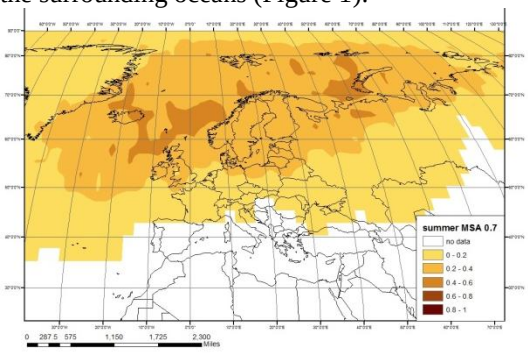

Figure 2. PSCF plot for MSA during summer months.

PSCF (potential source contribution function) results using HYSPLIT 5-day back-trajectories show for MSA in the summer show source areas primarily in the Norwegian and Barents Seas (Figure 2). Sea surface temperatures in the northern hemisphere have risen since the early 1970s, most dramatically in the North Atlantic (Thompson, 2010). Using the HadSST2 Dataset (Rayner, 2006), a significant correlation was found between average yearly MSA concentrations for the months of peak concentration (May, June, and July) and yearly SST anomalies in the region from 30W to 80E and 40N to 90N (Figure 3).

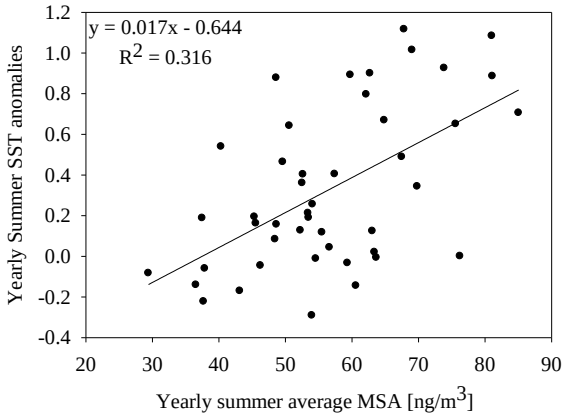

Figure 3. Yearly average summer (may, june, july) MSA concentrations and sea surface temperature anomalies.

Source apportionment of ten years' aerosol collected at Mt. Lulin in East Asia

C.-T. Lee[1], S.-C. Wu[1], George N.-H. Lin[2] and G.-C. Hong[1]

[1]Graduate Institute of Environmental Engineering, National Central University, Jhong-Li, 32001, Taiwan
[2]Department of Atmospheric Science, National Central University, Jhong-Li, 32001, Taiwan
Keywords: biomass burning aerosol, aerosol chemical composition, long-range transport, source apportionment.
Presenting author email: ctlee@cc.ncu.edu.tw

Biomass burning (BB) in Indochina draws a great attention because its plume spreads in a regional scale to cause significant effects on solar radiation budget in East Asia (Street et al., 2003). Taiwan is located downstream of the prevailing westerly for receiving the air masses transported from BB source area in Indochina.

Atmospheric aerosol has been collected at Mt. Lulin (2,862 m a.s.l.) from 2003 to 2012. Comprehensive aerosol properties were resolved for $PM_{2.5}$ water-soluble ions, carbonaceous content (using the U.S. IMPROVE protocol), water-soluble/insoluble organic carbons (WSOC/WIOC), low-molecular-weight dicarboxylates (C2-C5), and monosaccharide anhydrides. In this study, K^+, NO_3^-, levoglucosan, OC3, and EC1-OP of $PM_{2.5}$ were found enhanced greatly in the transported BB plume than that of Non-BB (NBB). The aforementioned aerosol species are thus used as tracers to represent BB source contributions.

To apportion source contributions of aerosol to Mt. Lulin, a statistical method Positive Matrix Factorization (PMF) (USEPA, 2008) was adopted. Figure 1 shows that six major source types are identified for the air masses transported from BB source region during BB period. When arranged in terms of $PM_{2.5}$ contribution from high to low, these source types are secondary sulfate plus WSOM plus BB (28.7%), BB plus organic matter (OM) plus soil (25.4%), BB plus WSOM (17.6%), secondary aerosol plus dicarboxylates plus BB (12%), WSOM plus BB plus Diesel emissions (10.0%), and secondary aerosol plus sea salt (6.2%).

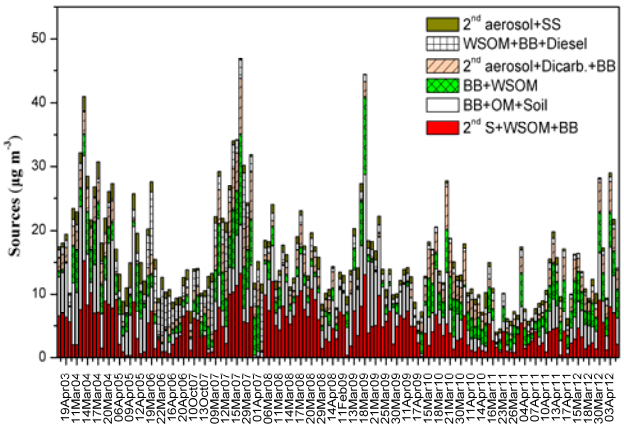

Figure 1. Time series of source contributions to the aerosol collected at Mt. Lulin for the air masses transported from BB source region during BB period.

It is noted that 93.8% of $PM_{2.5}$ mass concentration is contributed from BB source region during BB period. This confirms the consistency between PMF source apportionment and trajectory classification for the transported BB aerosol. It also implies that BB plume was mixed with other air masses during its transport before reaching the downstream Mt. Lulin site.

In contrast, WSOM, secondary sulfate, and OM contributed more than other sources to $PM_{2.5}$ during NBB period. The air masses were mostly originated from ocean (including Pacific Ocean and South China Sea) except for some mixing with marine and anthropogenic primary pollutants transported from the coastline of China mainland to the Mt. Lulin site.

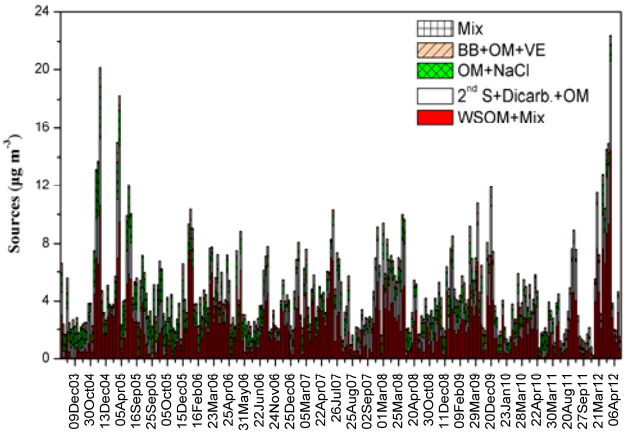

Figure 2. Time series of source contributions to the aerosol collected at Mt. Lulin for the air masses transported from non-BB source region.

In summary, ten years' aerosol data collected at Mt. Lulin shows that the air masses in the free atmosphere are enriched with organic aerosol. Meanwhile, aerosol source apportionment indicates that BB plume could mix with other minor sources during long-range transport and NBB air masses mainly contain secondary aerosol.

On the potential of volcanic ash and powder sample investigation with FIB/SEM EBSD-EDS

K.I. Lieke[1,2] and H. Alimadadi[1]

[1]Center for Electron Nanoscopy, Technical University of Denmark, 2800 Kgs. Lyngby, Denmark
[2] National Research Center for the Working Environment, 2100 Copenhagen, Denmark
Keywords: EBSD, FIB/SEM, volcanic ash.
Presenting author email: KirstenLieke@gmx.de

We present a method for sample preparation of single particles and powder samples for characterization with microscopic techniques, i.e. focused ion beam (FIB), electron backscatter diffraction (EBSD) and energy dispersive X-ray fluorescence (EDS).

In terms of analytical and preparation methods, particulate matter are non-ideal samples. Particles have rough surfaces and may consist of multiple mineral phases and glasses. These phases may have different hardness and densities. Furthermore, charging may occur depending on the conductivity of the material. All of these can potentially impede proper microscopic data acquisitions. In case of EBSD, due to the 60° - 80° tilting which is normally applied, the prepared surface should be as flat as possible, otherwise backscatter electrons are shadowed and do not reach the detector. EDS measurement may also suffer from irregular surfaces due to shadowing as well as deflection of the electron beam or outgoing X-rays. Because of different sputtering rate of different phases, ion milling may be far from optimal for multiphase materials and re-deposition of milled material can be an issue on irregular surfaces.

Determination of the chemical and mineralogical composition of volcanic ash is crucial for estimating their hardness, density and melting points, which are needed to calculate radiative properties (optical properties for detection and recognition, climate effects) their transport trajectories (plume development and atmospheric live time) and harm to aircrafts (sand blasting effect to aircraft windows and engine failure by plugging of engine parts).

To determine the mineral content in single particles or grains, bulk methods such X-ray powder diffraction fail, since large diffracting volume is needed. In contrast, EBSD combined with EDS provides crystallographic and chemical information on a sub-micrometer scale. By simultaneous utilization of the two techniques, phase boundaries and grain boundaries can be confidently determined. Hence, the surface area fraction of mineral grains can be estimated. In addition, by acquisition of maps from various cross-sections, i.e. improving the statistics, a volumetric estimations of mineral and glass content of the bulk can be obtained.

Transported volcanic ash particles are large (2-50 µm e.g. Schumann et al. 2011), they are non-conductive in large parts and the matrix is supposedly glassy (Lieke et al. 2013), they have rough surfaces and their mineral composition may vary. Hence, they are far from ideal for the mentioned microscopic characterization techniques.

To overcome the mentioned shortcomings, samples were prepared by embedding small amounts of powder in an epoxy blended with colloidal graphite and silver particles. The blend is designed for satisfactory conductivity, stability under electron beam and for mechanical milling. Careful evacuation is applied to make the embedding material porosity-free. The dried mixture was cut, grinded and polished under angles of 45 and 54 degrees, to enable mounting the sample in ion milling (52°) and EBSD (70°) positions. Ion milling can optionally be applied for further sample preparation or for extension of analysis in the third dimension. Silver paint was used to glow the samples to a holder. Coating (gold or copper) was applied before the last polishing step (0.05 µm), to remain conductivity over gaps, holes and cavities that may have formed during grinding.

The preparation method was successful for data acquisition in a Helios Nanolab 600 DualBeam instrument (FEI, Eindhoven, The Netherlands) equipped with EDAX (Mahwah, IL, USA) EDS and EBSD detectors.

Identified phases embedded in glassy matrix were Rutile and Plagioclase, whereas Olivine was identified as single grains.

In the present work, the microscopic characterization of particles is shown on the example of volcanic ash particles from the recent Eyjafjalla eruption on Iceland, collected upon deposition in the vicinity of the volcano. That opens future perspectives for the investigation of other challenging particulate samples.

The particle samples were kindly provided by Andreas Vogel, FH Düsseldorf, Germany. We gratefully acknowledge an inspiring working environment at DTU-CEN. Excellent technical assistance, expertise and fruitful discussion were provided by Adam Fuller, Zoltan Imre Balogh and Berit Wenzel.

Keywords: ^{7}Be, cosmogenic radionuclide, atmospheric aerosols, meteorology.
Presenting author email: eliger@uma.es

Cosmogenic particles hitting the atmosphere lead to the production of ^{7}Be ($T_{1/2}$=53.3 days) in the lower stratosphere and upper troposphere. Once ^{7}Be is formed is rapidly associated with submicron aerosol particles and participates in the formation and growth of the accumulation mode (from 0.07 to 2 μm) aerosols, which is a major reservoir of pollutants in the atmosphere (Ioannidou *et al.*, 2011). This naturally occurring radionuclide is a most important isotope in studying atmospheric processes because of its convenient half-life and sufficiently detectable γ-radiation (Eγ = 0.477 MeV), which has served for studying precipitation scavenging, vertical and horizontal removal of air masses, aerosol transit and residence times in the troposphere. ^{7}Be surface air activity shows a strong dependence on altitude, latitude, local climate and seasonal variations.

The aim of the present study is to explain the behaviour of aerosols, associated with ^{7}Be, in the surface atmosphere using exploratory data analysis in order to obtain information on their possible mechanisms of transport and deposition. Long-term variations of the radionuclide concentrations are discussed in relation with precipitation, temperature, temperature interval, relative humidity, solar radiation, pressure, wind and Saharan dust events. Least significant difference test (LSD) and principal component analysis (PCA) with varimax rotation have been applied to study the datasets.

Airborne particulate samples were collected weekly during an 8 years period (January 2005 till December 2012) at Malaga, on the Southeastern coast of Spain, (36° 43′ 40″ N; 4° 28′ 8″ W; 54 m a.s.l). The sampling point is located approximately 5 km away from the coastline and the local sources of anthropogenic aerosols are limited to emissions from cars. Due to its geographical vicinity with the African continent, our study area is frequently affected by intrusions of Saharan air. The Sahara desert is one of the principal sources of natural dust in the northern hemisphere.

Aerosol particles were continuously collected in cellulose filter with 0.8-μm pore size. Gamma measurements were performed with a coaxial-type germanium detector. A total of 96 samples of aerosols were analyzed and ^{7}Be specific activity was determined. The meteorological parameters studied during the sampling period were provided by the Spanish National Institute of Meteorology (AEMET). Data for the number of days with high probability of episodes of Saharan intrusions have been obtained from the CALIMA project which is the result of Commendation of Management Agreement between the Ministry of Environment and Rural and Marine Affairs (MARM) and the State Agency National Research Council.

The mean specific activity of ^{7}Be in near-surface air measured over the 8-year studied period was 4.28 ±1.88 mBq m^{-3}, with a minimum of 0.34 mBq m^{-3} and a maximum of 14.9 mBq m^{-3}. Concentrations show seasonal variations with values above the annual mean occurring mainly in the spring and summer months of each year. LSD test was applied to find which months differed significantly in order to put the samples into homogeneous groups.

The activity concentrations of ^{7}Be have a significant positive relationship with Saharan dust events (r=0.519), temperature (r=0.44) and solar radiation (r=0.399). On the contrary, a negative correlation was observed with the amount of precipitation (r= -0.33) and relative humidity (r=-0.31). In the period January–June transport of Saharan dust toward Spain is mainly due to the cyclonic activities over the West or South of Portugal, while in the summer this transport is governed by the anti-cyclonic activities over the East or Southeast of Iberian Peninsula (Rodríguez *et al.*, 2001).

The results of the PCA analysis showed that the monthly behaviour of ^{7}Be aerosols in our sampling coastal site was represented by three groups which explain 71.55% of total variance. The first principal component explained 42.45% of the total variance of the dataset and it was positively correlated with ^{7}Be, Sahara dust events, temperature and radiation and negatively with relative humidity and precipitation.

Airborne measurements of ship emissions

H. Lihavainen, E. Asmi, J.-P. Jalkanen, A. Hyvärinen, T. Laurila, J. Walden and R. Hillamo

Finnish Meteorological Institute, Helsinki, FI-00101, Finland
Keywords: ship emissions, health, climate, aerosol
Presenting author email: heikki.lihavainen@fmi.fi

Baltic Sea and North Sea, including the English Channel, were designated as SOx Emisson Control Areas (SECA) in May 2006 and November 2007 by the International Maritime Organization. In these sea regions the maximum sulphur content of marine fuels was restricted to 1.5% (weight/weight) and further reduced to 1.0% from July 2010 in SECA countries. These actions have significantly reduced the ship emitted SOx and sulphur containing fractions of particulate matter thus mitigating some of the detrimental effects to human health. Further, from Jan. 1st, 2010 a requirement for the use of 0.1% of sulphur (0.1%S) fuel in the European port areas became effective. From the beginning of 2015 sulphur is to be removed from marine fuels and only the use of 0.1%S marine gas oil is allowed in SECAs according to the new EU directive (2012/33/EC), whereas shipping globally have to switch to 0.5%S fuel by 2020. There should exist methods how to monitor the fuel sulfur content of the ships. One method is to measure gas phase SO_2 and CO_2 ratio from ship plume.

The analysis of costs and effects of the sulphur reductions have mostly included only the effects on human health, but they can also have impacts on the climate (Lauer *et al*., 2009). Emissions of sulphate aerosol are thought to have significant climate cooling impacts, either directly by scattering incoming solar radiation or indirectly by acting as cloud condensation nuclei and thus modifying cloud albedo. On the other hand, black carbon (BC) aerosol can warm the climate when it absorbs solar radiation in the atmosphere as well as by reducing the surface albedo in snow and ice covered regions, such as the. The emissions of these two aerosol types were recently connected to ship fuel sulphur content and the operational conditions of marine engines (Lack and Corbett, 2012). Current widely available ship emission inventories offer only limited support in assessing the climate impact of international shipping, because they lack the information how and where the ships are run during voyages and port stays. Significant uncertainties can exist in determining the time spent at sea, engine load profiles used, emission factors applied and emissions occurring during port operations.

Recently, Jalkanen *et al.* (2009) introduced the Ship Traffic Emission Assessment Model (STEAM) which uses Automatic Identification System (AIS) and is able to track individual vessels with unprecedented accuracy. However, in order to model the effects of fuel sulphur content, engine load profiles and ship operations accurately, a solid experimental groundwork is needed. Comprehensive studies, especially experimental, on ship emissions are rare (Murphy et al., 2009).

We had two major goals in this study; to test the method to monitor marine fuel sulphur content and to make detailed measurements on aerosol properties to gain better understanding on climate and health effect of ship emitted aerosols now and in the future. We studied ship emission with various flying platforms with different kind of instrumentation. Used platforms were one engine Cessna 172, two engine SHORT SC-7 Skyvan and AS350 helicopter. In Cessna and helicopter had the most simple instrumentation since the instrumentation are run by batteries, whereas Skyvan is prepared to carry heavier loads, like aerosol mass spectrometer. It has also electricity available on board.

With the basic instrumentation gas phase CO_2, CH_4, H_2O and SO_2 and particle number concentration (>4 nm), temperature and humidity was measured. In figure 1 is example from one flight in ship plume with Cessna. It shows that this method could be developed to a standard method to monitor the sulphur content of the ship fuel as well as for detailed studies of chemical, physical and optical properties of ship plumes.

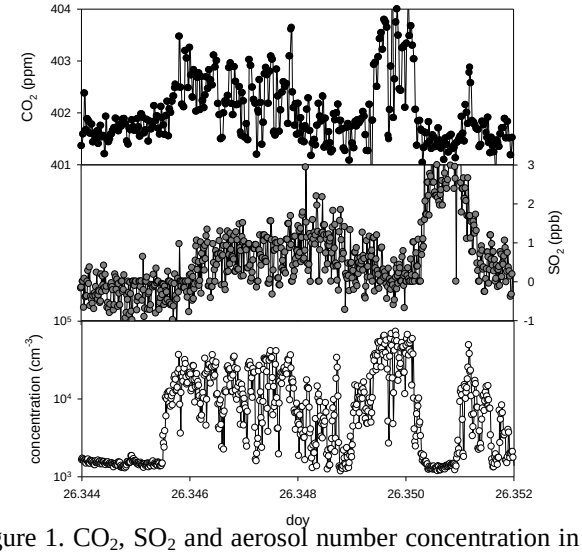

Figure 1. CO_2, SO_2 and aerosol number concentration in ship plume when approaching a vessel.

The work was supported by the European Regional Development Fund, Central Baltic INTERREG IV A Programme (project SNOOP). We would like to thank Airspark Oy, Aalto University Skyvan team and Helitour for flying platforms.

Relationship between the tropospheric aerosol size distribution and cloud droplet effective radius in a rural region of São Paulo State

M. Lima-Souza[1], A. G. Allen[1], L. Caetano-Silva[1] and A. A. Cardoso[1]

[1]Department of Analytical Chemistry, Universidade Estadual Paulista, Araraquara, São Paulo, 14800-900, Brazil
Keywords: Aerosols, size distribution, clouds, SMPS, Aqua, Terra
Presenting author email: michelelsouza@gmail.com

The composition of the aerosol in the lower troposphere of the central region of the Brazilian State of São Paulo is governed mainly by the relative intensities of different anthropogenic sources: sugar cane burning, soil dust resuspension, industrial emissions, and road transport.[1,2] The resulting primary and secondary aerosols are present at concentrations that far exceed natural background levels.

Because of these emissions, the regional aerosol is substantially modified in terms of its chemical composition and its hygroscopic characteristics, and this is expected to affect the processes involved in cloud formation and, consequently, precipitation. The solubility of the particles suggests that they should be able to act efficiently as cloud condensation nuclei (CCN). It is therefore important to understand how different categories of aerosol might influence the processes of cloud formation and precipitation, due to the potential impacts on both agriculture and the water supply.

Size distributed number concentrations of ambient aerosols were measured at a rural site in the municipality of Araraquara, located in the interior of São Paulo State within one of Brazil's most important intensive sugar cane producing regions. Other significant economic activities here include citrus production and the industrial processing of the agricultural products.

The number concentrations of the aerosols were measured as a function of particle size using a TSI Model 3080 electrostatic classifier fitted with a Model 3081 differential mobility analyzer, connected to a condensation particle counter (CPC, TSI Model 3775) and operated in the scanning mobility particle sizer (SMPS) configuration. The size interval of the particles measured was 14.6-661.2 nm, and data were collected continuously, every 10 minutes, between August 2011 and November 2012.

In parallel with the ground-level measurements, the cloud droplet effective radius (r_e) corresponding to clouds present above the sampling site was retrieved from the database of the MODIS (Moderate Resolution Imaging Spectroradiometer) instruments carried on board NASA's Terra and Aqua satellites. The area considered for the satellite data was a rectangle (approximately 47 km x 47 km) described by the geographical coordinates: -21.564S, -48.452W (upper left corner); -22.063S, -47.953W (lower right corner). The satellite overpasses occurred during the periods (UTC): 12:30-14:30 (Terra); 16:00-17:30 (Aqua).

The SMPS data used considered an average of five individual measurements, centered on the time of the satellite overpass. The data were grouped according to both the total number concentration and the type of aerosol size distribution observed, considering the presence of an Aitken mode or an accumulation mode (as well as a number of mixed cases). The existence of an Aitken mode, without any obvious accumulation mode, was considered to reflect the presence of fresh particles, including those derived from recent nucleation, while a single accumulation mode was indicative of the presence of particles that had experienced aging within the atmosphere (Fig. 1).

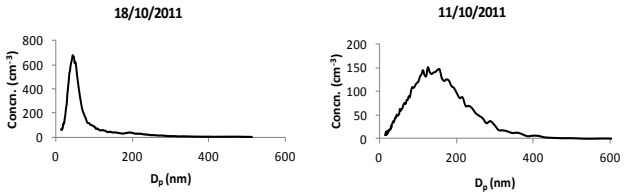

Fig.1. Examples of events characterized by Aitken (left) and accumulation (right) modes in the size distribution.

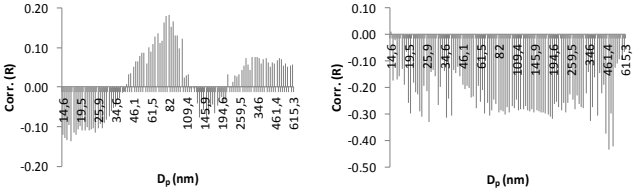

Fig. 2. Correlations obtained between r_e (Aqua data) and the size distributed aerosol number concentration during Aitken mode (left) and accumulation mode (right) events.

During Aitken events, the value of the coefficient (R) for the correlation between r_e and aerosol number concentrations showed a variable relationship as a function of particle size, while during accumulation mode periods, negative values of R were obtained for all size fractions (Fig. 2). The findings suggest that the relationship between tropospheric aerosol loadings and cloud properties in the study region may be more complex than previously thought, since cloud droplet size can show either a positive or a negative relationship with the aerosol number population in the lower troposphere.

Keywords: open burning, water-soluble ions, agricultural waste, size distribution.
Presenting author email: lincc@mail.npust.edu.tw

This study investigates the chemical characteristics of particles that were collected from the open burning of jujube tree branches (agricultural waste), and evaluates the impact of such burning on regional air quality. The atmospheric particulate samples were collected in a jujube farm at Pingtung City in southern Taiwan. The area of jujube farm was 800 m^2 and the weight of jujube tree branch waste was 4.5 T. The sampling time was divided into three periods: before (background), during, and after open burning. During the open burning period, the A, B, C, and D samples were taken from four locations with distances of 1, 7, 11, and 16 m, respectively, away from the open burning site. The particle size distribution was collected using a micro-orifice uniform deposition impactor (MOUDI) and the particulate water-soluble ions in fine (D_p < 2.5 μm) and coarse (2.5 < D_p < 10 μm) particles (or particulate matter (PM)) were collected using a Dichot sampler. The masses and water soluble ions of particles collected on filters were analyzed using a digital balance and an ion chromatographer (IC, DIONEX ICS-3000), respectively.

The results indicate that the $PM_{2.5}$ concentrations at sampling sites A, B, C, and D during open burning were 103, 17.2, 13.5, and 5.59 times the background value, respectively, or on average, 34.9 times the background value. The average $PM_{2.5}/PM_{10}$ ratio at sample sites A during open burning (0.91) was higher than those before (0.62) and after burning (0.52). Also, the concentrations of $PM_{2.5}$ and $PM_{2.5\text{-}10}$ sharply dropped as the distance between the sampling point and the burning source increased. Ryu *et al.* (2007) also found that the average concentrations of fine or coarse particles in the early summer in the rural areas of Korea were higher during biomass burning than during a haze or normal period. In this study, the average $PM_{2.5}/PM_{10}$ ratio during open burning was 0.90, which exceeded that (0.79) obtained in Korea during a season of extensive open burning (Ryu *et al.*, 2007). In this study, before open burning, the particles had a bi-modal size distribution with one main peak in the coarse size range (3.2–5.6 μm) and the other peak in the fine size range (1–1.8 μm); during open burning, the particle size distribution was uni-modal, with a peak in the fine size range (Figure 1).

As shown in Figure 2, before and after jujube fruit branches were burned in the open space, NO_3^- had the highest concentration of all of the water-soluble ions in the particles, followed by SO_4^{2-}, and then NH_4^+. This result is similar to that obtained for particulate matter in the atmosphere. However, the concentrations of particle-bound Cl^- and K^+ rose sharply during open burning. Before burning, the concentration of Cl^- in $PM_{2.5}$ was 1.69 μg m^{-3}. The Cl^- concentrations in $PM_{2.5}$ that was collected at samples sites A, B, C, and D during open burning were 136, 61.8, 57.3, and 18.0 μg m^{-3}, respectively. The highest of these values was 84.5 times the background value. The K^+ concentration of samples that were collected at sites A, B, C, and D were 5–197 times higher than the background value, 0.87 μg m^{-3}. Khalil and Rasmussen (2003) indicated that K and Cl can be used as a tracer of wood smoke.

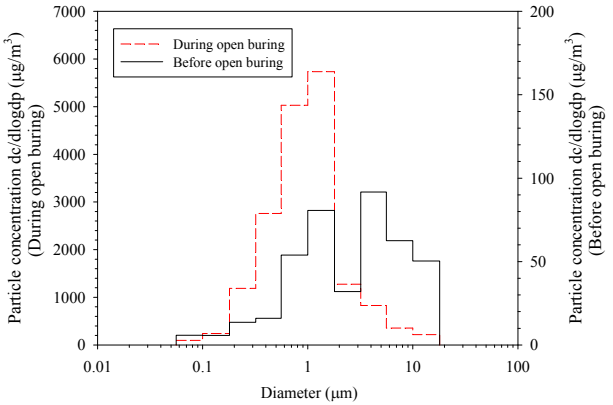

Figure 1. Size distributions of the particles collected before and during open burning.

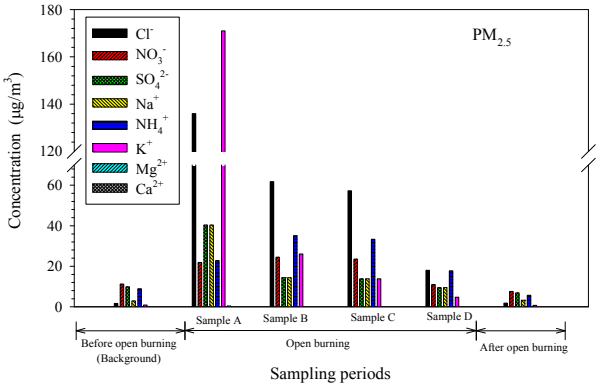

Figure 2. Concentrations of water-soluble ion in fine particles. (Sites A, B, C, and D were 1, 7, 11, and 16 m, respectively, from the open burning site.)

Investigating the Small-Scale Vertical and Horizontal Variability of the Atmospheric Boundary Layer Aerosol using Unmanned Aerial Vehicles

B. Wehner[1], A. Lampert[2], A. Scholtz[2], J. Bange[3], A. Platis[3], and M. Hermann[1]

[1]Leibniz Institute for Tropospheric Research (TROPOS), 04318 Leipzig, Germany
[2]Institute of Aerospace Systems, TU Braunschweig, 38108 Braunschweig, Germany
[3]Universität Tübingen, Center for Applied Geophysics, 72076 Tübingen, Germany
Keywords: new particle formation, UAV, boundary layer aerosol.
Presenting author email: birgit@tropos.de

Introduction

Beside numerous ground based measurements only few aerosol data from higher altitudes taken by airborne instrumentation are available. These data showed a number of interesting phenomena, such as new particle formation often induced by turbulence. However, such data are rare and more continuous aerosol and turbulence measurements in higher altitudes are needed to close this gap.

One approach to realize airborne measurements with low logistical effort compared to aircraft measurements is the application of unmanned aerial vehicles (UAV) for atmospheric studies. The new UAV Carolo P360 “ALADINA” (see Figure 1) equipped with aerosol instrumentation provides a unique and flexible tool for characterizing the vertical and horizontal variability of the boundary layer aerosol. The Carolo P360 with a wingspan of 3.6 m is designed to carry up to 2.5 kg of payload in the front compartment. With electrical propulsion, it has an endurance of about 40 minutes. The cruising speed is 25 m/s.

Figure 1. Picture of the UAV ALADINA.

Instrumentation

For aerosol measurements, ALADINA will be equipped with a set of light-weight instruments. To reach the weight limit of 2.5 kg for the payload, commercially available instruments were chosen and modified in terms of space and weight. Two Condensation Particle Counters, CPCs, (TSI, model 3007, TSI Inc., St. Paul, USA) with different lower cut-offs will be used to measure the total particle number concentration between ~6 nm and 1 μm (N_6) and ~12 nm and 1 μm (N_{12}), respectively. The difference between N_6 and N_{12} will be used as indicator for new particle formation. To reduce weight, housing, internal batteries, and display of the CPCs were removed.

Larger aerosol particles will be measured using an Optical Particle Counter, OPC (Met One, model GT-526, Met One Instruments Inc., Washington, USA). This OPC counts particles in 6 size channels from 0.3 to 5.0 μm. Again, housing, battery, and display were removed.

The aerosol instruments will be characterized and improved in the laboratory with respect to the lower detection diameter and the response time of the CPCs.

Moreover, an additional meteorological payload for measuring the turbulent 3D wind vector, temperature and humidity is constructed by Tübingen University. These sensors and an aerosol inlet will be mounted in front of the UAV.

Electrical power for all three instruments will be provided by a common battery. A measurement and data acquisition system is developed at Tübingen University with the possibility of real-time data transfer by a telemetry downlink. This new UAV system will be flight tested for proper instrument operation while airborne.

Experiment

A first field experiment is planned in September 2013 in Melpitz, the research site of TROPOS. Here, the UAV aerosol and meteorological measurements will be completed by ground-based and helicopter-borne measurements. In addition, Lidar measurements will provide continuous measurements of the vertical structure. The UAV has the potential to close the gap of atmospheric aerosol measurements between long-term ground-based observations and expensive helicopter-borne measurements. Complementary to these measurements, UAV observations allow for investigating the small-scale and short-term aerosol variability in vertical and horizontal direction at low cost and with minimal logistical requirements. Two additional UAV of type MASC of Tübingen University equipped with turbulence instrumentation add the opportunity to study the interaction of the aerosol concentration with turbulent transport and exchange processes of the surface and the atmosphere. The combination of different flight patterns of the three UAV allows new insights in atmospheric boundary layer processes.

The association of children's lung function and air pollution in Kaohsiung, Taiwan

Yeh, CL[1], Mena, KD.[2], Ou, CS[3], and Chen, PS[1*]

[1]Department of Public Health, Kaohsiung Medical University, Kaohsiung, 80708,Taiwan
[2]Department of Public Health, University of Texas Health Science Center, Houston, El Paso, 79902,USA
[3]Graduate Institute of Occupational Safety and Health, Kaohsiung Medical University, Kaohsiung, 80708,Taiwan
Keywords: lung function, air pollution, children.
Presenting author email:protamine1199@yahoo.com.tw

Introduction

Recently, the association between the air pollution and human health has been widely mentioned. Children are more sensitive to air pollution then adult due to their higher metabolism rate and smaller body size. In most of the previous studies, data from air monitoring station were used to evaluate children exposure whereas questionnaire was used to evaluate their health effect. In the present study, we measured children`s lung function and air pollutants including CO, CO_2, NO_2, O_3, PM_1, $PM_{2.5}$, PM_{10}, ultrafine particles, fungal and bacterial bioaerosols in classrooms to evaluate the association between air pollutants and children's lung function.

Materials and Methods

Three elementary schools, reference, industry and traffic school, were selected in Kaohsiung, Taiwan. Twenty classrooms were randomly selected in each elementary school with a total sample size of sixty classrooms. Temperature, relative humidity, CO, CO_2, NO_2 (Airboxx, KD UK), O_3 (Ozone Monitor, Model 202, 2B Technologies, Inc),PM_1,$PM_{2.5}$, PM_{10} (DUSTTRAK™ DRX Aerosol Monitor; Model 8533, TSI USA), ultrafine particles (P-TRAK® Ultrafine Particle Counter ; Model 8525, TSI USA) were monitored in real-time from 8 am to 4 pm between April 2009 and November 2009. We also sampled fungal and bacterial bioaerosols indoor and outdoor of classroom at 8 am and 4 pm (MAS-100, MERCK USA). Tryptic soy agar (TSA) and Malt extract agar (MEA) was used for cultivated of bacteria and fungus, respectively. Lung function was measured for 1026 schoolchildren (HI-801, JAPAN). To investigate the explainability of air pollution for children's lung function, we analyze the air pollution concentration and the abnormal rate of lung function in the same classroom by using multiple regression.

Results and Discussion

The abnormal rate of lung function's parameter was analyzed as the product variables, and the concentrations of air pollutants were analyzed as the explain variables. If combining the data of three schools, ultrafine particles (R^2=10%) and $PM_{2.5}$ (R^2=13.3%) could significantly affect vital capacity (VC)'s abnormal rate. The abnormal rate of VC is defined as (measured VC/predicted VC)*100% below 70%. Ultrafine particles and $PM_{2.5}$ could explain 10%, and 13% of VC's abnormal rate, respectively. For traffic school, ultrafine particles (R^2=13.2%), $PM_{2.5}$ (R^2=19.9%), and O_3 (R^2=19.9%) could significantly explain each R^2= 20% of VC's abnormal rate, respectively. In industry school, the significant factors for VC's abnormal rate were ultrafine particles (R^2=13.1%), indoor fungi (R^2=7.1%), bacteria (R^2=7.5%), and CO (R^2=39.4%). In referece school, ultrafine particles (R^2=12.1%) could significantly affect VC's abnormal rate. Regarding forced expiratory volume (FVC), the significant affecting factors for FVC's abnormal rate were ultrafine particles (R^2=10.92%) and $PM_{2.5}$ (R^2=6.25%). Ultrafine particles, the only significant factor for both industry and traffic school, could explain 12% and 27% of FVC's abnormal rate in traffic and industry school, respectively. In background school, ultrafine (R^2=8.4%), indoor fungi (R^2=6.87%), and CO (R^2=39.4%) were the significant factors.

Table1. The explainability of significant air pollutants for the abnormal rate of children's Vital capacity (VC) by Stepwise model

Traffic	pollutant	Ultrafine	$PM_{2.5}$	O_3	
	partial R^2	13.2%	19.9%	7.0%	
Industry	pollutant	CO	Ultrafine	Bacteria	Fungi
	partial R^2	39.4%	13.1%	7.5%	7.1%
Reference	pollutant	Ultrafine			
	partial R^2	12.1%			
Three schools	pollutant	Ultrafine	$PM_{2.5}$		
	partial R^2	10.0%	13.3%

Seasonal physical and optical properties of atmospheric aerosol at Princess Elisabeth station, East Antarctica

A. Mangold[1], H. De Backer[1], A. Delcloo[1], V. De Bock[1], C. Hermans[2], I. Gorodetskaya[3] and W. Maenhaut[4]

[1]Royal Meteorological Institute of Belgium, Brussels, Belgium; [2]Belgium Institute for Space Aeronomy, Brussels, Belgium; [3]Catholic University of Leuven, Leuven, Belgium; [4]Ghent University, Ghent, Belgium
Keywords: Antarctica, atmospheric aerosol, optical properties, physical properties
Presenting author email: alexander.mangold@meteo.be

Aerosol optical and physical properties have been measured during recent austral summers and winters at the Belgian Antarctic research station Princess Elisabeth, inaugurated in February 2009. Princess Elisabeth station is situated around 180 km inland from the coast, north of the Sør Rondane Mountains in Dronning Maud Land, East Antarctica, on the Utsteinen ridge (71°57'S, 23°20'E, 1390 m asl; Pattyn *et al.*, 2010). The station is manned during austral summer. In winter, the station operates in automatic mode with remote control.

Measured aerosol properties comprise aerosol size distribution (laser aerosol spectrometer, LAS, TSI3340), total aerosol number (condensation particle counter, CPC, TSI3776), total aerosol mass concentration (TEOM-FDMS), mass concentration of light-absorbing aerosol and absorption coefficient (Magee 7-wavelength aethalometer) and total scattering coefficients (Ecotech 3-wavelength nephelometer).

All instruments were in simultaneous operation during summers 2011/12 and 2012/13 and are currently installed for continuous operation, including this austral winter. The aethalometer and TEOM-FDMS have been measuring since December 2010 and also during two winter months in 2011 and six in 2012. The LAS could measure during two winter months in 2012.

Besides these instruments for boundary layer aerosol characterisation, a 8-wavelength sunphotometer, (AErosol RObotic NETwork; aeronet.gsfc.nasa.gov; CIMEL CE318), provides aerosol information like aerosol optical depth (AOD) for the total atmospheric column during austral summer since February 2009.

Since February 2009, there are continuous data of an automatic weather station (Gorodetskaya *et al*., 2013) in order to interpret the meteorological conditions.

The aethalometer is operated at a nominal flow of 5.5 litre/min and an integration time of 60 min. The mean mass concentration of light-absorbing particles in winter 2011 was 6.0±4.7 ng/m^{-3} at 660/880 nm, and 10.5±5.6 ng/m^{-3} at 370/470 nm. The respective values for summer 2011/12 were 7.6±6.1 ng/m^{-3} and 11.6±6.8 ng/m^{-3}. The mean absorption coefficients, calculated using the instrument's cross sections, were 0.10±0.08 Mm^{-1} at 880 nm (soot particles absorb strongest at this wavelength) and 0.43±0.22 Mm^{-1} at 370 nm in winter 2011. The values for summer 2011/12 were 0.13±0.12 Mm^{-1}, and 0.49±0.28 Mm^{-1}, respectively. The mean absorption Angström exponent (370/470 to 660/880/950 nm) was 2.0±1.2 in winter 2011 and 1.8±1.2 in summer 2011/12. The differences between the wavelengths indicate that several absorbing aerosol types were present, as, e.g., pure soot has an absorption Angstrom exponent around 1. The single scattering albedo (SSA) could be derived from simultaneous aethalometer and nephelometer measurements in February 2012 (Table 1). The aethalometer data has been interpolated between wavelengths. SSA values showed high uncertainty, mainly due to low aerosol concentrations and the uncertainties of the absorption coefficient determination. SSA values around 0.9 would have been expected.

Table 1: Optical parameters February 2012:

λ	total scatter Mm^{-1}	absorption Mm^{-1}	single scatt. albedo (= sca/(sca+abs))
425nm	1.07±0.53	0.48±0.23	0.69±0.34
525nm	1.06±0.50	0.35±0.19	0.75±0.35
635nm	0.94±0.61	0.20±0.13	0.82±0.38

The CPC measures particles in the diameter range 3 to 3000 nm. Figure 1a shows data of February 2012. Simultaneous size distribution measurements revealed diurnal cycles in the size range 3–90 nm for 12 and 13 February 2012, indicative of locally formed aerosol.

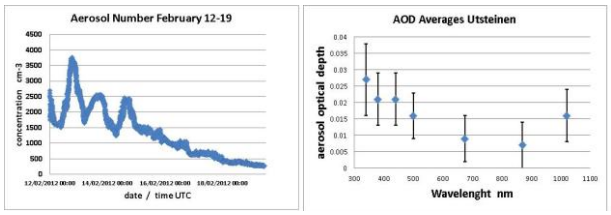

Figure. 1: a) CPC number concentration February 2012; b) total AOD averages February 2009 to February 2013

Figure 1b shows the average AOD values from the sunphotometer for all summer seasons. The average Angström exponent (440–880 nm) was 2.0±0.6, indicating a dominance of sub-micron particles.

We will present further seasonal aerosol properties from austral winters 2011/2012/2013 and respective summers.

$\delta^{13}C$ of size segregated aerosol particles collected in Preila and Baltic Sea

A. Masalaite, A. Garbaras and V. Remeikis
Center for Physical Sciences and Technology, Vilnius, LT-02300, Lithuania
Keywords: size segregated aerosol particles, carbon isotopic ratio
Presenting author email: agne.masalaite@ftmc.lt

Marine aerosol contributes significantly to the global aerosol load and consequently has an important impact on both the Earth's albedo and climate (O'Dowd, 2004).

The aim of this work was to identify size segregated aerosol particles origin using the carbon stable isotopes method.

Experimental

The aerosol samples were collected at the Air pollution research station in Preila (55°55′N, 21°00′E, 5 m above sea level) which is located in western Lithuania on the coast of the Baltic Sea, on the Curonian Spit from 26 November 2012 to 12 January 2013 and in Baltic Sea during the cruise with the R/W "Oceania" on 09 – 17 November 2012. The nearest source of anthropogenic pollution, the Klaipeda city, is at the 50 km distance. Thus, carbonaceous atmospheric aerosols were transported to the Preila site by continental and marine air masses. A Micro-Orifice Uniform Deposition Impactor "MOUDI 110" was used to collect samples in size intervals ranging from 18 μm to 0.056 μm. Aluminium foils of 47mm diameter (pre-fired for 5 h at 600^0C) were used. A total of 7 collections in Preila and 2 collections in Baltic Sea were done. In addition, the low volume PM_1 sampler was used. As the main aim of the study was to identify the origin of incoming carbonaceous aerosols, the HYSPLIT air mass backward trajectory model was used for the analysis of results (Draxler, 2003).

Total carbon isotopic ratios ($\delta^{13}C$) were measured at each stage of MOUDI and at quartz fibre filters of PM_1 using the elemental analyzer (FlashEA 1112) connected to the stable isotope ratio mass spectrometer (ThermoFinnigan Delta Plus Advantage). Simultaneously the carbon amount at each stage was measured using the elemental analyzer with a thermal conductivity detector (Garbaras, 2008). The 1/4th part of the foil/ quartz fibre filter was placed into the tin capsule and combusted in the oxidation furnace at the temperature of 1020º C and with the oxygen excess. Carbon of the sample oxidized into CO_2 gas, which passed to the mass spectrometer ionization cell through the gas distribution device ConFlow III.

Results

During the experiment the aerosol carbon isotopic ratio variation between accumulation and coarse modes in Preila ranged from -24.3 ‰ to -29.3 ‰ and in Baltic Sea from -24.7 ‰ to -28.2 ‰. It implies that in both cases the carbonaceous particles in the same size range were from almost the same sources. The $\delta^{13}C$ values for the aerosol particles PM_1 transported from longer distances depended on the air mass transport directions. Air mass transports during the Preila experiment were few characters. At first it was mainly from West and Southwest - more from the continent (United Kingdom, Germany, Denmark, Belgium, Netherland, Poland, and Russia) in such transport scenario the main source of carbonaceous aerosols in accumulation mode could be transport emissions and coal burning, moreover average of carbon isotopic ratio for accumulation mode was -28.1‰. However after ten days when it was from West and one episode was purely from Russia, Sweden and Norway the average $\delta^{13}C$ = -26.2‰.. The last episode was from South with the average $\delta^{13}C$ = -26.5‰. All these air mass transports changes have a good agreement with aerosol carbon isotopic ratio taking into account influence of coal burning, transport emissions and marine aerosol.

Results from Baltic Sea (Fig.1) demonstrate a good agreement of MOUDI and PM_1.

Keywords: Size distribution, uranium, thorium.
Presenting author email: olivier.masson@irsn.fr

Uranium and thorium-labelled aerosols are emitted by the stack of a UF_4 processing plant. Labelled-aerosols may also come from resuspension of soils particles from the surrounding environment and from areas devoted to the storage of waste. At 1.1 km from the plant stack, a size distribution study of aerosol carriers of the radionuclides of interest was conducted. This was performed during two distinct periods: one when the facility shut down for servicing (no atmospheric release) and the other when the facility was in operation. These trials were conducted using simultaneously six High Volume Impactors (HVI, Tisch TE-235) having 5+1 stages. Each sampling lasted two weeks at a flow rate of ~70 m^3/h per impactor and thus an overall flow rate of around 430 m^3/h. Thanks to the elevated air volume sampled (~ 92000 m^3) and very sensitive measurements, activity levels of thorium-234 (^{234}Th) of the ^{238}U decay series were quantified for each stage at some µBq/m^3 corresponding to a cumulative airborne activity of about 15 µBq/m^3 during the shutdown period. (Fig. 1).

Airborne activity levels are on average 5 times higher during operation of the facility except for the finest fraction that remains poorly affected by the releases. During the shutdown period, activity higher levels onto coarse particles can be explained by resuspension of former deposit onto soils. The corresponding Activity Median Aerodynamic Diameter (AMAD) and respective Geometric Standard Deviation (GSD) are listed in Table 1. The presented values are within the range of those compiled by Dorrian and Bailey (1997) but significantly lower than the default AMAD value (5µm) used for occupational exposures (ICPR 66) or those found in the fluoridation and precipitation workplaces of this facility (5.1 and 6.4 µm, respectively; Ansoborlo et al., (2001). The larger AMAD during operation is due to the release of coarse particles from the stack. Some of them remain suspended at 1.1 km. Regardless of the dust concentration, particles having the higher ^{234}Th load are within the [0.95-1.5µm[size range (Fig. 2).

	AMAD (µBq/m^3)	GSD (µBq/m^3)
Shutdown	0.84	17.0
Operation	1.6	4.7

Table 1. AMAD and GSD for ^{234}Th between shutdown and operation conditions

Compared to the typical weighted activity found in the uranium concentrate (yellow-cake), the weighted activity of the aerosols are ~ 4500 times lower.

Such information is useful to strikes and validate environmental dispersion/deposition model at short distance scale. Further investigations on the finest fraction are required to precise the contribution of the particle that enter deeply into the lungs.

Metals present in atmospheric particulate matter are associated with both natural and anthropogenic processes. Natural sources of metals in the atmosphere include volcanic activity and wind-blown dust, while anthropogenic sources include industrial processes, traffic emissions, incineration and fossil fuel combustion (Allen, Nemitz et al. 2001). The presence of certain metals in the atmosphere is of interest due to associated health effects.

The concentration of metals in atmospheric aerosols is traditionally measured using off-line techniques with particles being collected onto a substrate which is later analysed using techniques such as ICP-MS (Inductively Coupled Plasma - Mass Spectrometry), XRF (X-Ray Fluorescence) and IC (Ion Chromatography). These methods can quantitatively determine the metal component of particulate matter, but typically suffer from poor time resolution. This can lead to short-lived events being missed. More recent techniques such as PIXE (Particle induced X-ray Emission) allow samples to be analysed with an hourly temporal resolution (Chiari, Lucarelli et al. 2005). However, none of these off-line techniques can provide information on the mixing state of metals in the particles, which is useful for identification of their sources.

The interest in measuring the mixing state of individual aerosol particles has led to the development of single particle mass spectrometers. One such single particle instrument is the Aerosol Time of Flight Mass Spectrometer (ATOFMS), which provides size resolved single particle dual ion mass spectra of particles in the size range 100 nm to 3000 nm. This allows the characterisation of the primary composition of single particles (e.g. elemental/organic carbon and transition metals) along with the determination of secondary species present in the particle (such as nitrate and sulfate ions).

The ability of the ATOFMS to determine the presence of metals in ambient particles was utilised during several sampling campaigns to determine if ATOFMS can be used to measure metal concentrations in real-time. The comparisons were made during campaigns held in Cork (Ireland), Paris (France) and Barcelona (Spain). The ATOFMS ion signals for the metals of interest were compared with measurements made using IC, PILS-IC and PIXE.

Several comparisons between the ATOFMS ion signal and the quantitative techniques provided poor correlations, with the ATOFMS ion signal intensity not being proportional to the ambient concentration. The reason for the poor correlations with the quantitative techniques may be due to the matrix effects associated with the mixing state of the particle being sampled. The mixing state can affect the ionisation of the metal in sampling with the ATOFMS. The strongest correlations were found for comparisons between the ATOFMS and PIXE measurements for several metals including Al, Fe, Zn, Mn and Pb. Fig. 1 shows the correlation between ATOFMS and PIXE measurements for aluminium. The improved correlations for these metals is likely due to them having a specific source, with several of the metals such as Pb, Zn and Mn also occurring in short sharp peaks in concentration these factors may result in the ATOFMS ion signal responding to changes in concentration in a more proportional fashion.

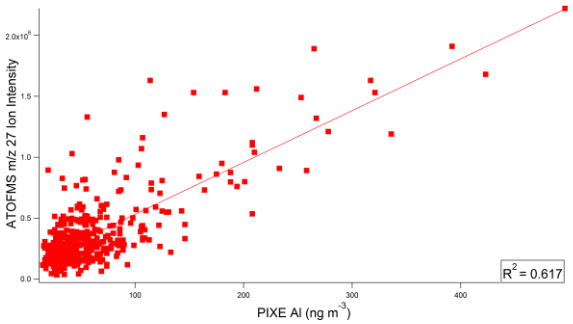

Fig. 1. Correlations between ATOFMS ion intensity (m/z 27) and PIXE mass concentrations for aluminium.

Keywords: PBDEs, dismantling, indoor, outdoor.
Presenting author email: ssi10@mail.ksu.edu.tw

As a class of brominated fire retardants (BFRs), polybrominated diphenyl ethers (PBDEs) are only used to decrease the flammability of consumer products including electronics (e.g. air conditioner, TV sets, and cellular phones), automobiles, furniture, and electrical wirings and textile application (Alaee *et al.*, 2003). PBDE contamination has been raising the global concern due to their lipophilicity, persistence, and bioaccumulation. PBDEs are ubiquitously existed in indoor environment due to their persistence and the widespread use in consumer products. Therefore, PBDEs have been recognized as the significant persistent pollutants of the indoor environment in recent years.

Since PBDEs are highly lipophilic and can accumulate in human fatty tissues, they have been investigated in most human tissues including breast milk (Chao *et al.*, 2007), cord blood (Lin *et al.*, 2011), venous blood (Lim *et al.*, 2008), placenta (Gómara *et al.*, 2007), and adipose tissue (Petreas *et al.*, 2010). PBDE levels in blood from workers of e-waste dismantling plants were significantly higher than those from computer clerks and hospital cleaners (Sjödin *et al.*, 1999). The recent report indicated that emission levels of predominant PBDE congeners (i.e. BDE-209) from indoor air to outdoors were roughly accounted for 90% of total PBDE emissions to outdoor air in Sweden, indicating that contaminated indoor air is an important source of PBDE contamination to outdoor air (Björklund *et al.*, 2012). Recently, PBDEs in car dust was found (Kalachova *et al.*, 2012). Little is known about PBDEs in indoor and outdoor air from automobile dismantling plant.

In this study, three automobile dismantling plants were selected in southern Taiwan to be investigated in 2012/10 and 2013/1. Indoor air in dismantling plants and ambient air nearby the corresponding plants was simultaneously sampled by high-volume PS-1 air samplers for 48 h. Air samples in on-duty and off-duty time were separately collected. $^{13}C_{12}$-labeled PBDEs were added into the samples before the extraction. The extract was cleaned up as follows. After the extraction, gas and particle phase was combined together. The first cleanup involved treatment with concentrated sulfuric acid. The next cleanup procedure involved a multi-layered silica column. The final cleanup procedure involved an acid alumina column. The eluate was collected, concentrated to near dryness by using N_2, and then transferred to a vial. A total of 50 μl of ^{13}C-labeled BDE-139 was added to a vial containing the eluate as an internal standard after the clean-up prior to injection. The final extract was reduced in volume to 0.2 mL under a stream of nitrogen. Fourteen PBDEs (BDE-28, 47, 49, 99, 100, 153, 154, 183, 196, 197, 203, 207, 208, and 209) were analyzed by high resolution gas chromatograph with high resolution mass spectrometry.

Levels of Σ_{14}PBDEs were 1200-8750 pg/m^3 in indoor air from automobile dismantling plants and 254-2740 pg/m^3 in the ambient air from corresponding plants, respectively. BDE-209 was the predominant congener consisting for 63-86% of the total in indoor and outdoor air. Although PBDEs in indoor air was higher than that in outdoor from dismantlers, no statistically significant differences were found for individual PBDE levels in paired of indoor and outdoor air samples, indicating that air PBDE levels in indoor and outdoor were not different.

Atmospheric aerosols affect terrestrial visibility by absorbing and reflecting incoming solar radiation, and they also influence climate and alter human health. Aerosols can be directly emitted from natural and anthropogenic sources or formed directly in the atmosphere through nucleation from gas phase species. New particle formation events have been observed frequently and worldwide but it is not fully understood how particles form at molecular level, creating one of the largest sources of uncertainty in atmospheric models and climate predictions (Zhang, 2010).

Several mechanisms have been proposed to explain nucleation events in the continental troposphere, including binary H_2SO_4/H_2O and ternary $H_2SO_4/H_2O/NH_3$ nucleation, ion-mediated nucleation, and nucleation enhanced by organic compounds (Metzger et al., 2010). In particular, dicarboxylic acids present in the troposphere have been proposed as favorable candidates to enhance the formation of the critical nucleus, as one of their carboxylic groups would be strongly hydrogen-bonded to H_2SO_4, whereas the free –COOH group would allow the growth of the complex until an aerosol particle is formed (Xu and Zhang, 2010; Gao-Lei Hou et al., 2013).

As a first step in exploring the configuration of the critical nucleus, we have conducted a rotational spectroscopic study of succinic acid (SA), which is a relatively simple dicarboxylic acid that has been detected in the troposphere. Rotational spectroscopy provides the most accurate vision of the molecular structure through precise moments of inertia.

In this work, we have applied the technique of Fourier Transform Microwave Spectroscopy (FTMW) in a supersonic jet, which is a high sensitivity and resolution technique. Expansion of a gaseous sample in a supersonic jet allows rapid cooling of the sample to only a few Kelvin so most molecules relax to the lowest ro-vibrational energy levels. SA was vaporized by UV ultrafast laser ablation avoiding any decomposition of the sample via heating conventional methods (Cocinero et al., 2012). The vaporized sample was seeded into an expanding stream of Ne forming a supersonic jet, where the molecules were probed by time-domain rotational spectroscopy. The experimental study was supplemented by *ab initio* (MP2) and DFT (M062X and B3LYP) calculations describing the conformational landscape and rotational parameters.

The rotational spectrum detected the presence of a single most stable conformation, for which accurate rotational and centrifugal distortion parameters have been determined. The rotational parameters were found in good agreement with the predictions for the predicted global minimum. The study was extended to all monosubstituted isotopic species (^{13}C, ^{18}O, D(O)), which were positively identified, leading to an accurate determination of the effective and substitution structures of the molecule, and hence, we were able to accurately determine all bond lengths, valence and dihedrals angles.

The next step of this study will be to detect intermolecular complexes formed by succinic acid and sulfuric acid. The ultimate goal is to provide experimental microscopic evidence of the geometric arrangement and energetic stability of a feasible critical nucleus to account for new particle formation in the atmosphere.

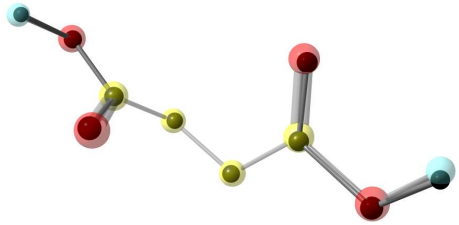

Figure 1: A comparison of the substitution and *ab initio* structures of SA. The full molecular structure is the theoretical structure. The smaller dark spheres are the experimental atom positions.

The influence of the Sahara storm on the aerosol optical properties in Lithuania

G. Mordas, V. Ulevicius and N. Prokopciuk

Center for physical sciences and technology, Savanorių 231, LT-02300 Vilnius, Lithuania.
Keywords: Light scattering coefficient, number concentration, long range transport.
Presenting author email: genrik@ftmc.lt

Introduction

Atmospheric aerosol particles have direct and indirect effects on a human health, people life conditions and the global climate. The effects are dependent on aerosol particle physicochemical properties, which are formatted by natural and anthropogenic aerosol sources located in this region. In this study, we assembly ground based measurements, satellite measurements, a modelling of dust distribution and calculations of the backward trajectories with aim to show the effect of the far located (several thousand km) Sahara storm on the aerosol optical properties in Lithuania.

Methods

The ground-based measurements were performed in the in Vilnius city (54°38'36", 25°10'58") during July 2012. They give insights into the physical and optical properties of the urban aerosols measuring the aerosol scattering coefficient with the particle size distribution. The aerosol scattering coefficient was measured with the integrating nephelometer TSI 3563 at three wavelength λ=450, 550 and 700 nm. Measurements of the particle number concentration (D_{pa}>0.5µm) and the particle size distribution in the range from 0.5 to 10.0 µm was performed by aerodynamic particle sizer TSI 3321. The ground based measurements was reached by analyse of the air mass backward trajectories HYSPLIT4. That allows selecting the air masses by sectors, which have characterised properties of the aerosol particles. Helpful, it was an investigation of the regional dust distribution by Met Office Unified Model. The Met Office provides quantitative SEVIRI satellite retrievals of the aerosol optical depths (AOD) at 550 nm.

Results

The analyse of the air mass backward trajectories allowed dividing measurement period on several episodes. From 1 to 8 of July, the South-West sector (Mediterranean see, North Africa was dominated. The West sector (Atlantic Ocean, Great Britain, Norway) was observed at 9-24 of July. From 25 to 31, there were continental air mass from Ukraine and Russia. The significant differences were measured in the aerosol particle scattering coefficient and the particle number concentration (D_{pa}>0.5µm). The cleanest air mass came from West sector. The South-West sector was characterised the highest values of the particle number concentration (D_{pa}>0.5µm) and the aerosol scattering coefficient. So, the scattering coefficient was varied from 3.5 to 369 Mm^{-1} during measured period. The clean air mass from Atlantic Ocean had averaged scanning coefficient of 10 Mm^{-1} comparing with 70 Mm^{-1} from Mediterranean see. The highest pick was 369 Mm^{-1} at 3 of July. The averaged Angstram exponent for 450/700nm wavelength pair was 2.0. That is typical for aerosols affected by urban (Vrekoussis *et al.*, 2005). However, the Angstram coefficient decreased rapidly at 3 of July, it was 1.4, when the value of the aerosol scattering coefficient and the particle number concentration (D_{pa}>0.5µm) had the highest values (Fig.1) The calculation of the backward trajectories showed that the air masses came from the Nord Africa. In the Sahara desert, it was a storm during several days. The regional dust distribution based on the AOD measurements and dust transport were modeled. The results showed the invasion of the dust polluted air mass from Sahara on the Baltic region (Fig.2). Additionally, the chemical composition of a precipitation indicates increase in calcium which air masses brought from the region of North Africa.

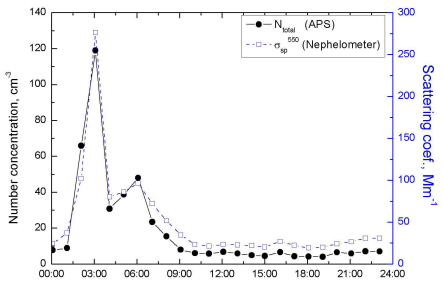

Fig.1. Aerosol scattering coefficient and particle number concentration (D_{pa}>0.5µm) during 3 of July.

Measurements of the aerosol particle physical properties and particle chemical composition in Vilnius city

G. Mordas, V. Ulevicius, I. Garbariene and K. Kvietkus

Center for physical sciences and technology, Savanorių 231, LT-02300 Vilnius, Lithuania.
Keywords: Chemical composition, size distribution, light scattering coefficient.
Presenting author email: genrik@ftmc.lt

The investigation of the atmospheric aerosols physical properties and the particle chemical composition allow understanding the aerosol particle dynamical processes in the atmosphere, finding danger pollution sources and solving important problems for human health, live conditions and climate. In this work, we concentrated on a study of the atmospheric aerosols in the urban environment of Vilnius city. The study gives insights into the aerosol chemical composition, particle optical and physical properties measuring the chemical composition of the non-refractory fraction of submicron aerosol particles, the light scattering coefficient and the particle size distribution. The measurements were reached by modelling of the backward trajectories of the coming air mass and calculations of the aerosol optical depths.

The aerosol chemical composition was measured by Quadrupole Aerosol Mass Spectrometer (Q-AMS). The light scattering coefficient was examined for the wavelength of 450, 550 and 700 nm using the integrating nephelometer TSI3563. The aerosol particle size distribution was measured with scanning mobility particle sizer TSI3936 and with the aerodynamical particle sizer TSI3321. Thus, the range of the measured particle size distribution was from 3 nm to 10 µm. The bottom range was determined by detection efficiency of the used condensation particle counter TSI3076 and particle diffusion losses in the sampling line. The upper limit is affected by geometry of the used sampling system and ambient conditions. The ambient conditions were measured at 10 m height meteorological station. In the macro scale, the coming air masses were characterised by HYSPLIT 4. A model of Navy Aerosol Analysis and Prediction System gives information about aerosol optical depths measured by MODIS satellite and regional dust and sulfate distributions.

The particle chemical composition (organic matter, sulfate, nitrate and ammonium) of the non-refractory fraction of submicron aerosol particles (D_{va}<1µm) were investigated during spring. The typical measured particle chemical composition is presented in Fig. 1. It shows that the organic matter comprised the largest fraction (74%) of the non-refractory fraction of submicron aerosol particles, while sulfate, nitrate and ammonium made up 14%, 8% and 4%. The average concentrations of organic matter, sulfate, nitrate and ammonium were 7.40, 1.36, 0.76, 0.39 µg m^{-3}, respectively. The average mode diameter of the organic matter and nitrate was 300 nm. However, the sulfate had a characterized mode diameter of 400 nm. The typical particle size distribution is presented in the Fig. 2. It illustrates the increasing of the total particle number concentration affected by production of the primary and secondary aerosol particles of nucleation and Aitken modes. The primary organic particles detected in the urban environment are manly directly emitted from local combustion sources: light and heavy vehicles, house heating and industry. The emitted particles are modified immediately by various atmospheric oxidants. As result, the physicochemical properties (size, scattering coefficient and particle chemical composition) changed a lot comparing to their precursor primary particles (Donahue et al., 2009). The secondary organic particles are formed from the reactions of the volatile organic compounds affected by meteorological conditions. Thus, the assembly of different processes: primary aerosol particle emissions, secondary particle formations with continuous particle growth, the effect of the far located pollution sources on the regional environment, were investigated in our study.

Exploring the effect of deep-convective cloud systems on particle mass and number: source or sink?

B.N. Murphy[1, 2], I. Riipinen[2], and A. M. L. Ekman[1]

[1]Department of Meteorology, Stockholm University, Stockholm, 10691, Sweden
[2]Department of Applied Environmental Engineering, Stockholm University, Stockholm, 11148, Sweden
Keywords: cloud-aerosol interactions, nucleation, organic aerosol, aqueous-phase chemistry
Presenting author email: Benjamin.murphy@itm.su.se

Incomplete knowledge of aerosol-cloud interactions contributes significant uncertainty to the understanding of the Earth's climate sensitivity, and thus to the large-scale theoretical models used to predict future climate properties. The total number, size, and composition of an aerosol population entrained into a cloud system can affect cloud physical features (e.g. updraft velocity or precipitation rate) while cloud properties can affect features of the aerosol population (e.g. through wet scavenging efficiency or aqueous-phase chemical processing) (Yin *et al.*, 2005; Ekman *et al.*, 2006). This tightly-coupled system exhibits complicated feedbacks that are hard to discern in a theoretical model without faithfully representing the detailed transport, microphysical and chemical processes taking place. We present a new three-dimensional cloud-resolving model, CRM-ORG, which accounts for the processing of inorganic and organic aerosol components in a fully-coupled, dynamic simulation. We apply this model to a case study of a deep convective cloud under clean conditions above the tropical Amazon, and use it to elucidate the net influence of the cloud system on aerosol mass, number, and composition throughout the atmospheric column.

Following the Volatility Basis Set approach of Donahue *et al.* (2006), the CRM-ORG model incorporates a suite of lumped species to describe the oxidation products of isoprene and monoterpene compounds across a spectrum of volatility. The mass transfer of these species to/from particles and cloud drops is treated dynamically along with explicit representation of aqueous-phase chemical reactions relevant to the production of low-volatility organic compounds that partition significantly to the particulate phase after cloud drop evaporation. The model also accounts for particle nucleation and growth due to condensation of inorganic as well as organic vapors, and this work probes the sensitivity of the model's results to both the formulation of the nucleation mechanism and the volatility of condensable organic vapors.

The detailed considerations of organic aerosol formation and growth are implemented into the three-dimensional cloud-resolving model described by Wang *et al.* (1993) and Ekman *et al.* (2006). This elastic, non-hydrostatic model solves prognostic equations for momentum, air mass density, ice-liquid potential temperature, water vapor and four hydrometeor types. The model then considers chemical species in the gas, particulate and aqueous phases in addition to species adsorbed onto solid water particles. The sulfate and organic aerosol species are represented with three internally-mixed modes (one each in the nucleation, Aitken and accumulation size ranges). Important aerosol microphysical processes, such as coagulation and condensation, are considered in the model.

We compare the predicted aerosol and cloud properties from CRM-ORG to airborne measurements made during actual deep convective events in the Amazon. These observational constraints will gives us confidence in the ability of the model to faithfully represent the complex effects of clouds on aerosol mass and number in the tropical environment. In order to gain a more general understanding of these interactions, we report the net effect of cloud processing on aerosol mass and number at various altitudes throughout the column. Of particular focus is the generation of new particles in the relatively clean background environment of the upper troposphere where substantial amounts of trace gases and particles are injected within the cloud outflow.

Several other models have explored the effects and feedbacks between organic aerosols and clouds in adiabatic parcel or two-dimensional models (Ervens *et al.*, 2005; Yin *et al.*, 2005). These studies opted to consider more detailed representations of chemistry or spectrally-resolved microphysics while sacrificing an atmospherically relevant description of transport. The configuration of CRM-ORG, on the other hand, achieves a realistic description of the spatial complexity of a deep convective system, while maintaining enough chemical and microphysical detail to explore aerosol-cloud interactions in depth. We compare our model's results and sensitivities to those of past studies to highlight the influence of model configuration.

Presenting author email: kimmo.neitola@fmi.fi

Exact determination of sulphuric acid concentration is crucial for predicting the nucleation rates and subsequent growth. In our study, we have noticed a discrepancy of about one to two orders of magnitude between sulphuric acid monomer and total sulphate concentrations measured from the same source of sulphuric acid vapour, with similar particle formation rates.

A thermally controlled saturator half filled with neat sulphuric acid (~97%) was used to produce the sulphuric acid vapour. The production method was first tested and then used in combination with a flow tube in a H_2O – H_2SO_4 nucleation experiment. Particle formation rates and size distributions were measured with several CPCs (TSI models 3776, 3025A and PSM) and with a DMPS system, respectively.

Sulphuric acid concentrations were detected with two independent methods. First, with two different mass spectrometers, CIMS (e.g. Eisele and Tanner, 1993) and CI-APi-TOF (Junninen et al., 2010). Second, with online ion chromatograph MARGA 2S ADI 2080 (ten Brink et al., 2007). MARGA was used also to detect background concentration of ammonia. Mass spectrometers were used to detect sulphuric acid monomer concentration, whereas MARGA measures the total sulphate concentration.

Results were compared to the previous measurements done in our laboratory (Brus et al., 2010), where a furnace was used as a source of sulphuric acid vapour and Bubblers were used to measure total sulphate concentration. Bubbler method is analogous to the MARGA with the difference that it is offline method. Results were also compared to the predicted values calculated using vapour pressure of sulphuric acid (Kulmala and Laaksonen 1990).

Figure 1 shows comparison of observed nucleation rates as a function of total sulphate or sulphuric acid monomer concentration between two different production methods and between two independent sulphuric acid detection methods. All results were obtained in similar conditions (RH 30%, T = 298K). Here one can observe that with similar nucleation rates and experimental conditions total sulphate and sulphuric acid monomer concentrations has a discrepancy of one to two orders of magnitude.

The discrepancy between the total sulphate and sulphuric acid monomer concentration cannot be explained by formation of larger clusters (dimer, trimer, etc.) as the concentration of dimer was always 1% or less of monomer concentration, with decreasing trend when moving to larger clusters. Losses of sulphuric acid to particles and to the walls were determined and it is shown that losses cannot explain the discrepancy either.

We suggest that the sulphuric acid is hidden into pool of clusters that are not detected by the particle counters nor identified from the mass spectra of CI-APi-TOF.

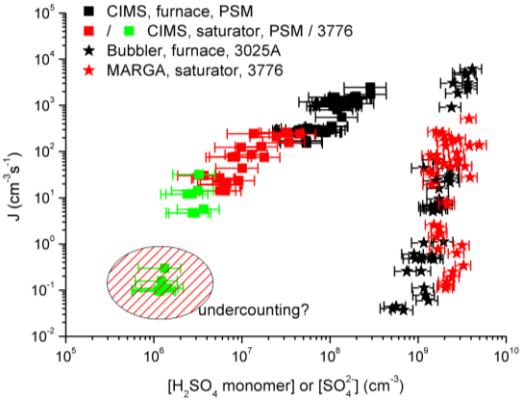

Figure 1. Comparison between our previous results and the results from this study from H_2O - H_2SO_4 nucleation experiment (Neitola et al., 2013).

Air mass history on 1-year long new aerosol particle formation dataset in Budapest

Z.A. Németh and I. Salma

Institute of Chemistry, Eötvös University, H-1518 Budapest, P.O. Box 32, Hungary
Keywords: atmospheric nucleation, DMPS, backward trajectory.
Presenting author email: nemeth@caesar.elte.hu

As part of an urban aerosol research project, number size distributions of particles were measured at Lágymányos Campus of the Eötvös University, located in central Budapest, Hungary continuously between November 2008 and November 2009. The measurements were performed by a flow-switching type differential mobility particle sizer (DMPS) in the electric mobility diameter range of 6–1000 nm in 30 channels with a time resolution of ca. 10 min. Meteorological data were obtained from the Urban Climatological Station of the Hungarian Meteorological Service operated within the university campus.

The measurement days were classified on the basis of Dal Maso et al. (2005). For the 1-year period, there were 31 days that belonged to the nucleation event, class 1A (Salma et al., 2011). The start (t1) and end (t2) times of the beginning of the nucleation, and the end times of the condensational particle growth were determined from the contour plots by examining the changes in the channel contents and meteorological data (Kristensson et al., 2008). The times t1 and t2 were shifted by an interval that was needed for the particles to grow from 2 to 6 nm utilizing the actual growth rate between 2.0 and 13.3 nm/h.

Wind roses were constructed by taking the wind speed and wind direction data into consideration from t1−1 h to t1+6 h for the nucleation events, and for 0–24 h for the non-nucleation days. Wind speed varied from 0.15 to 13.2 m/s with a median of 2.7 m/s for the nucleation events. The prevailing wind direction was SE as shown in Figure 1.

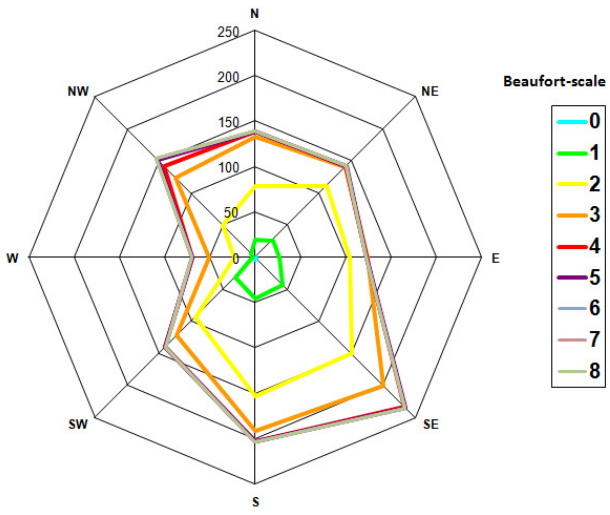

Figure 1. Wind rose for class 1A nucleation events.

For the non-nucleation days, the wind speed changed from 0.10 to 15.8 m/s with a median of 2.4 m/s, and the prevailing wind direction was NE. For the nucleation events, the range of the wind speed was smaller while the mean wind speed was somewhat larger than the non-nucleation days.

Air mass history was also investigated for class 1A nucleation events. Backward trajectories were calculated by the HYSPLIT code of the National Oceanic and Atmospheric Administration Air Resources Laboratory using meteorological data from the GDAS database (Draxler and Rolph, 2013). The trajectories arriving at the receptor site (47.474° N, 19.062° E) in a height of 200, 500, 2300 m above ground level were derived. The most distant (starting) point of the trajectories corresponded to the times when the particle growth was finished or by which the nucleation mode could be separated from the Aitken mode. The trajectories were calculated for every individual event with a resolution of 1 h to the ending time. The coordinates from the trajectories were plotted on a single geographical map. The plot revealed that the estimated horizontal dimension of the nucleating air mass extends far beyond the city, and that there are several distinct directions within the Carpathian basin where the nucleating air mass originates from. These directions were similar to the prevailing wind direction of the wind rose generated for the nucleation events.

Financial support of the Hungarian Scientific Research Fund (contract K84091) is appreciated.

Comparison of particle concentrations obtained at urban and regional background environments

J.F. Nicolás[1], J. Crespo[1], E. Yubero[1], R. Soler[1]

[1]Atmospheric Pollution Laboratory, Miguel Hernández University, Avda. Universidad, 03202, Elche, Spain
Keywords: Particle concentration, Mountain station, Mineral dust, Urban aerosol.
Presenting author email: j.nicolas@umh.es

The study focuses on characterizing the particle number concentration registered at a regional background station (RS) and comparing it with the one obtained at an urban background site (US).

The stations are inside the province of Alicante in southeastern Spain. This region belongs to the Western Mediterranean Basin. RS (38°39´N; 0°16´W; 1558 m a.s.l) is located on top of a mountain range, in a military area (EVA nº 5) of the Ministry of Defence, 25 km from the Mediterranean coast. The station is located specifically at the named "Aitana peak". US (38°16´N; 0°41´W; 95 m a.s.l), is located in the city of Elche, 12 km from the coast. Specifically, the measurement site is placed on the roof of a building at the Miguel Hernández University, approximately 15 m a.g.l. The study period comprised from October 2011 to September 2012. The instruments used to measure particle concentrations were two optical counters. The instruments permit the determination of a fraction of fine mode (from 0.25 to 1 μm) and the coarse mode particles (size >1 μm).

Table 1 shows monthly and global average values of the coarse and fine particles at RS and US. Regarding the fine particle concentration at US (N_{FUS}), the winter and summer months were when the highest levels were registered. N_{FUS} obtained an absolute peak during August. The coarse particle concentration at US (N_{CUS}) showed a clear discontinuity between the colder months (November-March), with values below 0.15 cm^{-3}, and the warmer ones, in which the concentration became three times higher with a maximum in June (0.57 cm^{-3}).

Table 1. Monthly average values (cm^{-3}) of fine and coarse particles at RS and US.

Month	N_{FUS}	N_{FRS}	N_{CUS}	N_{CRS}
Oct-11	136.92	61.47	0.34	0.23
Nov-11	99.49	n.d	0.15	n.d
Dec-11	92.11	18.72	0.11	0.14
Jan-12	125.89	24.90	0.14	0.06
Feb-12	101.92	59.80	0.13	0.12
Mar-12	133.94	83.68	0.15	0.24
Apr-12	73.36	31.93	0.37	0.16
May-12	86.79	45.83	0.43	0.30
Jun-12	104.81	57.51	0.57	0.72
Jul-12	115.05	96.41	0.31	0.63
Ago-12	139.71	69.41	0.44	0.86
Sep-12	137.38	75.43	0.30	0.30
Annual	112.28	54.95	0.29	0.33

At RS, the fine particles showed a similar monthly tendency as the one seen at US. Fine particle concentration at RS (N_{FRS}) obtained maximum levels during the warmer period (from July to September). Although slightly lower than in summer, N_{FRS} showed high values during February and March as well. N_{FRS} made up between 20 and 85% of N_{FUS}. This percentage varies according to the season, with minimum values in January and February and maximum values in spring and summer. The annual average was: $N_{FRS}=0.5 \cdot N_{FUS}$. The coarse particle concentration at RS (N_{CRS}) was quite higher during summer than the rest of year. Standing out in a significant way as $N_{CRS}>N_{CUS}$ during summer-time. It is likely to due to between June and August the 55% of days were affected by Saharan dust outbreaks and these air mass entrances affected more at RS than at US. For this reason, N_{CRS} annual average value was slightly higher than N_{CUS} one.

In Fig. 1 we can compare the particle size distributions obtained at RS and US. The distributions are calculated for the colder (December-January and February) and warmer (June-July and August) months.

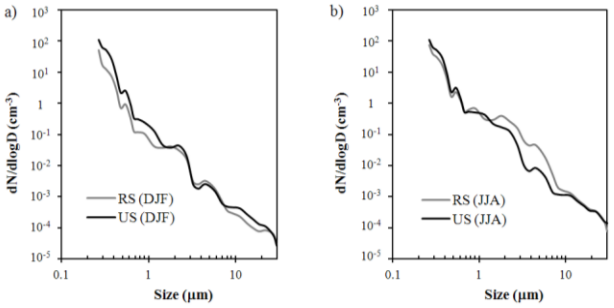

Figure 1. Average number size distributions obtained at RS and US during: a) cold months; b) warm months.

In general, the size distributions at both stations during the cold period (Fig. 1a) were quite similar, although the particle number concentration up to 2 μm registered at US was higher. In the warm months (Fig. 1b), we observe two differences with respect the distributions obtained in winter. First, the particle concentration difference in the accumulation mode particles between RS and US decreased, although the concentration at US remained slightly higher. On the other hand, the particle concentration in coarse mode up to 10 μm was higher at RS, establishing the major difference in the range 3-5 μm as a result of the significant impact of Saharan dust outbreaks at RS.

This work was supported by the Spanish Ministry of Science and Innovation under the CGL2009-08036 (PASSE) project and by the Spanish Ministry of Economy and Competitivity under the CGL2012-39623-C02-02 (PRISMA-AITANA) project. We would like to thank the military area (EVA nº 5) for its assistance in this work.

Enhancement of the collision efficiency between basidiospores and cloud droplets by electrostatic charges carried on freshly emitted basidiospores

M. Saar[1], M. Noppel[2] and J. Salm[2]

[1]Department of Botany, Institute of Agricultural and Environmental Sciences, Estonian University of Life Sciences, Tartu, 51014, Estonia
[2]Institute of Physics, University of Tartu, Tartu, 50090, Estonia
Keywords: bioaerosols, coagulation, ballistospore, washout.
Presenting author email: madis.noppel@ut.ee

In the coarse biogenic particles of the atmospheric aerosol, basidiospores are among the main fungal components (Fröhlich-Nowoiskya *et al.*, 2009). In bulk (about 20 000 species) of basidiomyceteous fungi, sexual spores expel themselves from their perches. Becoming airborne, these ballistic basidiospores (diameter 2−16 μm) carry an electrostatic charge (from tens to one thousand elementary charges) (Saar and Salm, 2013). Washout is one of mechanisms of sedimentation of fungal spores, but the role of basidiospore primary electric charges in this process is not yet studied. The effect of electric charges on collisions between water droplets or between water droplets and aerosol particles has been studied for a long time, up to the present time (Fletcher, 2012). In (Tripathi and Harrison, 2002), the considered ranges of the size and density of aerosol particles include those of basidiospores (Table 1). Based on this result, we evaluated the effect of charges for basidiospores of *Phellinus tremulae* and *P. nigricans*, members of the *P. igniarius* group, one of the most important wood-rotting fungi of many of deciduous trees.

These basidiospores are subglobose, smooth, with density of 1 g cm^{-3} or a bit more (1.2 g cm^{-3}), and represent the smallest and the biggest spores in the group. In *P. tremulae*, the mean equivalent diameter is 4.4 μm (99.7% of the variation of mean spore sizes is within the range of 3.9−4.7 μm) and the mean primary electric charge is 117 e (95% confidence intervals of mean spore charges is within the range of 46−222 e), and in *P. nigricans*, 6.1 μm (5.6−6.5 μm) and 204 e (107−496 e) (Saar, 2013). In the case of the droplet diameter D = 84 μm, the particle charge q enhances the collision efficiency if it has magnitude $|q|\geq 50$ e in particles of 4 μm or $|q|\geq 100$ e in particles of 6 μm. This shows, that in both *P. nigricans* and *P. tremulae* the primary charge enhances collision efficiency between basidiospores and cloud, fog or drizzle droplets of diameter about 80 μm.

Results of Tripathi and Harrison (2002) for the droplets D = 104 μm and the particles with density 2 g cm^{-3} show that the enhancement of collision between *P. nigricans* and *P. tremulae* spores and droplets may cease in the vicinity of D = 100 μm. Here as well as in the case of medium size cloud droplets the numerical calculation of particle's trajectories is needed to investigate collision efficiency.

Table 1. Collision efficiency for a droplet of diameter 84 μm and charged particles of 1 g cm^{-3} and 4−8 μm, expressed with respect to the collision efficiency in the case of neutral particles (0.00063 for d=4 μm, 0.0013 for d=5 μm, 0.0028 for d=6 μm, and 0.04 for d=8 μm).

Particle charge (e)	Particle diameter (μm)			
	4	5	6	8
10	1	1	1	1
20	1	1	1	1
50	1.4	1.2	1	1
100	2.4	1.5	1.1	1
500	28.6	11.5	5.0	1.1

The primary electrostatic charges of basidiospores could enhance the collision efficiency between spores and water droplets with D<100 μm not only near the ground, but also in the higher layers of the atmosphere. Due to the relaxation time of 23 minutes, highly charged spores can spread over a considerably area depending on the wind velocity (Saar and Salm, 2013).

This work was supported by the Doctoral School of Earth Sciences and Ecology created under the auspice of European Social Fund and, in part, by the Estonian Science Foundation through grant 8342.

Gas-aerosol interaction can significantly alter the concentration of gases in the atmosphere thus playing a role in the global heat balance and climate change. In particular, the atmospheric minor gases behaviour under high aerosol loading conditions such as desert dust episodes or nucleation processes are tasks demanding growing attention in last years due to their potential impact even at large scale. The AMISOC Project (Atmospheric Minor Species relevant to the Ozone Chemistry at both sides of the Sub-tropical jet) aims to improve the knowledge of the minor constituents of the atmosphere playing a role in the ozone chemistry. The core of the project is: two coordinated field campaigns, the development and improvement of instrumentation, modeling and applications system.

AMISOC started with an experimental campaign carried out at 'El Arenosillo' – Atmospheric Sounding Station from 20 May to 15 June 2012. This observatory is located southwestern Spain (37.1ºN, 6.7ºW) on the Atlantic Ocean coast. The location allows the first detection of Saharan dust plumes transported northward to Europe (Córdoba-Jabonero et al., 2011), and can be also affected by events with high levels of surface ozone (Adame et al., 2010) and ultrafine particles (Sorribas et al., 2011), due to natural or anthropogenic emissions under high levels of solar radiation.

This work shows the preliminary analysis of the microphysical and optical aerosol properties during the AMISOC-ARN campaign, as a first step to extend our understanding about the gas-aerosol interaction.

Mean value ± standard deviation for total particle concentration within (14-604) nm was 7750±6500 cm^{-3}, showing the highest levels at noon during the new particle formation events. Depending on wind direction, formation and growth properties of the new particles, seven new particle formation episodes were selected with the aim to analyze them with regard to iodine monoxide (IO), glyoxal (C_2) and sulfate (SO_2) concentrations.

Two desert dust episodes with impact on the columnar-integrated aerosol properties were detected during the AMISOC campaign: (1) 30 May - 3 June 2012 and (2) 6 - 7 June 2012. Mean AOD and Angström parameter (α) during the first episode were 0.30 and 0.61, respectively, and those same aerosol properties during the second one were 0.21 and 0.39. So, the particle contribution of fine size range was higher during the event from 30 May to 3 June (higher α) and the extinction process was strongest (higher AOD) than the other episode. Moreover, the impact on surface level of the first desert dust episode was also observed within the sub-micron and super-micron aerosol size ranges. Figure 1 shows the evolution of the particle volume size distribution during the episode, showing the strong impact on particle diameter about 10 μm was during the first hours of the episode.

The influence of the episode on the global heat balance was also observed with an increase of the scattering light with respect to non-dusty days from 32 Mm^{-1} to 69 Mm^{-1} and absorption light from 2.5 Mm^{-1} to 4.2 Mm^{-1}. It produces an increase of the radiative forcing from -4 W m^{-2} to -12 W m^{-2}.

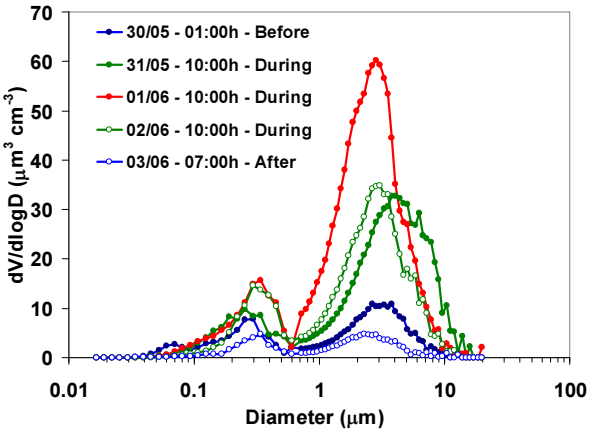

Figure 1. Evolution of the volume size distribution during a desert dust event from 30 May to 3 June 2012

Presenting author email: fjolmo@ugr.es

Photometric measurements of solar extinction and sky radiance are currently used in inversion methods to retrieve microphysical values such as size and refraction index. However, this method cannot yield proper information regarding some microphysical (particle shape) and optical (backscatter, depolarization, lidar ratio) properties; and concentration values can be retrieved at a column-integrated basis only, lacking access to layer-by-layer information.

In the case of bimodal particle populations, accurate data is difficult to obtain concerning shape or composition for both modes. Such is, for example, the case in large-scale dust episodes, where North African dust is carried across the Mediterranean basin to Europe, and across the Atlantic Ocean to the Caribbean and the United States.

In these cases, dust episodes form mixtures with other particles produced in combustion processes, either natural or anthropogenic. The resulting population can be described as a mixture of two particle modes: a submicron-sized (fine) mode of combustion-produced particles, and a micron-sized (coarse) mode of dust particles. The assessment of the concentration of both particle modes is necessary to determine the physical and optical properties of the aerosol, with consequences in both local and global environments.

In the present work, a combination of column-integrated (CIMEL) and layer-by-layer (Lidar) measurements are used to retrieve detailed information regarding the distribution of both fine and coarse particle modes in each particular layer The particle size distribution (PSD) as retrieved from CIMEL inversion data is fitted to a bimodal log-normal size distribution. A solution is then chosen as a set of input parameters describing the composition (refraction index) and shape of both modes (fine and coarse), as well as the fine/coarse ratio. Particles in each mode are modelled as a 50% volume mixture of prolate and oblate spheroids with the same axial ratio.

A pre-calculated database of kernel functions (“BETA”), based on the T-matrix theory, is used to fit simulated data to experimental layer-specific parameters like particles extinction, backscatter and depolarization at several wavelengths, in order to retrieve the fine/coarse mode ratio and the full (fine+coarse) particle concentration. Once the full, layer-by-layer particle concentration has been obtained, simulated data can be compared to other CIMEL experimental measurements (asymmetry parameter at several other wavelengths).

Our approach does not resort to least-squares methods to obtain the best solution (“best” meaning “minimizing the difference between experimental and simulated data”). Instead, our approach is statistical: all solutions are considered acceptable as long as they agree to experimental data to within experimental uncertainty. By iterating the procedure for all possible kinds of particle shape and composition values, a set of acceptable solutions is obtained that can yield statistical information about fine and coarse mode distributions within each layer. The experimental uncertainty level can also be modified in order to get an assessment of the model's sensitivity

On the contribution of ephemeral lakes to the aerosol load

J.A.G. Orza, M. Cabello, E. Doménech, L. Pérez

SCOLAb and Aeolian Research Group, University Miguel Hernández, Elche 03202, Spain
Keywords: mineral dust, resuspension, meteorology.
Presenting author email: ja.garcia@umh.es

The role of dry lakebeds as sources for aeolian export of soil particulates is studied in relation to their inundation extent and meteorological conditions. We focus on two areas: (1) El Hondo Nature Park in southeastern Spain, 2,400 ha, composed by two large reservoirs and several natural lagoons and pools surrounded by a salt marsh, and (2) the region of the Chotts in southern Tunisia, including el-Djerid and el-Gharsa vast saline lakes of 495,000 and 42,000 ha, respectively. The period 2005-2012 is considered.

Despite their differences in spatial extension and some geomorphologic features, both settings are topographic lows with flat terrain and scarce or absent vegetation, which experience ephemeral variations in inundation extent. The desiccated surface is susceptible to deflation by wind, resulting in soil emissions from the sediments lying on the surface and from evaporite minerals.

Several field campaigns were conducted in El Hondo during the period 2009-2012, aimed to analyze wind erosion and suspended particulate levels downwind in connection with the atmospheric and soil conditions. Measurements included size distribution of suspended particles, PM10 concentration and chemical composition; saltation profiles, composition and granulometry; and meteorological and soil parameters.

Previous studies in the Chotts have used very coarse inundation data and the TOMS AI to measure the dust loading (Mahowald et al., 2003). An indication of an increase in dust loading when lake beds are dry was obtained, but no clear conclusions could be drawn due to the additional contribution of the Saharan dust in the area. We make use of more detailed inundation data and the `present weather´ observations of local dust recorded in SYNOP reports at Tozeur, as well as meteorological and visibility data in the area (METARs and SYNOPs).

Variations in water sheet and salt crusted surface, as retrieved from the 7-2-1 spectral bands of MODIS, are driven primarily by the precipitation regime. In El Hondo, conditions may change dramatically due to additional anthropic intervention, as inflow and outflow are ultimately managed by humans.

The majority of the dust storms registered at El Hondo were associated to the passage of Atlantic frontal systems with no rainfall. W/NW/SW winds > 9 m/s (at 2 m above the ground) and average friction velocity of 0.46 m/s triggered these erosion events. Soil emissions from El Hondo had an impact on coastal touristic villages and some of the dust plumes could be observed in MODIS images.

Dust locally entrained in Tozeur was associated (80% of the cases) to horizontal visibility < 5 km, relative humidity < 75% and windspeed ≥ 8 m/s (at 10 m above the ground), mostly of E component (55%) and then W (28%). Events were primarily of synoptic origin and were registered from March to May.

Dust storms occurred in both settings when, in addition to high wind conditions, large dried areas were available. The inundation extent in the Chotts was large in March-May 2009 leading to a decrease in the frequency of erosion events in that period with respect to other years.

We acknowledge support from the Spanish Government (EroHondo, CGL2008-05160).

Investigation of the truncation correction of the polar nephelometer Ecotech Aurora4000

M. Paixão[1], T. Müller[1], S. Pfeifer[1] and A. Wiedensohler[1]

[1]Department of Physics, Leibniz Institute for Tropospheric Research, Leipzig, Germany
Keywords: aerosol optics, nephelometer, scattering coefficient, phase function.
Presenting author email: paixao@tropos.de

In this work we present an investigation of the truncation of near-forward scattering of the polar nephelometer Aurora4000, Ecotech Pty Ltd.

Aerosol particles are known to contribute to climate change (Forster, 2007). The asymmetry parameter or phase function of aerosol particles plays a key role in a proper evaluation of its radiative forcing effect. The polar nephelometer measures the scattering coefficient of the aerosol for up to 18 angular sectors between 0 and 90 degrees. In this way, it's possible to evaluate a quasi-phase function of the aerosol.

Methods for reducing the uncertainties of angular non idealities of the nephelometer intensity function are widely discussed in literature (Anderson and Ogren, 1998; Massoli et al., 2009; Bond et al., 2009; Müller et al., 2011) and correction factors are based on Mie calculation or on parameterization of the Angström exponent. The truncation angle, generally accepted as 10 degrees for Aurora4000, is based on technical drawings and was never measured experimentally.

In order to investigate the truncation error, measurements of aerosol extinction and scattering coefficients were made. Polystyrene latex spheres (PSL) with diameter of 491 ± 4 nm were used, with concentration varying from 20 – 73 #/cm^3. As these particles are non-absorbing, the extinction is equal to the scattering coefficient. For extinction measurements we used a Cavity Attenuated Phase Shift Spectroscopy (CAPS), Aerodyne Ltd., at the wavelength 530 nm.

Preliminary results

Three methods for truncation correction were tested: a) Polar correction (Müller et al., 2012), using the information of the scattering coefficient sectors 10 and 20 degrees; b) Angström exponent measured by the nephelometer itself (Müller et al., 2011); c) calculations using Mie theory and the size distribution of the latex spheres. The Figure 1 shows the comparison of those methods and the error bars correspond to the standard deviation of 5 minutes average of extinction coefficient. The corrections are in good agreement in the region of 20 – 50 Mm^{-1}, probably because the concentration reached a more constant level.

Also the angular scattering was investigated and the measurements are in good agreement with the expected from Mie theory, as seen in Figure 2.

More experiments will be done furthermore with different particle sizes and ambient aerosol. The purpose is to test the instrument limits and improve accuracy.

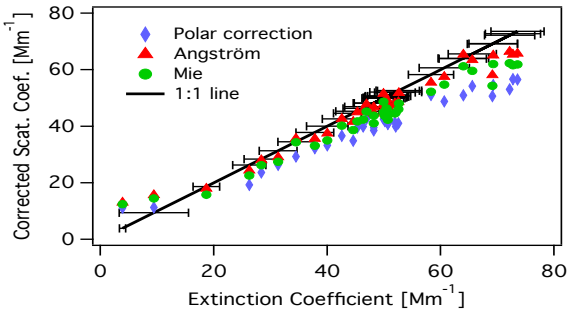

Figure 1. Correlation plot of the scattering coefficient measured by the polar nephelometer corrected using: a) polar correction; b) Angström exponent (Müller et al., 2011); c) Mie calculations using the nominal size distribution of latex spheres; and the extinction coefficient measured by CAPS. The error bars are the standard deviation of the extinction measurements.

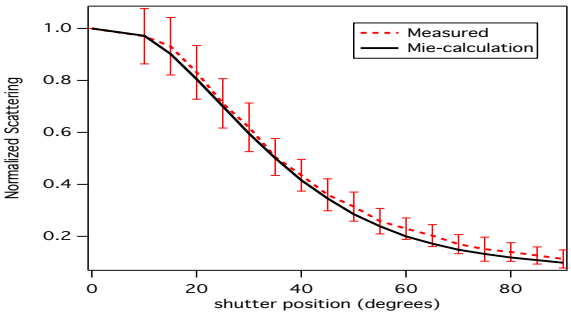

Figure 2. Scattering coefficient of angular sectors normalized by the total scattering measured by the polar nephelometer and calculated using Mie theory. The error bars are standard deviation of the average.

Estimation of viscosity of SOA particles based on coalescence times

A. Pajunoja[1], J. Malila[1], L. Hao[1], K. E. J. Lehtinen[1,2], and A. Virtanen[1]

[1]Department of Applied Physics, University of Eastern Finland, P. O. Box 1627 FI-70210 Kuopio, Finland
[2]Finnish Meteorological Institute, Kuopio Unit, P. O. Box 1627, FI-70210 Kuopio, Finland
Keywords: SOA, coalescence, viscosity, VOC
Presenting author email: aki.pajunoja@uef.fi

Secondary organic aerosol (SOA) formed from partitioning of oxidation products of volatile organic compounds (VOC) accounts for a significant portion of atmospheric particulate matter. The phase of SOA particles affects their behaviour in the atmosphere and ultimately also the climate in ways that fall under topical scientific interests (Riipinen *et al.*, 2012).

Virtanen *et al.* (2010) concluded that biogenic SOA particles can be amorphous solids. In a recent study, Abramson *et al.* (2013) estimated that the viscosity of α-pinene SOA particles is approximately 10^8 Pa·s, implying highly viscous (*i.e.* semi-solid) liquid particles. In this study we analyze the coalescence of agglomerates to estimate the viscosity of SOA particles. In the coalescence process, the (surface) free energy of agglomerated particles is minimized by reconstruction of the particles into spheres. For viscous amorphous particles, the characteristic time for coalescence is (Frenkel, 1945)

$$\tau = \mu d_p / \sigma, \quad (1)$$

where μ is the viscosity of particles, d_p particle diameter, and σ surface tension. A similar analysis recently used for levitated polystyrene microspheres was by Trevitt *et al.* (2009).

We performed chamber experiments using living Scots Pine (*Pinus sylvestris* L.) trees as a biological source of VOCs (Hao *et al.*, 2009). Other precursors (α-pinene, SO_2) were also investigated and the levels of ozone and trimethylethylene (TME), to produce OH, were controlled. The filter samples for scanning electron microscope (SEM) analysis were collected from the chamber (flow 0.2 l/min, sampling times 5–10 min).

The results of scanning mobility particle sizer (SMPS), aerosol mass spectrometer (AMS) and SEM were compared to characterize the particle size, O:C-ratio, SO_4/ORG-ratio, NH_4/SO_4 ratio and particle shape. O:C-ratio was calculated to be around 0.3 for every samples. Scanning electron microscope images of the SOA particles are shown in Figure 1. In Fig. 1a individual agglomerates with primary particle size around 40–80 nm and in Fig. 1b spherical SOA particles with particle size around 30–90 nm are shown. The storage time of these samples was two (2) months before image analysis was performed and agglomerates were still observed. Thus the structural deformation from agglomerates to spheres is remarkably slow and the characteristic coalescence time, τ, is longer than two months.

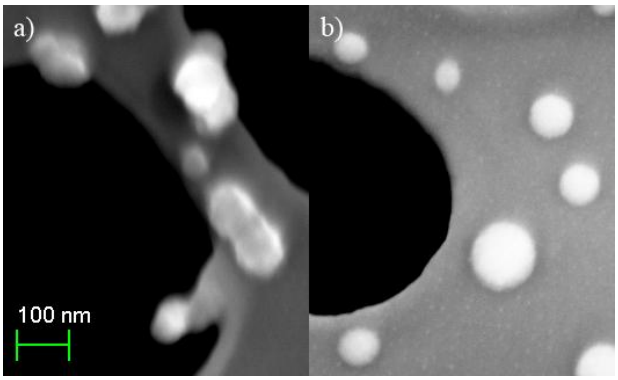

Figure 1: SEM images of the agglomerated SOA particles formed from pine + SO_2 + TME **(a)** and spherical SOA particles formed from oxidation of α-pinene **(b)**.

By using the equation (1), the viscosity of SOA particles can be estimated. As we do not know the detailed molecular composition of SOA, we used the estimated O:C-ratio to pinpoint a suitable model compound, *cis*-pinonic acid, with σ = 35 mJ/m^2. (www.chemspider.com/Chemical-Strucure.209536.html) This yields $\mu \geq 10^{12}$ Pa·s for SOA particles from pine + SO_2 + TME, and $\mu << 10^{12}$ Pa·s for SOA from pure α-pinene oxidation products. These results are consistent with earlier research (Virtanen *et al.*, 2010: Saukko et al., 2012; Abramson *et al.*, 2013), and bear out the hypothesis of highly viscous or even glassy SOA particles in the ambient atmosphere.

This research has been supported by the Academy of Finland (decision no 1118615, 259005 & 264989) and by the strategic funding of the University of Eastern Finland.

Studies of precipitable water vapor measurements with use of Microtops II Sun Photometer and Radiosonde RS92

P.Pakszys[1], T. Zieliński[1], T.Petelski[1], P.Makuch[1], A.Strzałkowska[1], P.Markuszewski[1], J.Kowalczyk[1]

[1]Institute of Oceanology PAS, ul. Powst. W-wy 55, 81-712 Sopot, Poland
Keywords: water vapor, Microtops, radiosonde, AOD.
Presenting author email: pakszys@iopan.gda.pl

Information about vertically integrated content of water vapor in the atmosphere and type, composition and concentration of aerosols is relevant in many types of atmospheric studies. Such information is required to understand mechanisms of global climate and its further modeling (Smirnov et al., 2000).

This work is devoted to analyses of Columnar Water Vapor values obtained from two instruments.

The measurements were carried out using Microtops II Sunphotometer during the cruise onboard s/y Oceania between 29 March and 20 April 2011 in the southern Baltic Sea, near the Polish town of Leba. Measurements were collected for the NASA program Maritime Aerosol Network. Data at the Leba station were collected with a Radiosonde DiGICORA RS92.

The first instrument, sunphotometer, allows us to collect data on days that are cloud-free. The Microtops II is capable of measuring the total ozone column, total precipitable water vapor and aerosol optical depth at 1020 nm (Morys et al. 2001; Ichoku et al., 2002). Each of these parameters is automatically derived.

The water vapor measurement is based on pair of radiometric measurements in the IR band. Simultaneous observations are performed through two filters with different transmission bandwidths centered around the same wavelength located in the water vapor band (Plana-Fattori, 1997). The 936 nm wavelength is strongly affected by water vapor absorption, the 1020 nm filter only by aerosol scattering.

Data collected by Microtops have been processed with the pre- and post-field calibration and automatic cloud clearing. Precipitable water vapor in the column was derived from the 936nm channel. Detailed data description is available on the AERONET webpage.

Radiosonde observations also play an important role in conducting research to help develop satellite techniques for retrieving temperature and humidity profiles (Garand et al. 1992; Connell et al.,1995).

The total precipitable water is the water that occurs in a vertical column of a unit cross-sectional area between any two specified levels, commonly expressed as from the earth's surface to the "top" of the atmosphere. The Integrated Precipitable Water Vapor (IPWV) is the height of liquid water that would result from the condensation of all water vapor in a column.

During the study 241 Microtops measurements were made, each of them in a series of five "shots". Then only the lowest value was used. Then the data were matched with the radiosonde data, based on date and time. As a result 12 measurements were left to compare.

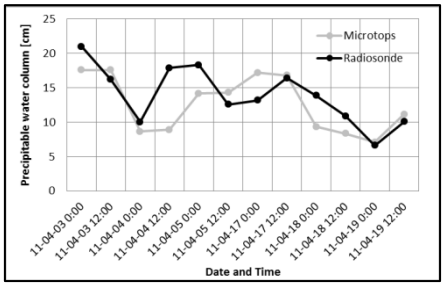

Figure 1. Comparison of data from Microtops II and a Radiosonde

The correlation is strong for both instruments (0.67). The correlation between aerosol optical depth and water vapor content in the total atmospheric column is strong (0.42). Also diurnal variations of the aerosol optical depth and precipitable water were insignificant ($\overline{AOD}$=0.09±0.03; $\overline{PWV}$=11.42±3.50).

These analyses are presented in order to quantify the accuracy of different techniques and algorithms to estimate WV present in the Earth's atmosphere. Nevertheless, the data comparison shows discrepancy at a lower level between the instruments.

Factor analysis of aerosol measurements in Tartu

M. Palo and M. Eller

Institute of Physics, University of Tartu, Ülikooli 18, 50090, Tartu, Estonia
Keywords: urban aerosol, factor analysis
Presenting author email: marispalo@hotmail.com

The aim of this work was to study the spectrum characteristics of urban aerosol measured in Tartu, Estonia and to test, whether it is possible to use factor analysis to describe the formation processes and possible sources of the measured aerosol.

The concentrations of particles were measured with electrical aerosol spectrometer (EAS), developed by Airel Ltd. EAS (Tammet *et al*., 2002) can measure size distribution of particles in 3.16 nm to 10 µm diameter range and has the size resolution of 8 channels per size decade and time resolution up to 1 second.

Factor analysis was used to investigate spectrum characteristics during nucleation events and non-event periods. Periods were determined visually by examination of aerosol size spectrum.

In the analysis, the number of factors was determined by the Kaiser criterion. Factors characterize correlative tendencies in aerosol size spectrum and can be associated with the formation processes and sources of the aerosol. Results of factor analysis were explained according to knowledge of human activities in the area, weather conditions and particle formation-, growth- and loss processes.

Aerosol spectrum from the periods without nucleation events had a lot of variability. In spring, the spectrum showed unsteady conditions, while in autumn and winter periods the spectrum demonstrated a daily pattern. The pattern is caused by local heating, traffic and stable weather conditions. On figure 1 factor 1 shows the accumulation of particles from local heating and traffic due to little dispersion.

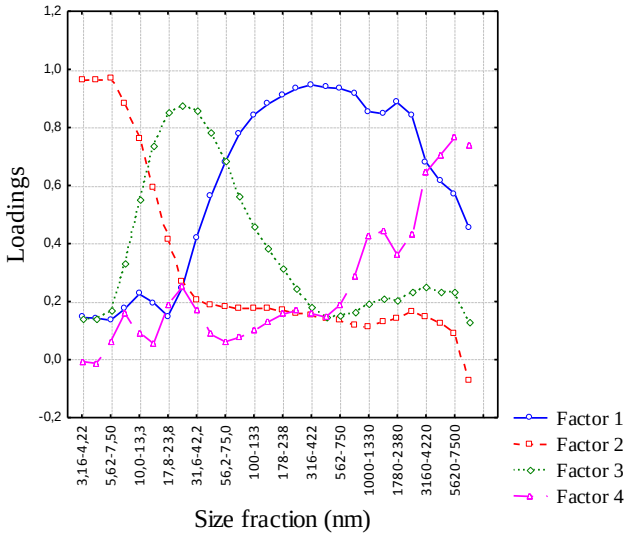

Figure 1. Results of factor analysis on a non-event period (12.12.2011-16.01.2012)

The factor analysis of nucleation periods revealed five factors. Nucleation mode was divided into three components; accumulation mode and coarse mode were also detected. The three factors in the nucleation mode were only present during nucleation events. These three modes can be linked with particle formation and growth from exhaust gases of traffic. Factor 2 on figure 2 shows accumulation of particles after growth processes and factor 1 is most likely connected to primary sources.

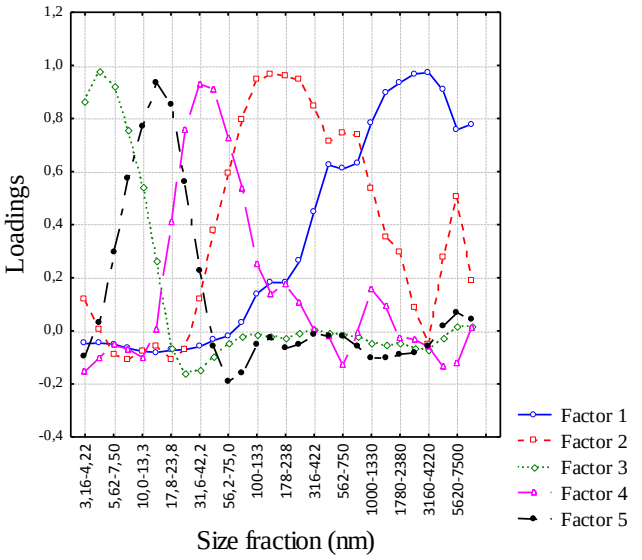

Figure 2. Results of factor analysis on nucleation event periods.

Factor analysis has previously been used to describe rural aerosol in North Estonia (Pugatšova, 2004) and urban air in other countries. However, it has rarely been used on multi-channel data. EAS measurements could also be performed with very high temporal resolution, to study aerosol distribution and development processes even in more detail in the future.

Hygroscopic properties of the anthropogenic aerosol in the Po-Valley, Italy

I. Pap[1], J.Größ[1], A. Hamed[1, 2], W. Birmili[1] and A. Wiedensohler[1]

[1]Department of Physics, Leibniz Institute for Tropospheric Research, Leipzig, 04318, Germany
[2]Department of Applied Physics, University of Eastern Finland, Kuopio, P. O. Box 70211, Finland

Keywords: hygroscopic growth, hydrophobic, hydrophilic, hygroscopicity parameter

Presenting author email: pap@tropos.de

The High Humidity Tandem Differential Mobility Analyzer (HH-TDMA) is designed to measure the hygroscopic growth factors (HGF) at sub-saturated conditions (up to 99 % RH) under highly temperature stabilized conditions. The HH-TDMA was employed to measure the water uptake of aerosol particles in the Po Valley region, which give us a good opportunity to measure the hygroscopic behaviour of these particles during the summer time. The campaign was performed in frame of the EU-PEGASOS project. The measurements were taken in the period at the station San Pietro Capofiume (SPC) in the time period from June 9 to July 10, 2012. HGF probability functions were calculated for four particle sizes (75, 100, 200 and 300 nm). These particles were measured at different RH: 90, 93 and 95.5 %. The HGF probability functions contain a hydrophobic and a hydrophilic mode, leading to a bimodal character in 62 % of the cases, during the whole measured period.

In order to describe the hygroscopic properties of particles, the hygroscopicity parameter κ was calculated using the Köhler theory. This was achieved by using the equation given by Petters and Kreidenweis, 2007. The hygroscopicity parameter κ was applied to all measured HGF probability functions.

The value of parameter κ classifies a certain aerosol fraction as hydrophobic or hydrophilic, similarly to the classification according to HGF. In general, a value close to 0 indicates that the aerosol fraction is hydrophobic. The aerosol fraction for 100 nm particles at 90 % is hydrophilic for a κ value higher than 0.2 (Liu, 2011).

The averaged HGF probability functions and the averaged κ probability functions over the measured period are shown in Figure 1. The distribution is shown for three different RHs for 200 nm particles. The distribution of κ is similar to the HGF distribution. Both, a hydrophilic and smaller, hydrophobic mode can be seen here. The difference between the HGF and the κ distribution is that, in the GF distribution, the hydrophilic peak is shifted with the change of RH, while this shift is negligible in the κ distribution. Due to these results, it can be concluded that κ is relatively constant with relative humidity, meaning no further material gets in solution with increasing RH.

The time series, shown in Figure 2, indicate that the number fraction of hydrophobic and hydrophilic particles varies greatly during the day and the external mixture of 100 nm particles changes drastically. More analysis on hygroscopicity at the SPC station related to the black carbon mass concentration will be presented in our studies.

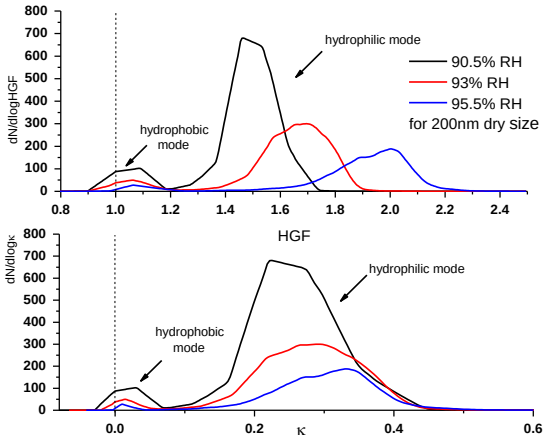

Figure 1: The averaged κ and HGF distribution for 200 nm at different RH. The black, red and blue line represents the particle number concentration density at 90.5, 93 and 95.5 % RH. The dashed line represents the original dry particle state.

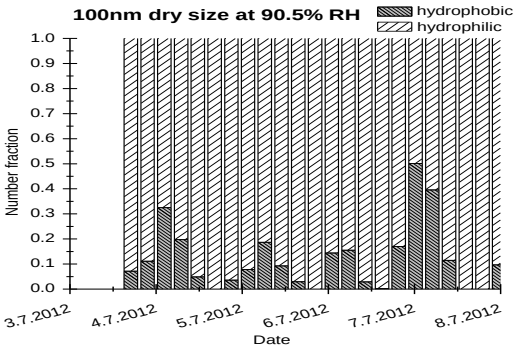

Figure 2: The number fractions of hydrophobic and hydrophilic particles of 100 nm particles at 90.5 % RH. Gray and brighter boxes represent the hydrophobic and hydrophilic number fraction

Rainout, washout and dry deposition contributions to the total deposition flux of heavy metal aerosol onto surfaces of a small urban catchment (Pin Sec, Nantes)

Keywords: rainout, washout, dry deposition, heavy metals.

Pollutants associated to atmospheric particles in urban areas throughout the world have been characterized in many studies. Pollutant sources are either natural (e.g. volcanoes, forest fires) or anthropogenic (traffic, industries, central heating). The nature of surfaces as well as weather conditions and atmospheric turbulence influence the aerosol deposition. Previous studies in Nantes (France) on the Pin Sec catchment allowed the estimation of wet and dry atmospheric deposition fluxes. Thanks to these results further studies can now estimate the origin of atmospheric heavy metals by distinguishing rainout (long range transport) and washout (local scavenging) processes (Bertrand *et al.*,2008). The objective of this communication is to present the rainout, washout and dry deposition contributions to the total deposition flux of heavy metal aerosol (Zn, Cu, Ni, Pb and V) on the Pin Sec catchment.

The experiment was conducted between the 1st of September 2010 and the 31st of August 2011. The dry deposition of heavy metals was estimated by Percot *et al.* (2012) using the dry deposition velocity of the tracer Beryllium 7 measured on urban surfaces by Roupsard *et al.* (2012). Regarding monthly wet deposition, the flux is calculated as the ratio of the mass of pollutants collected in a covered pluviometer. The rainout/washout ratio was determined by the Laguionie *et al.* (2013) method. This method uses monthly integrated data: heavy metal elements concentrations in rainwater and in aerosol particle sampled by Partisol ™, scavenging coefficient Λ (s^{-1}) determined by Laguionie *et al.* (2011) method, reload rate of the local atmosphere in heavy metal elements, and meteorological parameters.

In average, over the 10-month survey period, heavy metals (except for vanadium and lead) are mainly deposited by rainout process, showing evidence of long range sources (Figure 1). The rest of the atmospheric deposition is composed of dry deposition and washout which is the lowest part of deposition (4 % for zinc and nickel to 14 % for lead). These results are in good agreement with results of source emission showing that there is no evidence of emission of pollutants from local activity (traffic, industry,…) (Percot, 2012). Lead behaves differently: dry deposition and washout contributions (respectively 60 % and 26%) suggest the existence of a local source.

The consequences of these results and perspectives will be further discussed at the conference. Further experiments will be lead to better understand the impact of particle size and hygroscopicity on the scavenging coefficient.

This work was supported by the French National Research Agency (INOGEV research program), the French Institute of Science and Technology for Transport Development and Network and the French Institute of Radioprotection and Nuclear Safety.

Continuous Measurements with high Time Resolution of Semi-Volatile Components in the Atmospheric Aerosol

H. Grimm[1], M. Pesch[2], M. Richter[3], A. Comouth[4]

Grimm Aerosol Technik GmbH & Co. KG, 83404 Ainring, Germany
Keywords: aerosol instruments, atmospheric aerosol, PM10, semi volatile components (SVC)
Presenting author email: mp@grimm-aerosol.com

EU limit and guideline values for the protection of human health (DIRECTIVE 2008/50/EG) demand a continuous monitoring of the atmospharic aerosol, more precisely its fine dust fraction PM10 and PM2.5. The tresholds are being exceeded in many areas in Europe, primarily in congested urban areas, where many people are affected. Fine dust is rated harmful to health which therefore strongly needs action to be taken, in order to minimize this exposure.

The EU regulates, when exceeding the set limit and guideline values, to develop clean air plans, in which efficient reduction strategies have to be enlisted. These plans are based upon cause analysis, which assigns certain dust exposure to certain sources.
For monitoring the thresholds, many measuring technologies proved well, whereas in the past years especially the optical measuring technology gained in importance. The optical detection of the aerosol enables a non-contact, continuous, and temporally high resolved measurement of the aerosols in real-time, where next to the PM fractions also particle size as well as particle counts can be determined.

A significant part (up to 60% of the particle mass) of the atmospheric aerosol is determined by semi-volatile components (SVC), which varies depending on location and season. This meaningful fraction of the SVC impedes the exact determination of the aerosol mass: The volatile components get lost, when heating the aerosol while sampling, e.g. when using a heated sampling probe for drying the sample, or when dust clogged filters remain several days without cooling inside the sampler.

Thus it is important to determine the volatile fraction of the aerosol for two reasons: On the one hand this fraction is very helpful for the source identification of the dust, because different sources create different SVC fractions, and on the other hand it is very important to measure the SVC for comparing the results of different fine dust measuring devices, which reveal the difference in their losses of SVC while measuring.
Thus the gas-particle-conversion from nitrogen oxides to nitrates and ammonium compounds, or the condensation from gaseous emitted carbon hydrides leads to organic aerosols.

The company Grimm Aerosol Technik GmbH & Co. KG developed a compact, mobile, and highly efficient measuring instrument, which enables the continuous determination of the volatile fraction within the atmospheric aerosol. This device is in possession of two sampling probes with complementary characteristics:
One probe dries the particles by a nafion membrane in such a way, that no volatile aerosols get lost, while in the other probe the aerosol can be heated to a temperature of up to 300 °C. The aerosol is alternating being sucked through the sampling probes and subsequently analyzed inside the same optical chamber. This means, that in one interval all aerosol are analyzed and in the other one only the thermically stabilized aerosols. Forming this difference of both intervals, a determination of the volatile fraction is possible. There the volatile components are classified simultaneously into 31 size channels from 250 nm up to 32 µm, as well as a simultaneous detection of the PM10, PM2.5, and PM1 fractions (figure 1).

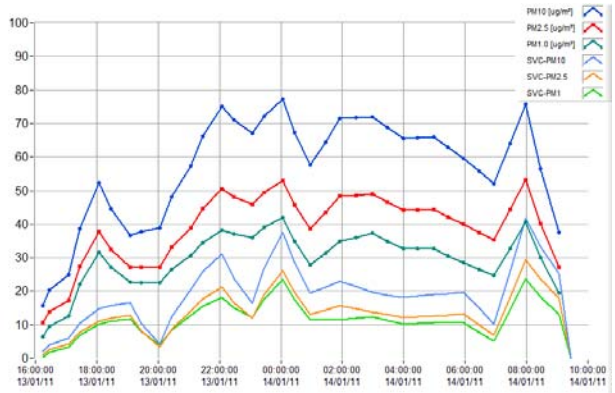

Figure 1: Temporal course of the PM fractions and its volatilecomponents at 100°C

The temporal resolution is 6 seconds. By limiting the size channels, measurements can be executed at 1 Hz, which enables the application of the Eddy-Correlation calculation for determination of aerosol flows.

Measurements at different locations prove the high temporal and spatial variability of the volatile aerosol components, and moreover provide valuable indication for the causes of fine dust exposure as well as a better understanding of the aerosol formation within the lower atmosphere.

The impact of the new guidelines for aviation introduced in Europe during some volcanic eruptions and the consequences were studied by the EU. On requests by several users in Europe we build a compact, light weight flying device for aircrafts to monitor the movement of the ash cloud as event by using various instrumentations as remote sensing techniques.

Our contribution to this concept was to build a fast monitoring sensor measuring the Aerosol
.

:

size distribution in the NANO and MICRO size range at any altitude and air speed, so that ash plume model forecasts could be evaluated against actual remote sensing data based on satellites and ground-based instruments.

The paper will describe the technology, evaluation tests and the experiences made at different installations allowing volcanologists, chemists and geological expert to monitor all of over Europe for disciplines.

Primary Biological DNA Database

D. Pickersgill[1,2], J. Wehking [2], I. Müller-Germann[1,2], U.Pöschl[1], V.R.Després[2]

[1]Multiphase-Chemistry, Max Planck Institute for Chemistry, P.O. Box 3060, D-55020 Mainz, Germany
[2]General Botany, Johannes Gutenberg University, Saarstraße 1, D-55099 Mainz, Germany

Keywords: Biological Aerosol, database, pollen

This work focuses on the design and implementation of a Database (DB) for DNA fragments isolated from primary biological aerosol particle (PBAP) samples (Després et al. 2012 and references therein), along with all relevant information such as taxonomic, sampling, locational and meteorological information. A data structure was designed, according to the relational model (Codd 1970), that maximises flexibility, eliminates data redundancy and logically links all relevant data needed for analyses. The data structure was implemented using the open-source relational DB management system (RDBMS) MySQL.

For testing and subsequent analysis, data from 1179 plant sequences were imported, that were sampled in Mainz from March 2006 to April 2007. The sequences were attributed to 158 plant OTUs (Blaxter et al., 2005) which were used for taxonomic identification. Taxonomic tree information for the OTUs was stored according to the Nested-Set-Model (Celko, 2004).

Using SQL-queries, the plant data-set was analysed. Generalised queries were written that calculate Chao1, Shannon index, Shannon evenness, Simpson index, Simpson Diversity and the normalised species richness for the meteorological seasons including the normalised standard error. Using the generalised queries, values were extracted for various subsets of the data-set. Three methods were developed to normalise OTUs found on a sample, which were used for statistical analysis (Pickersgill 2013).

In addition data from a literature search concerning the discovered plant species was imported e.g. the pollen size, pollen count, or flowering period. This allows in-depth analysis e.g. the comparison of pollen size and species detection on coarse vs fine particle filter samples with a cut-off at 3 µm. Even though the literature shows that the pollen size starts at ~20 µm for the smallest pollen (Fig. 1), 42% of the total OTUs from Mainz were sampled on the fine particle filters. We assume that this plant-DNA originates either from other fragmented plant tissues or from pollen that have burst. This is interesting, as by this bursting process respirable allergens become free and cause pollinosis in humans.

There is a need for using DB management systems to research and analyze the growing data set under the background of pollinosis and other interactions of bioaerosols with the biosphere and the atmosphere.

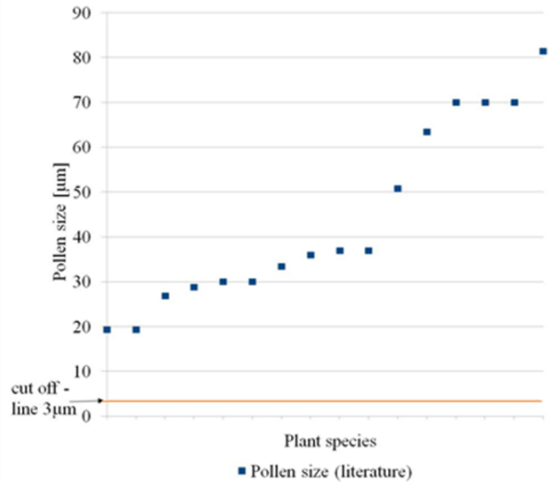

Figure 1. Pollen size (blue) of analyzed plant species of a fine particle filter with a cut-off of 3 µm (orange) in Mainz, Germany.

Abstract

Climate change is one of the most important global environmental problems affecting natural ecosystems, food production, availability of fresh water as well as human health.(1) In acoustic levitation, a sound wave is generated between a piezoelectric transducer and a flat or concave reflector; therefore, by altering the distance between transducer and reflector a standing wave can be created and small samples of solids or liquids can be levitated.(2) This study has been conducted to improve our understanding of the reactions of O_3 and NO_3 with a range of terpenes found in the Earth's atmosphere and of the formation and properties of associated organic aerosols. Combination of acoustic levitation with gas chromatography-mass spectrometry (GC-MS) has been achieved for the first time using headspace solid-phase micro-extraction (HS-SPME); this combination leads to identification of several products, during reaction of oxygen, ozone and nitrate radicals with acoustically levitated droplets of α-pinene and d-limonene. The experimental set-up is illustrated in Fig.1.

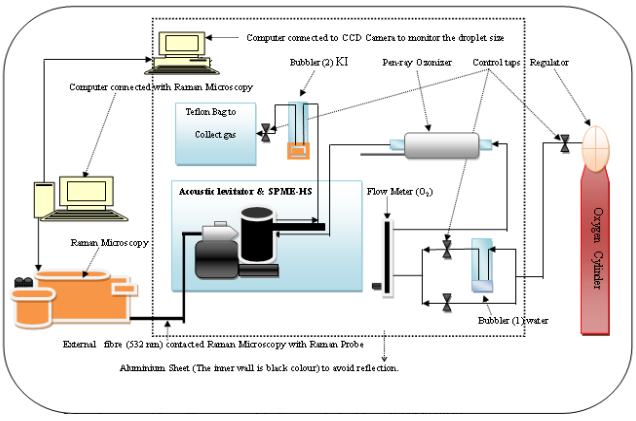

Fig.1: Experimental set-up for the acoustic levitator with HS-SPME-GC-MS analysis. The following conditions were employed: 174 mlmin^{-1} flow of N_2, 5 min extraction time, and using a 100-µm polydimethylsiloxane (PDMS) coated fibre.

Oxidation by oxygen and ozone of acoustically levitated droplets of α-pinene and d-limonene has been studied in an environmental chamber that allowed control of the gas-phase surroundings and relative humidity.
Several products for the reaction α- pinene with O_2 and O_3 could be identified mostly by comparison with reference samples in the same conditions including acetone, α-pinene epoxide, β-pinene, pinocarveol, verbenol, myrtenol, verbenone, pinenol, norpinone, norpinonaldehyde, and pinonoaldehyde. For the reaction of d-limonene with O_2 and O_3 the identified products are d-limonene oxide, carvone, carveol, limononaldehyde, carveol, keto-limononaldehyde, and limononic acid (see examples in Fig. 2 and Fig. 3).

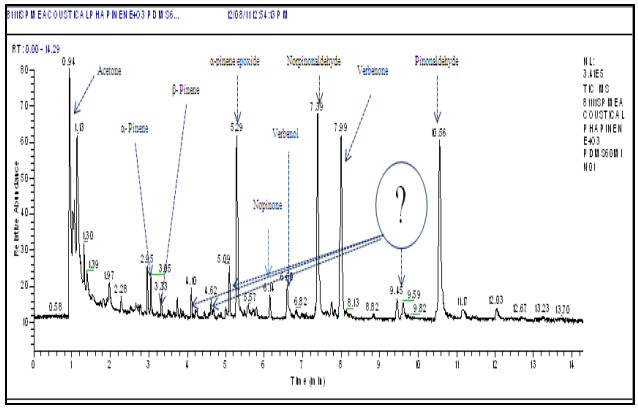

Figure 2: Products identified by HS-SPME-GC-MS for an acoustically levitated droplet of α-pinene after oxidative ageing (only GC trace shown for visual clarity).

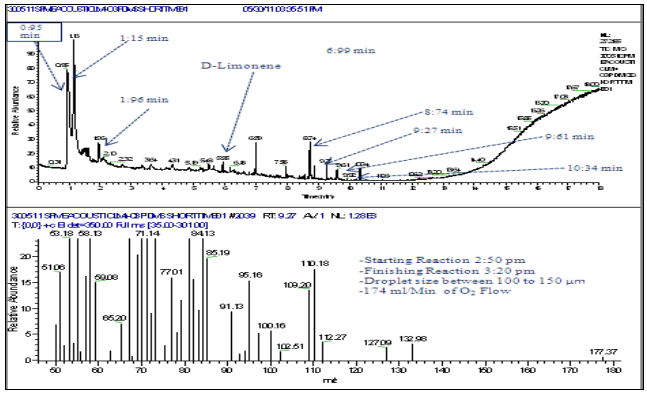

Fig. 3: Products identified by HS-SPME-GC-MS for a levitated droplet of d-limonene after oxidative ageing.

The variation of the total aerosol particle number concentration in fog in southern and south-eastern regions of the Baltic Sea

K. Plauškaitė[1], N. Špirkauskaitė[1], T. Zielinski[2], T. Petelski[2] and V. Ulevicius[1]

Keywords: aerosol particle number concentration, marine boundary layer, coastal site, fog.
Presenting author email: kristina@ar.fi.lt

The objective of this study was to determine the effect of air masses and meteorological conditions on the variation of total aerosol particle number concentration in marine boundary layer and simultaneously at the coastal site (Preila Environmental pollution research station, Lithuania) during the fog in the spring and autumn.

Measurements were performed during three cruises of r/v "Oceania" (Institute of Oceanology of PAS) in 2008 – 2010 mostly in southern and south-eastern parts of Baltic Sea. The total aerosol particle number concentration over open sea and at the Preila station was measured by using CPC (cut-off size 4.5 nm). Additionally, at the Preila station was measured aerosol size distribution by SMPS for the range 9 – 840 nm. To analyze transport pathways of air masses arriving at investigation sites (open sea and Preila station) the 72 hours air mass backward trajectories at 50, 500, 1000, 2000 and 2500 m heights above the sea or ground levels were calculated using the HYSPLIT-4 model, developed by NOAA/ARL (http://www.arl.noaa.gov/ready.htm, 2008). Meteorological parameters (air temperature, wind speed and direction, relative humidity) were measured at the Preila station and by the on-board system.

The analysis of data showed, that the variation of the total aerosol particle number concentration both in marine boundary layer and coastal zone (Fig. 1B) was smallest during evaporation fog, which was created by cold Polar air passing over warmer sea water. This type of fog is the most localized form (Heo *et al*, 2010) and was observed in Gulf of Gdansk during cruise on 26 September 2009. On the same time at the coastal site aerosol particle number concentration was typical of clean polar air mass. During the cruise on 22 – 23 September 2008, when fog was observed in more polluted polar continental air arriving from north-eastern directions and entering coastal site and the marine boundary layer, the aerosol particle number concentration over the open sea was similar to the case of 2009 but with higher variation of the concentration. However, at the same time at the aerosol particle number concentration at the Preila station was similar to the open sea concentration but with smaller variations in time (Fig. 1A).

The long continuous advection fog (~15 hour), which occurred when warm air mass from south-eastern direction passed over a cool water surface (Baltic Sea), was observed during cruise on the 7 – 8 April 2010 (Fig. 1C). The fog was observed simultaneously over open sea and coastal site causing the similar variations of aerosol particle number concentrations (the values of correlation coefficient were 0.79 and 0.82). Especially interesting phenomena is that during fogs, which were formed in calm anticyclone weather conditions, the total aerosol particle number concentrations over open sea during all cruises were about 4000 cm^{-3} level and may be conditioned by the specific environment of the Baltic Sea (e.g., 7‰ water salinity, typical amount of various phytoplankton (Chl-a (algal biomass) concentration varied from 3 to 30 mg m^{-3})) as a source of particles condensation nuclei in marine boundary layer.

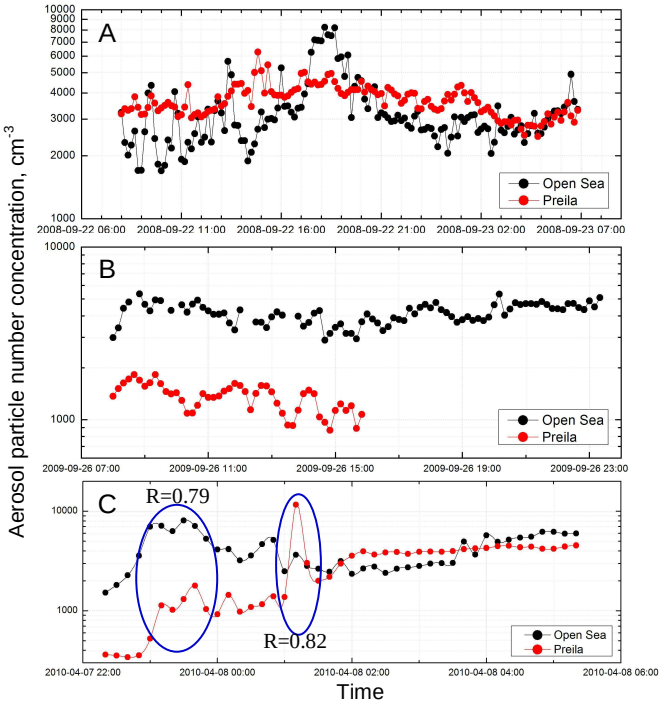

Figure 1. Variations of total aerosol number concentration during fog in marine boundary layer and at the coastal site in 2008 – 2010.

Autofluorescence of atmospheric bioaerosols – studies on biofluorophores and biological standard particles

C. Pöhlker[1], J. A. Huffman[1,2], J.-D. Förster[1], U. Pöschl[1]

[1]Biogeochemistry Department, Max Planck Institute for Chemistry, Mainz 55020, Germany
[2]Department of Chemistry and Biochemistry, University of Denver, Denver, Colorado 80208, USA
Keywords: Bioaerosols, Fluorescence, Pollen.
Presenting author email: c.pohlker@mpic.de

Primary biological aerosol particles (PBAP) such as pollen, fungal spores, bacteria, biogenic polymers and debris from larger organisms are known to influence atmospheric chemistry and physics, the biosphere and public health. PBAP account for up to ~30% of fine and up to ~70% of coarse particulate matter in urban, rural and pristine environment and are released with estimated emission rates of up to ~1000 Tg/a (Elbert et al. 2007).

Continuous measurements of the abundance, variability and diversity of PBAP have been difficult until recently, however. The application of online instruments able to detect autofluorescence from biological particles in real-time has been a promising development for the measurement of PBAP concentrations and fluxes in different environments (Huffman et al. 2010; Pöschl et al. 2010). The detected fluorescent biological aerosol particles (FBAP) can be regarded as a subset of PBAP, although the exact relationship between PBAP and FBAP is still being investigated.

Autofluorescence of FBAP is usually a superposition of fluorescence from a mixture of individual fluorescent molecules (fluorophores). Numerous biogenic fluorophores such as amino acids (e.g., tryptophan, tyrosine), coenzymes (e.g., NAD(P)H, riboflavin) and biopolymers (e.g., cellulose) emit fluorescent light due to heterocyclic aromatic rings or conjugated double bonds within their molecular structures. The tryptophan emission peak is a common feature of most bioparticles because the amino acid is a constituent of many proteins and peptides. The influence of the coenzymes NAD(P)H and riboflavin on the autofluorescence of bacteria can be regarded as an indicator for bacterial metabolism and has been utilized to discriminate between viable and non-viable organisms (Lakowicz 1999). However, very little information is available about other essential biofluorophores in fungal spores and pollen.

In order to better understand the autofluorescence behavior of FBAP, we have used fluorescence spectroscopy and fluorescence microscopy to analyze standard bioparticles, atmospherically relevant chemical substances and ambient aerosol samples (Pöhlker et al. 2012). In particular, we focused on pollen as an adequate bioaerosol type for this kind of explorative studies (Pöhlker et al. in prep.). Our aim is (i) to give a clear and general picture on the autofluorescence properties of native pollen and (ii) to illustrates, by means of *one* standard particle type, how offline fluorescence techniques can support the application of LIF in ambient air. Moreover, pollen represents atmospheric particles of high relevance, particularly due to its high allergenic potential with severe social and economic impacts. We suggest that our results can support the development and application of autofluorescence-based detectors for a specific monitoring of allergenic pollen in the atmosphere.

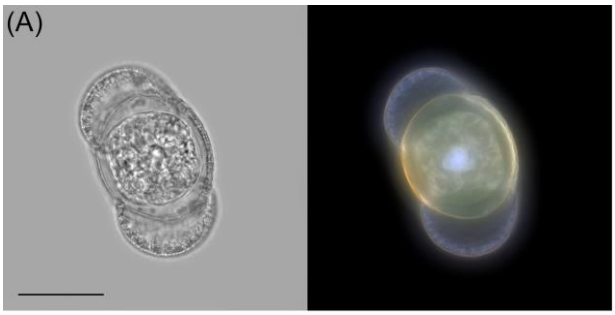

Figure 1. Microscopy images of *Pinus sylvestris* pollen in bright field (left) and fluorescence (right) mode. Micrographs illustrate the diverse autofluorescence properties with contributions from cell wall, cytosol, and organelles. Scale bar = 30 µm.

Observations of cloud effects on aerosol light absorption and scattering

[3]Finnish Meteorological Institute, Research and Development, P.O.Box 503, FI-00101 Helsinki, Finland
Keywords: aerosol cloud interaction, atmospheric aerosols, optical properties, scavenging.
Presenting author email: Harri.Portin@fmi.fi

The direct effect of aerosols to radiative forcing arises from light extinction by aerosol particles, i.e. light scattering from and absorption to the aerosols, and it still has a great uncertainty. Evaluation of its magnitude is complicated, because the optical properties depend on the wavelength of the incident light and the angular distribution of the scattered light, which, in turn, depends, e.g., on the size, concentration, and chemical composition of the aerosol particles.

The Puijo measurement station on the top of an observation tower (306 m a.s.l. and 224 m above the surrounding lake level) near the town of Kuopio in Finland has provided continuous data on aerosol-cloud interactions since 2006. Since then the station has been covered by clouds 15 % of the time and is occasionally influenced by e.g. sulphurous compounds and black carbon emitted from local sources. The former are good scatterers of light and the latter absorbs light efficiently.

With a special inlet setup (total and interstitial inlets) and a switching valve system we are able to separate the activated particles from the interstitial (non-activated) particles. This enables us to define the activation properties for aerosol size distribution between 3–800 nm, measured with two differential mobility particle sizers, light scattering at the wavelengths of 450, 550, and 700 nm, measured with a nephelometer (TSI Model 3563) and light absorption at the wavelength of 670 nm, measured with a Multi-Angle Absorption Photometer (Thermo Model 5012).

The level of cloud scavenging depends not only on the aerosol size but also its chemical composition and atmospheric age. We have found that during a cloud event the scattering and absorption values for non-activated particles compared to those for the activated particles are sometimes smaller and sometimes not (Leskinen *et al.* 2012). The decrease is, on an average, -22 % for absorption and -76 % for scattering.

The stronger decrease in scattering may be due to the fact that the absorptive material, e.g. fresh soot, is generally hydrophobic and therefore inhibits activation.. This results in a decrease in the single scattering albedo (SSA), which is the ratio of scattering to extinction (scattering + absorption). The SSA determines whether an aerosol layer causes net heating or cooling. For example, during two cloud events the SSA dropped from its initial value of 0.80–0.85 to as low as 0.4–0.5, on an average (Figure 1). A similar, but not as intensive, decrease in the SSA was observed by Berkowitz *et al.* (2011) in a foggy situation.

The scavenging is less efficient when the wind blows from the direction of local pollutant sources (the first cloud event in Figure 1) than when it blows from a cleaner sector with no local sources (the second cloud event in Figure 1). A similar observation was done by Sellegri *et al.* (2003) who concluded that the scavenging efficiency in clouds is enhanced by aging of organic species and subsequent mixing.

After the second cloud event the incoming air was clean and the scattering and absorption coefficients decreased to the same levels as during the second cloud. The low SSA values can be explained by the uncertainties in the low scattering and absorption coefficients and by the sensitivity of the SSA to the scattering coefficient value, especially in dry conditions.

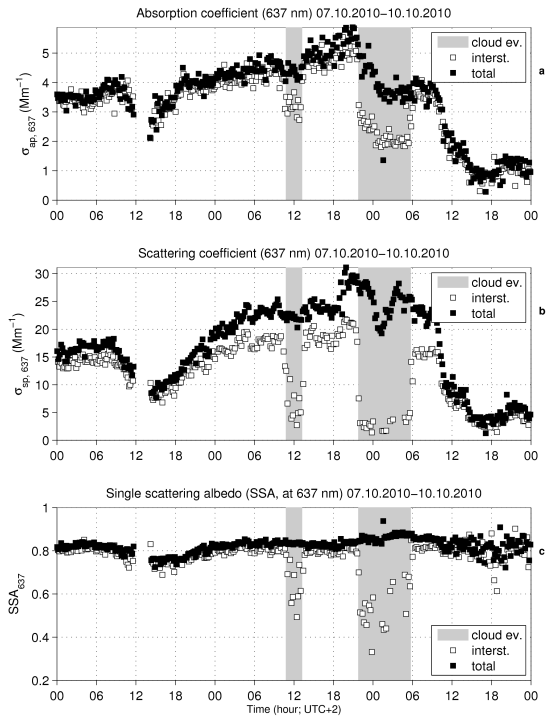

Figure 1. The evolution of (a) aerosol light absorption, (b) light scattering, and (c) single scattering albedo (SSA) around cloud events at Puijo in October 2010.

Keywords: PM_{10}; Saharan dust events; Volos; Greece.
Presenting author email: giproias@prd.uth.gr

Volos, a coastal medium-sized city in the region of Thessaly extended along the northern part of the Pagassitikos Gulf at the eastern seaboard of Central Greece, is among the cities which suffer from the air pollution in Greece. The case of Volos is an interesting example, where in the last decades the urbanization and the increased industrialization have resulted in the degradation of the air quality within the area, triggering health impacts. Meteorological factors play an important role in the air pollution development, while the complex topography of Volos exacerbates air pollution episodes.

In this study, the relationships between PM_{10} (particulate matter with diameter less than 10 μm) and meteorological parameters such as wind speed, relative humidity and air temperature have been analyzed from 2005 to 2009 on the basis of 24-hour continuous measurements. According to the results obtained from the multiple linear regression analysis, there is a strong relation between meteorological parameters and the particulate matter (Table 1) concentrations in Volos city. More specifically, the PM_{10} concentrations remain above the European Union (EU) limit values (Figure 1) for the whole part of the examined period (2005-2009) and this can be attributed to anthropogenic (industry and car traffic) and natural sources (Saharan episodes) of particulate pollution. The percentage of the total variance of PM_{10} concentrations explained by a single meteorological parameter for the cold period gets up to 10.6% (r^2) whereas, for the 5-year period, up to 6.8%. On the contrary, for the warm period it appears that the percentage of the total variance of PM_{10} concentrations explained by a single meteorological parameter gets up to only 2.5%.

Table 1. Pearson's correlation coefficients between the mean daily PM_{10} concentrations (μg/m^3) and the three meteorological parameters. Statistically significant values (at the 99% confidence level) are presented in bold.

Period	WS (m/s)	T (°C)	RH (%)
2005-2007	**-0.260**	**-0.184**	**-0.213**
Cold	**-0.326**	-0.092	**0.243**
Warm	**-0.159**	0.107	-0.078

Moreover, the calculation of the 72-hour air mass back trajectories during (eight) Saharan dust events, took place within the examined period, was carried out by applying the HYSPLIT 4 model of Air Resources Laboratory of NOAA for three different levels: 500, 1500 and 4000 m (a.m.s.l.). It is worthy to remark the high PM_{10} values observed, indicating the contribution of such natural events in exacerbating the air quality in the area of Volos.

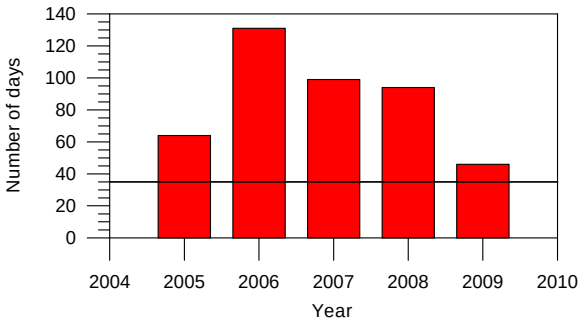

Figure 1. Temporal evolution of annual exceedances of mean daily PM_{10} concentrations at the city of Volos (2005-2009; the horizontal line indicates EU limit).

Study of the Impact of the Natural Production, in the Mediterranean Sea, of Coastal Marine Aerosols on the Dynamics and Microphysical Behavior of a Convective Cloud

R. Merrouchi[1], J. Piazzola[2], M. Chagdali[3] and S. Mourdane[3]

[1]National Meteorological Service of Morocco, BP 8106 Oisis. Casablanca, 20000, Morocco

Keywords: Clouds Coastal Marine Aerosols
Presenting author email: rabia.merrouchi@gmail.com

The coastal marine area represents a specific zone for cloud formation. Aerosols caught in updrafts in these areas may have a mixed origin: sea spray aerosols punctually generated at the sea surface are added to a continental contribution issued from natural and/or anthropogenic sources.

The aerosol mixture in coastal zones is strongly related to the changes in the wind direction that could be in turn accompanied by variations in meteorological parameters.

To study the impact of marine aerosols, especially those generated in coastal areas, on the dynamics and microphysical behavior of the clouds, two numerical models were coupled. The first, calculates the coastal marine aerosol spectrum that could be generated under a given weather condition at the sea surface. The predicted spectrum is then introduced, as initial aerosol spectra, to a cloud model with a detailed microphysics.

Design of Numerical Experiments

The cloud model ExMix (External Mixture) has been developed to study mixed-phase clouds by integrating a detailed microphysics of the whole process of formation, growth and precipitation (Monier et al, 2006). EXMIX is dedicated to the different mechanisms behind the cloud formation and decay. The microphysics processes governing the growth of the water droplets inside the cloud depend on both the initial size spectrum and the chemical composition of aerosols caught in the updrafts feeding the cloud.

To include coastal effects in the aerosol model for the prediction of aerosol concentrations, Piazzola et al, (2003) proposed the coastal Mediterranean aerosol model (MEDEX) based on an extensive series of measurements on the island of Porquerolles (off the French Mediterranean coast, located at about 5 km from the coastline). The main inputs of the coastal Mediterranean aerosol model are both the wind speed and the fetch. The Mediterranean coastal aerosol model is a modification of the Navy Aerosol Model (NAM) developed by Gathman (1983) and it is formulated analogously to the model Medex on the basis of an aerosol data set acquired on the island Inisheer.

The simulations performed have focused on a convective cloud (mixed phase) using three distinct initial aerosols spectra of different origins: the first concern an unpolluted continental aerosol spectrum observed in Puy de Dome-France. The second one is for marine aerosol spectra developed by Jaenicke (1988) and the last one is produced by the MEDEX model.

Results:

The transition from a continental aerosol spectrum to a marine aerosol spectrum is synonymous to the introduction of aerosol particles of large size. The impact of such change in the initial spectrum of aerosol is much felt in terms of dynamic and microphysical responses of the cloud. The results obtained show that in presence of marine aerosols, some microphysical properties of the cloud evolution as well as the conditions for triggering rainfall are affected, and hence, the collected quantities on the ground. In particular, results indicate that precipitations are formed earlier, at lower altitudes and induce a larger rain accumulation at the surface. Moreover, simulations also showed pronounced changes when taking into account the natural production of coastal marine aerosols with more pronounced changes inducing greater amounts of water contents within the cloud, and hence, more important rain accumulation on the ground (Figure 1).

Black carbon aerosol concentrations and mixing state in Pallas, Finland

T. Raatikainen[1], D. Brus[1], A.-P. Hyvärinen[1], J. Svensson[1] and H. Lihavainen[1]

[1]Finnish Meteorological Institute, Helsinki, Finland
Keywords: SP2, black carbon, soot particles, aerosol coating.
Presenting author email: tomi.raatikainen@fmi.fi

Black carbon (BC) aerosols have various climate effects. In addition to directly absorbing solar radiation, they have an effect on aerosol-cloud interactions and snow and ice albedo. Single Particle Soot Photometer (SP2) detects BC by using laser-induced incandescence and non-absorbing particles are identified from the scattered light (Stephens et al, 2003). Absorbing particles, with or without coating, are quickly heated to the incandescence temperature and the resulting peak signal, which is seen before evaporation, is proportional to the BC mass. Sizes of the purely scattering particles can be calculated from the peak intensity of the scattered light, which is seen when the particle is at the centre of the laser beam. However, particles containing both BC and scattering material heat up rapidly so that the scattering material evaporates before the centre of the laser beam. In this case, the initial scattering particle size can be extrapolated.

Two commonly used methods to extrapolate scattering sizes for evaporating particles are Leading Edge Optimization (LEO; Gao et al, 2008) and Normalized Derivative Method (NDM; Moteki and Kondo, 2008). The NDM is computationally demanding, and both methods can fail when, for example, the sample flow rate fluctuates. Significant flow rate fluctuations were observed in the SP2 measurements conducted at Pallas station in northern Finland during winter 2011-2012. To improve the coating thickness calculations, we have improved the NDM method so that the computationally heavy a priori estimate of the scattering signal is replaced by a linear fit to the normalized derivative and a fast posteriori likelihood test.

Figure 1 shows number concentrations of the different particle types. Concentrations are low in this pristine environment, but about 10 % of the observed (150-500 nm) particles contain BC. In addition, practically all BC particles are coated.

Figure 2 shows coating thickness distributions based on the original scattering sizes and those calculated with LEO, NDM and the new method. Due to the fluctuating flow rate, the NDM often fails to find a solution. The LEO method can find a solution, but it could overestimate coating thickness. The new method finds a reasonable solution for most particles (4715 of 5973) and the results show that most particles are thinly coated (68 % have less than 50 nm coating). This finding is in good agreement with the observation that 73 % of these particles experienced rapid coating evaporation determined from the lag time between scattering and incandescence peak signals. Further calibration experiments with mixed particles will be used to show that the new method finds the correct scattering size.

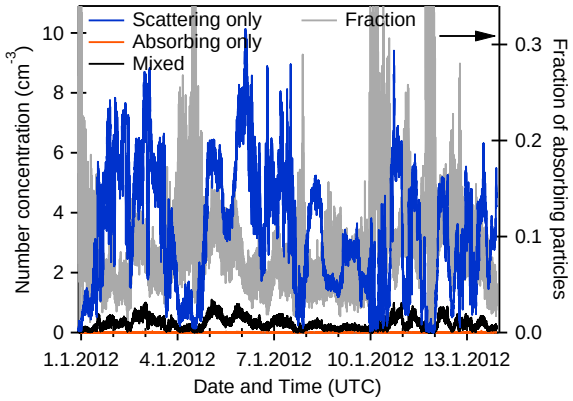

Figure 1. Total concentrations of scattering, absorbing and mixed particles from the 150-500 nm size range, and the fraction of absorbing particles.

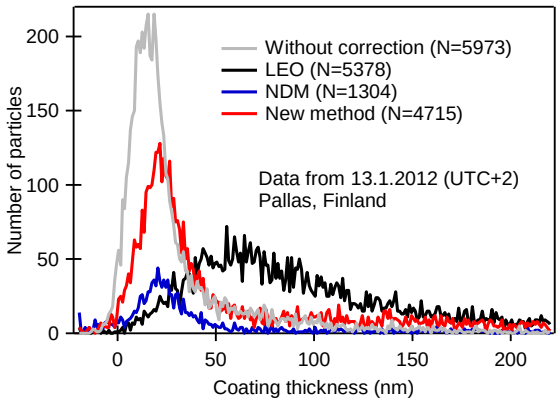

Figure 2. Coating thickness distributions for mixed particles which BC core diameter is 150-170 nm.

Particle emissions from bushfires extending into the rural-urban interface

F. Reisen[1], M. Bhujel[1] and P. Selleck[1]

[1]Centre for Australian Weather and Climate Research, CSIRO Marine and Atmospheric Research, Aspendale, Victoria 3195, Australia

Keywords: combustion, building materials, carbon, PAHs.

Presenting author email: Fabienne.Reisen@csiro.au

Bushfires extending into the rural urban interface (RUI) have become more common, particularly in Southern Australia, California and southern Europe and have resulted in losses of life and properties. Climate change is predicted to increase both fire severity and fire season duration while a forecasted population growth in the RUI will expose more residents and homes to an increased bushfire risk.

Bushfires can release substantial quantities of particulate matter into the air environments of communities, both nearby and distant. When bushfires extend into the RUI, vegetation fuels but also structural fuels will burn and release additional chemicals into the air which may cause an increased health risk. Currently information on the composition of emissions and smoke plumes from fires at the RUI is scarce.

In order to assess the particle emissions from fires in the RUI, small-scale fire tests using a cone calorimeter were conducted on 11 selected building and furnishing materials. Samples were collected for analysis of gravimetric mass, organic (OC) and elemental (EC) carbon and polycyclic aromatic hydrocarbons (PAHs) along with continuous measurements of CO, CO_2 and fine particles ($PM_{2.5}$).

The time series analysis of $PM_{2.5}$ showed highest emissions during combustion of polyester insulation and a wool/nylon carpet. Maximum $PM_{2.5}$ concentrations were approximately 5-8 times higher than those measured during combustion of pine. Among wood-based products, combustion of medium-density fibreboard (MDF) resulted in highest peak $PM_{2.5}$ concentrations.

Emission yields expressed as mass of compound generated per mass of material combusted were calculated for CO, CO_2, $PM_{2.5,}$ EC, OC and PAHs. Highest emission yields of $PM_{2.5}$ were measured for polyester and polystyrene, both materials emitting about 20 times more particles compared to wood. Wood-based products had the lowest $PM_{2.5}$ yields.

Wood-based materials had the lowest carbon emission yields while polyester, carpet and polystyrene had the highest carbon emission yields (approximately 10 times higher). In general there was a larger fraction of EC compared to OC, with the exception of plasterboard and polystyrene where we observed a significant OC fraction (70-98%). The presence of glues and resins in manufactured wood products also increased the organic fraction of particles.

Highest PAH yields were observed for polyester, followed by polystyrene and carpet. The wood-based products had the lowest PAH yields (Figure 1). Naphthalene made up the majority of the total PAH yields (37-90%). Other PAHs with significant contributions included phenanthrene, fluoranthene and pyrene. Benzo(a)pyrene, a known human carcinogen contributed between 0.6 and 4.2% to the total PAH yields, with the highest contribution from the combustion of polyester.

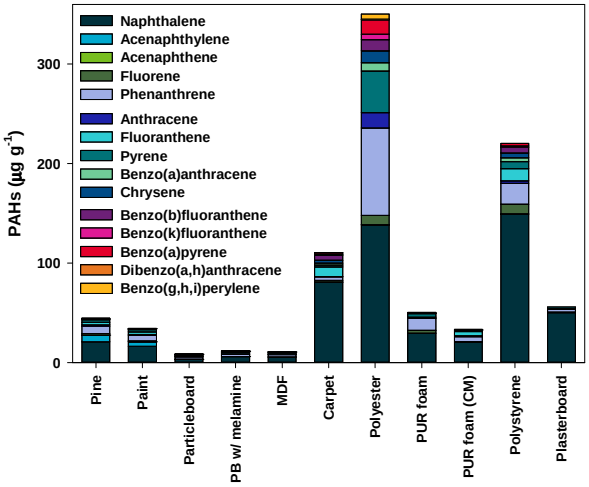

Figure 1. Distribution of individual PAHs emitted during combustion of selected materials

The study revealed that among the 11 materials that were tested, the most pollution resulted from the combustion of a wool/nylon carpet and polyester insulation. These materials ranked high in emissions of CO, particles, EC, OC and PAHs. However, as wood-based products make up the majority of mass in structures, the emissions from those materials may contribute more significantly to total emissions and hence to exposures. The emissions characterized in the small-scale fire tests will serve as input into a high time-resolution dispersion model that will enable to determine short-term modelled ground concentrations and provide an estimate of potentially hazardous exposures.

Measurements of the variation in hygroscopic growth of organic aerosol with oxygen-to-carbon ratio (O/C)

A.M.J. Rickards, R.E.H. Miles, J.F. Davies, F.H. Marshall, and J.P. Reid

Bristol Aerosol Research Centre, School of Chemistry, University of Bristol, Bristol, BS8 1TS, United Kingdom
Keywords: hygroscopicity, kappa, O/C, single particle analysis.
Presenting author email: Andrew.Rickards@bristol.ac.uk

Aerosols play a vital role in influencing radiative forcing through both the direct and indirect effect. The radiative forcing due to the indirect effect, where the aerosol droplets act as cloud condensation nuclei, has been shown by the IPCC to have an uncertainty similar in magnitude to the effect from carbon dioxide and to be of opposite sign (Forster et al., 2007). To reduce this uncertainty it is important to characterise how aerosol droplets of different compositions grow in size when exposed to increasing relative humidity (RH). This is referred to as aerosol hygroscopicity, and quantifies the equilibrium size of particles and also the extent of their light extinction.

Hygroscopic growth can be represented by a radial growth factor (GF). This is the ratio of the wet to dry particle sizes, and varies as a function of RH. To create a universal measure of hygroscopicity, Petters and Kreidenweis (Petters & Kreidenweis, 2007) have parameterised the GF in terms of a hygroscopicity parameter kappa, κ, and RH. It has been suggested in various studies that κ correlates with the magnitude of the m/z 44 ion fragment expressed as a fraction of the total organic ion signal, taken from aerosol mass spectrometry measurements. This ion fragment is usually attributed to the presence of a CO_2^+ ion, and has in turn been suggested to correlate with the oxygen to carbon ratio (O/C), indicative of the photochemical age of secondary organic aerosol (SOA) (Duplissy et al., 2011).

In this study, hygroscopicity measurements on single aerosol droplets of known composition were made using both aerosol optical tweezers (AOT) and an electrodynamic balance (EDB). The AOT allowed simultaneous determination of droplet size and refractive index at a particular RH through analysis of whispering gallery modes in the Raman spectra. This could then be converted into a radial GF. Kinetic measurements of the evaporative flux and equilibration of initially dilute droplets were made using the EDB at a well-defined RH. The mass flux equations of Kulmala et al. (Kulmala, Vesala, & Wagner, 1993) were employed to calculate the droplet water activity during evaporation, and thus deduce the hygroscopicity up to water activities approaching saturation. Initial focus was on compounds with O/C = 1, with the aim of determining how tightly constrained κ is for a fixed O/C ratio. The research was then expanded to look at compounds with a significantly higher and lower O/C to determine whether these were distinguishable from compounds with O/C = 1 on the basis of κ. Figure 1 shows an example of a GF measurement for the compound galactose.

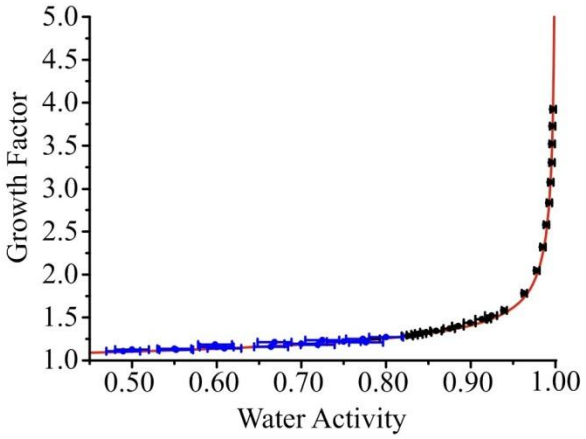

Figure 1. Experimental GF data for galactose from AOT (points below 0.8) and EDB (points above 0.8) compared to the AIOMFAC prediction (solid line).

In addition, published experimental data for κ were compiled and compared against O/C. The reported aerosol κ values include studies at subsaturated conditions and supersaturated conditions, single particle measurements and ensemble measurements, and a variety of experimental systems from field measurements to chamber SOA.

Experimental data and comparison with literature results strongly suggests the use of O/C as an indicator of κ should be more fully evaluated. O/C is a coarse parameter and ignores differences in chemical structure that may affect hygroscopicity.

The EMEP network aims at providing scientific support on atmospheric monitoring and modelling, emission inventories and projections, and integrated assessment modelling. To reach these objectives, it has encouraged long- and short-term measurement periods in order to improve the scientific knowledge on PM levels, sources and formation processes at the European scale.

Within this framework and in coordination with the existing ChArMEx French program and ACTRIS EU project, two intensive periods have been held between June 8 and July 12, 2012 for summer and January 11 to February 8, 2013 for winter. Five locations in France (cf. Figure 1) were equipped with various on-line and off-line instruments (cf. Table 1) aiming at measuring PM chemical and physical properties, as well as precursor gases (both organic and inorganic).

The main objectives of these two campaigns were to (i) provide a large quality controlled database of PM levels and chemical composition for sites under rural, mid-altitude, urban or marine influences during two contrasted seasons; (ii) measure simultaneously PM compounds and their precursors to better understand processes such as secondary organic aerosols (SOA) formation or condensation of semi-volatile species; (iii) assess the importance of vertical exchanges in the variability of PM ground levels, especially in case of dust events; (iv) determine PM sources and their relative contributions.

Preliminary results will be presented and discussed.

The authors acknowledge funding from the French Agency of Environment and Energy Management (ADEME grants 1262C0022 and 1262C0039), the MISTRALS/ChArMEx program, the EU-FP7 ACTRIS program, CTC-CORSiCA and the CaPPA project (ANR-10-LABX-005).

Context and objectives

During the Fukushima nuclear plant accident, dry deposition has contributed to transfer particulate radionuclides (Katata et al., 2011). However, only few data on dry deposition in urban environment exists in the literature and very little is known (Fowler *et al.* 2009). The dry deposition transfer is quantified with the deposition velocity V_d (m s^{-1}), ratio between the aerosol dry deposition flux F (particles m^{-2} s^{-1}) and the aerosol concentration in the air C (particles m^{-3}). V_d depends on aerosol and deposit surface characteristics, and on meteorological conditions. Beryllium 7 (^{7}Be) is a natural radionuclide that can be used as a tracer to quantify V_d of the accumulation mode of the atmospheric aerosol.

The aim of the study is to develop and acquire an experimental method to measure V_d with urban surfaces, and onto ^{7}Be as a tracer, and to measure associated meteorological parameters. Results will be analysed and compared to the data of the literature to put in evidence the principal physical phenomena of deposition on urban surfaces.

Material and method

The experimental device is set up in the suburban of Nantes (France). It is composed of an assembly support equipped with urban surfaces (vertical glass and cement facing; horizontal asphalt and synthetic grass; slate, tile and zinc angled at 30°) directly exposed to the atmospheric aerosol to sample its deposits and to measure deposition fluxes. A roller blind protect it against precipitations. A Partisol® samples atmospheric aerosol on filter to measure the concentration of atmospheric ^{7}Be. An ultrasonic anemometer measures the wind speed at 1 m from the assembly support. Meteorological parameters are measured with a meteorological station. Each experiment was carried out for one month to sample quantifiable ^{7}Be deposits. Experiments are led during 15 consecutive months. ^{7}Be is measured by gamma spectrometry at the LRC. Filters containing atmospheric aerosol are put in geometries (cylindrical boxes) and directly measured. ^{7}Be deposit on urban surfaces must be recovered by washing with an acidic solution and put in geometries (50 mL container) to be measured. A method is developed to make corrections on measured activities that are underestimated with the washing method.

Results and discussions

Fig.1 shows the results of experiment. They are in the same order of magnitude than those measured by Roed (1987) using Tchernobyl radionuclides as tracers. However, for glass and cement facing, deposition velocities are higher than those measured by Maro *et al.* (2010) for the same surfaces with a generated fluorescein aerosol on 1 hour duration.

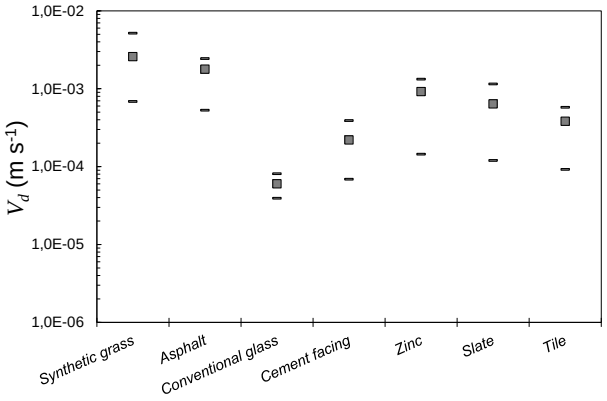

Fig. 1: V_d mean, minimum and maximum measured on each surface.

This highlights the role of additional physical phenomena on the long durations (1 month). The proposed hypothesis is the growing of atmospheric particles by water vapor condensation during dew episodes. Dry deposition velocities could be higher because of deposition rises by impaction and settling.

Conclusions

A measurement method of V_d using atmospheric ^{7}Be as a tracer has been developed. It permits to quantify V_d for real urban surfaces and to measure associated meteorological parameters. Results show differences in the order of magnitude between V_d measured on short duration expositions (~1 h) and on long duration expositions (~1 month). This involves an additional physical phenomenon contributing to the dry deposition on long durations. Further experiments will be necessary to explain differences between short and long durations. Particularly, continuous measurements of the atmospheric aerosol distribution will allow to verify the growing of particles and to measure their diameters during the dew episodes.

c.ruzene@mpic.de

There is a need to expand our knowledge of the diversity and biogeography of airborne microorganisms, since air connects all ecosystems at the Earth's surface. One of the most important phenomenon which can illustrate the role of the atmosphere as a dispersal mechanism for particulate matter is dust storms, that happen when the top soils from large deserts become airborne, and they can travel great distances through the atmosphere (Goudie and Middleton, 2001). More than half of the dust being transported in the atmosphere is believed to have originated from the Sahara-Sahel region in Africa (Kellog and Griffin, 2006). These dust storms are carrying microorganisms along with the mineral particles (Griffin, 2007).

Studies have shown that the global microbial taxa are not homogeneously distributed in the air, and the regional differences and how they come to be needs to be further understood (Fröhlich-Nowoisky *et al*, 2012). In order to better understand the relationship between microorganism transport and dust, the present study aims to seek for a rhythm in the airborne contents found in African dust events.

Air filter samples were collected between January 2011 and January 2012 in the Santiago Island from the Cape Verde archipelago. The sampling was done with a Hi-Vol with a PM10 head inlet and flow rate of 1,13 m^3min^{-1}.

Deoxyribonucleic acid (DNA) of filter sample aliquots were extracted, amplified, cloned and analysed as previously described (Fröhlich-Nowoisky *et al*, 2009). Primer pairs were used for targeting Fungi and Archaea.

Preliminary results show high species richness and seasonal cycles for different groups of Fungi and Archaea. In Archaea, there is a predominance of *Thaumarchaeota*, a recently defined phylum which contains all known ammonia-oxidizing Archaea (Stahl and de la Torre, 2012). Among *Euryarchaeota*, there are members of *Halobacteriales* and *Thermoplasmatales*, which are groups of extremophilic microorganisms. Although *Thaumarchaeota* are more diverse the whole year, the species richness for both phyla is highest in winter, which is the season with more dust storms, and lowest in spring.

For Fungi, *Basidiomycota* are slightly more diverse than *Ascomycota*. Members of the *Agaricomycetes* are predominant for *Basidiomycota*, with *Dothideomycetes* and *Sordariomycetes* appearing more often for *Ascomycota*. *Ascomycota* have higher species richness during summer and lower species richness during fall and winter, with a minimum in winter. *Basidiomycota* have a maximum of species richness in fall, with the lowest values observed during spring.

To expand the present data set, further results obtained from sequences that are still being analysed will be revealed.

Primary Biogenic Aerosol Particles (PBAP) such as fungal spores and bacteria can act as CCN and IN in the atmosphere, so they have an impact on the global climate and precipitation. PBAP may contain living organisms, which can have various health effects for humans and animals. For these reasons, information on the concentration, size distribution, sources and types of PBAP are needed in various environments. Laser induced fluorescence (LIF) is a potential real-time method to detect PBAP. The LIF technique is selective for detecting biological molecules such as tryptophan, NADH and flavins that are present in bacterial cells and fungal spores. The focus on our previous studies was developing LIF based real time measurement technique for biological weapons detection (e.g. Manninen et al., 2009). The idea is processed to use similar measurement technique for atmospheric relevant fungal spores and bacteria. In recent studies, we found that airborne fungal spores and bacteria may have dissimilar fluorescence spectra, so it can be usable criteria in classification of atmospheric fungal spores and bacteria (Saari et al., 2013).

Our previous studies have focused on obtaining information of effective fluorescence measurement parameters of airborne fungal spores and bacteria that are the dominant in the PBAP number concentration fraction. There are still many problems to solve in LIF-based PBAP measurements. The fluorescence intensity from the aerosol particle depends mainly on the PBAP size and chemical composition but also on the instrumentation parameters. For these reasons, there is always a detection limit for smaller PBAP. So the particle size information is always necessary in the classification. We made parallel tests with the commercial UV-APS (TSI Corporation) and a self-made LIF-instrument called by BioScout. We found significant differences in counting efficiencies between the instruments for some common bacteria in laboratory conditions.

In this study, outdoor measurements were made with UV-APS and BioScout in urban environment during four time periods at winter, spring, summer and autumn. The results indicate that there are two dominant fluorescence particle modes during the measurement periods. We assume that the modes are mainly coming from fungal spores and bacteria. The concentrations and ratio of the fluorescent particle modes vary between the season periods. Sometimes there is strong diurnal variation in the fluorescent particle concentrations (Fig. 1). We found also that BioScout have much better fluorescent particle counting efficiency as compared to UV-APS. This is consistent with our laboratory results.

In conclusion, two LIF based instruments were tested in laboratory conditions and in urban environment. Preliminary results of outdoor measurements are promising. Real-time LIF technique seems to be suitable for atmospheric PBAP detection, but there are still many questions to answer and work to do. Investigation of the emission sources and transportation of PBAP needs meteorological data analysis and long term PBAP measurements with several instruments in various environments.

An observational study on air pollution conditions in two continuous haze periods in winter in Nanjing, China

Y.J. Zhang[1], L.L. Tang[2], H.L. Zhang[1] and L. Tang[1]

Keywords: Haze; Atmospheric particulate matter; Water-soluble ions; Pollution characteristics
Presenting author email: Yunj_mail@163.com

Two serious haze pollution courses occurred in Jiangsu Province, affected by the continuous haze weather conditions in the Central and East China in January 2013. According to the observed data from Jiangsu Environment Monitoring Center, the characteristics of particulate matter and gaseous pollutants these haze periods were analyzed. Results showed that the daily averaged mass concentrations of $PM_{2.5}$ were176-205 μg/m^3 as 5-6 times than the standards of EPA, and the maximum hourly value is 336 μg/m^3. Positive relationship between $PM_{2.5}$ and PM_{10} was found with correlation coefficients (R^2) as 0.87. Fine particles plays an important role in the two pollution process as $PM_{2.5}$ accounted for 70-86% of PM_{10}, The mass concentrations of SO_4^{2-}, NO_3^- and NH_4^+ exhibited higher values in submicron particles ($PM_{1.0}$) with the total mass concentrations of them accounting for 83% and 51% of those for $PM_{2.5}$. Meanwhile, the mass concentrations of $PM_{1.0}$ showed positive relationships with SO_4^{2-}, NO_3^- and NH_4^+, with the R^2 as 0.57, 0.65 and 0.73, respectively. While they exhibited worse correlations with $PM_{2.5}$ mass concentrations, indicating that these ions preferred to concentrate in the fine particles. A positive correlation between NH_4^+ with SO_4^{2-} and NO_3^- was found with R^2 as 0.8 and 0.85. The secondary aerosol obviously affected visibility. Positive relationship between black carton (BC) and visibility existed with R^2 as 0.31. BC make lower contribution to visibility when compared with the secondary aerosol which may be the key factors for the cause of the continuous haze weather conditions in the two periods.

East Asia is one of the main source regions of aerosol pollution. It has been estimated that emission from industry and automobiles, dust emission from the large desert areas, and forest fire smoke in Siberia contribute to one-fourth to one-third of the total global emissions of the organic matter, soot, and dust (Ginoux *et al*., 2004). Dust storms that originate in the Taklamakan desert of China and the Gobi desert of Inner Mongolia occur frequently and are one major source of the dust emission in East Asia (Huang *et al*., 2005). Korea is located in the downwind area of the Asian continent and is significatly influenced by long-range transported dust in each spring season. Durinng transportthe dust particles could mix and react with other chemical components (e.g., SO_4^{2-}, NO_3^- and sea salt), which modify the optical and microphysical properties of the Asian dust.

In this study the particle depolarization ratio were retrieved from the observation with a multiwavelength Raman lidar at Gwangju, Korea (35.11˚N, 126.54˚E). The measurements were carried out on 24 February and 9 March 2004. Using the particle depolarization ratio, the non-dust particles were distinguished from the Asian dust plume, and the proportion of the non-dust particle to total dust plume was retrieved as shown in figure 1.

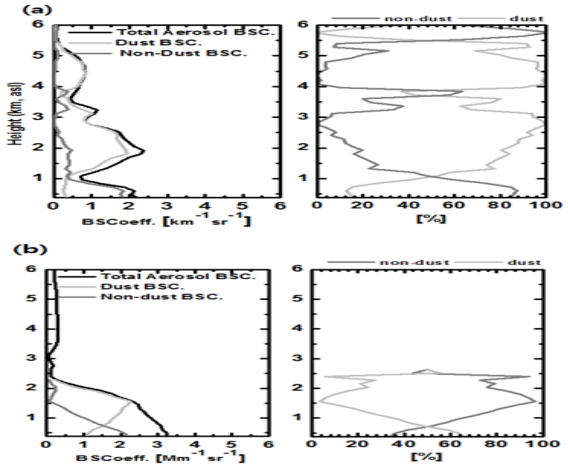

Figure 1. The vertical profiles of backscattering coefficient. The backscattering coefficient of total aerosol (black solid line), dust (light gray solid line) and non-dust particle (gray solid line) at 532 nm and the proportion of dust (gray color) and non-dust (light gray color) particle to the total aerosol (a) 24th Feb (b) 9th Mar

The calculated proportion of the non-dust particle was used for the retrieval of backscatter coefficients at 355, 532, and 1064nm and extinction coefficients at 355 and 532 nm of non-dust particles in the dust plume. Microphysical parameters of non-dust particles including single-scattering albedo at 532 nm were retrieved using retrieved optical values. The retrieved single-scattering albedo of non-dust particles was 0.92-0.95 below 1 km height and 0.82-0.91 above 1 km height on 24 February and 0.81±0.03 on 9 March 2004 as shown figure 2.

Improvements to harmonize different soot measurement techniques in air quality monitoring networks

A. Schladitz[1], G. Löschau[1] and H.G. Kath[2]

[1]Saxon State Agency for Environment, Agriculture and Geology, Dresden, Saxony, 01326, Germany

Keywords: Black carbon, Elemental carbon, Air quality guidelines
Presenting author email: alexander.schladitz@smul.sachsen.de

Measurements of soot particles in ambient air are depended on the definition of soot (Andreae and Gelencsér, 2006). While elemental carbon (EC) is analysed with thermal methods, black carbon (BC) is measured via optical methods by analysing the transmitted and reflected signal from a sample filter. So far, there exist intercomparison studies of BC and EC (e.g. Nordmann *et al.*, 2009) and between non-standardized measurement techniques for EC (Hitzenberger *et al.*, 2006). Up to now, intercomparison studies of BC and EC along different size fractions (PM_1, $PM_{2.5}$ and PM_{10}) for a longer time period (more than a year) are missing.

As a precaution to protect the human health and environment and in conjunction with new WHO air quality guidelines, BC and EC are simultaneously measured on certain hot spots within the Saxon air quality network (Dresden-Nord and Dresden-Winckelmannstr.). However, in the European air quality guideline 2008/50/EG neither a target value nor a limit value for EC or BC is included. Within the cross-border EU-project UltraSchwarz, BC is continuously measured and EC is measured every 6th day in Annaberg-Buchholz (Saxony; D) and Ústí nad Labem (Usti region, CZ). For consistency, BC is measured with a MAAP 5012 (Thermo Inc., Waltham, MA, USA) in all named sites downstream of a PM_1 - inlet and a membrane dryer in between. The membrane dryer guarantees that no measurement artefacts of BC on the deposited filter occur due to enhanced aerosol humidity. The relative humidity of the aerosol is monitored continuously and BC values with RH > 40% were disregarded. Sampling of EC occurs on quartz microfiber filters QFH 150 (Albet-Hahnemuehle, Dassel, D) downstream of a $PM_{2.5}$ - inlet for Annaberg-Buchholz and Ústí n. L. and a PM_1 - inlet for Dresden-Nord and Dresden-Winckelmannstr., respectively. EC is characterized by guideline VDI 2465 Part 1 using a carbon analyser (Ströhlein, Cuolomat 702).

Figure 1 shows a comparative measurement of BC (PM_1 – inlet) and EC (PM_1, $PM_{2.5}$ – inlet) at one site. Interestingly, both EC values do not differ significantly. Former measurements revealed that the EC mass fraction from traffic emissions is much smaller than $PM_{2.5}$, while the EC mass fraction originating from tire abrasion is larger than $PM_{2.5}$.

Figure 2 shows an intercomparison of BC and EC for all sites, partially with a different classification (ub = urban background, rs = roadside). All sites expect for Dresden-Winckelmannstr. show significant relation ($R^2 > 0.9$). A reason for the weak correlation for Dresden-Winckelmannstr. could be the less polluted season in summer 2012 with BC and EC values < 2µg/m^3 and a low daily variation. The measurement shall be repeated in the more polluted season.

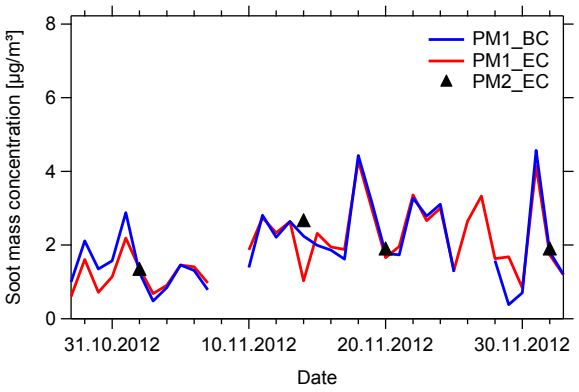

Figure 1: BC and EC time series for different size fractions for the site Annaberg-Buchholz.

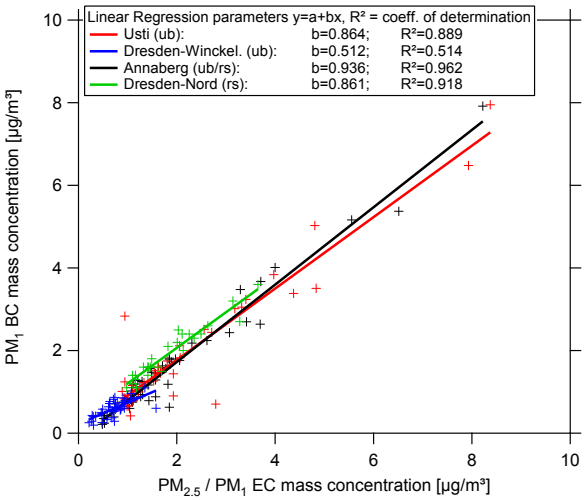

Figure 2: Intercomparison of BC and EC for different sites and classification (data from 1.1.2012 – 31.1.2013). For reasons of clarity the error bars were disregarded.

Presenting author email: susan.schmidt@mpic.de

During the ACRIDICON-Zugspitze campaign (17.09.2012 - 04.10.2012) at the research station Schneefernerhaus (German Alps, 2650 m a.s.l.) we investigated the chemical compositions of cloud residuals as well as the composition of the atmospheric background aerosol with a single particle mass spectrometer.

The cloud residuals were sampled with a counterflow virtual impactor (CVI; Mertes et al., 2005). During non-cloud periods this inlet was used as an aerosol-inlet to sample and analyse the background aerosol.

The chemical analysis of the cloud residuals and the background aerosol particles was done with the bipolar single particle mass spectrometer ALABAMA (Aircraft-based Laser Ablation Aerosol Mass Spectrometer) with a particle size range of 150 to 900 nm (Brands et al., 2011). Additionally the particle size was measured by an optical particle counter (OPC, Grimm 1.129) with a particle size range from 0.25 to 52 µm.

Over the whole time period about 3300 useable spectra were acquired during background aerosol measurements and about 5500 useable spectra of cloud residuals during cloud events. For further investigations only those spectra that have both polarities were used, in order to facilitate the assignment of these particles to distinct particle types. The evaluation of the data was done with the software package CRISP (Klimach et al., 2010) which contains three different sorting algorithms. This program allows for assignment for the mass spectra into different clusters that contain similar mass spectra. In this case the spectra were separated with the fuzzy c-means algorithm (Hinz et al., 1999).

The comparison of the chemical compositions of the cloud residuals and the particles of the background aerosol does not show any significant differences. This suggests that in the analysed size range all particles are activated as cloud droplets independent of their chemical composition. In both cases the main clusters contain particles with secondary inorganic compounds like sulphate and nitrate and potassium. For the cloud residuals this particle type represents 28% and for the background aerosol particles 24% of all investigated mass spectra.

Additionally, both the cloud residuals and the background aerosol particles show mainly particle types with secondary inorganic components internally mixed with organic compounds and/or carbon fragments.

The main difference between cloud residuals and background aerosol is that more particles containing lead were found in the cloud residuals (36 spectra in cloud residuals and only 3 in background aerosol). Whether the lead containing particles are preferably activated as cloud droplets or this finding is a result of different air mass origin has to be investigated.

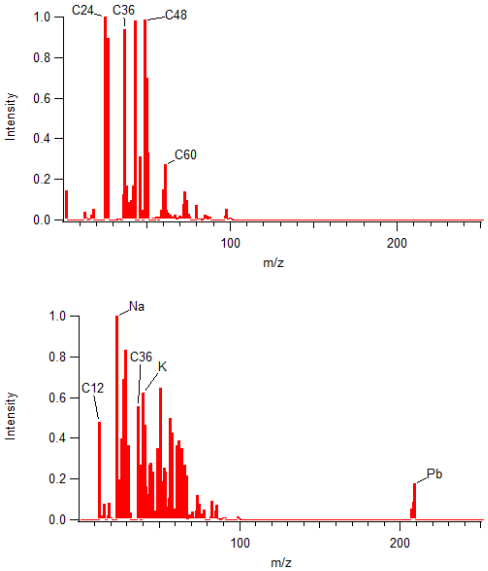

Fig. 1: Average spectra from the particle type which include lead of the background aerosol; above: anions, below: cations.

During a field campaign at the High Alpine Research Station Jungfraujoch (JFJ, Swiss Alps, 3570 m a.s.l.) which was conducted in January/February 2013 in the framework of the research unit INUIT (Ice Nuclei research UnIT), we investigated the physico-chemical properties of ambient ice nuclei (IN) and ice particle residuals (IPR). By combining a pumped counterflow virtual impactor (PCVI) and online aerosol mass spectrometry, ice nuclei from ambient air, that were activated by an IN counter (FINCH) and pre-selected by the PCVI, were fed into an aerosol mass spectrometer and analyzed for their chemical composition, as well as for their microphysical properties. Additionally, ice crystals were sampled from ambient mixed-phase clouds by a unique Ice-CVI (Mertes et al, 2007) and their residues (IPR) were also analyzed in-situ by aerosol mass spectrometry.

Previous investigations conducted at the Jungfraujoch have shown that mineral dust particles dominate the ice particle residue number (Kamphus et al., 2010) but also black carbon was found to be enriched in these residual particles (Mertes et al., 2007; Cozic et al., 2008). The objective of the INUIT-JFJ 2013 campaign was to extend our understanding of ice formation beyond the previous findings with new instrumental techniques.

The chemical analysis of the IPR and IN was performed with the single particle mass spectrometer ALABAMA (Aircraft-based Laser Ablation Aerosol Mass Spectrometer) that covers a particle size range of 150 to 900 nm (Brands et al, 2011). Additionally, particle size was measured by an optical particle counter (OPC, Grimm 1.129) with a particle size range from 0.25 to 32 µm.

We acquired more than 600 mass spectra of IPR sampled by the Ice-CVI. The evaluation of the data will be done with the software package CRISP (Klimach et al., 2010). This program allows for the assignment of the mass spectra into different clusters that contain similar mass spectra. In this case the spectra will be sorted with the fuzzy c-means algorithm (Hinz et al. 1999).

The first preliminary analysis of the acquired IPR data shows that the most abundant particle type (17% of all mass spectra) has components of mineral dust like lithium (Li), sodium (Na), potassium (K), aluminum (Al), iron (Fe) but also organic compounds (Fig. 1). Another particle type (11% of all mass spectra) found in the IPR contains carbon fragments, organic compounds (OC), sodium, aluminum and potassium. These findings partially agree with the results from previous researches. After completion of the campaign, a more detailed analysis of the data will give further insights into the chemical nature of ice nuclei and ice particle residuals.

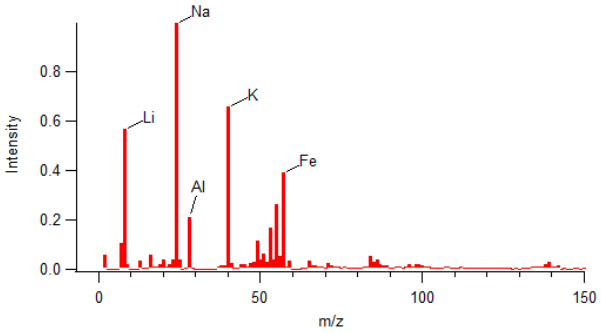

Fig. 1: Average mass spectrum of those mass spectra of ice residuals that were assigned to the largest cluster (17% of all spectra). The observed ions are characteristic for mineral dust.

New Homogeneous Ice Nucleation Results from Measurements at a Large Atmospheric Simulation Chamber

T. Schmitt, O. Möhler, D. Duft, M. Haarig, K. Höhler, A. Kiselev, I. Steinke and T. Leisner

Institute for Meteorology and Climate Research, Karlsruhe Institute of Technology, Hermann-von-Helmholtz-Platz 1, 76344 Eggenstein-Leopoldshafen, Germany
Keywords: cloud chamber, ice nucleation
Presenting author email: thea.schmitt@student.kit.edu

Phase transitions in clouds such as droplet formation by the condensation of water vapour or droplet freezing are in most cases heterogeneous processes triggered by aerosols. On the other hand, homogeneous ice nucleation without the participation of aerosols is an important process in deep convective systems, where almost pure water droplets are supercooled until homogeneous freezing occurs at temperatures below about 238 K.

A well cited theory which describes homogeneous ice nucleation was published by Pruppacher and Klett (1997). It is called classical nucleation theory and includes a number of uncertain parameters like the interface tension between the supercooled liquid and the ice phase or the activation energy. Therefore it is difficult to exactly formulate classical nucleation theory for a certain nucleating system like supercooled water drops. What is done instead is to fit classical nucleation theory formulations to experimental data, which also involve errors and uncertainties.

Here we present a reanalysis of droplet freezing experiments at the AIDA (Aerosol Interaction and Dynamics in the Atmosphere) cloud chamber at KIT, Karlsruhe, Germany, which follows experimental methods described by Benz *et al* (2005) who already published first homogeneous ice nucleation rates in supercooled water droplets derived from measurements at the AIDA facility.

At the large aerosol and cloud chamber AIDA the interaction between aerosol particles and clouds is being investigated. The facility operates under atmospherically relevant conditions within a wide range of temperature, pressure and humidity, whereby investigations of both tropospheric mixed-phase clouds and cirrus clouds can be realised. By controlled adiabatic expansions the ascent of an air parcel can be simulated. In order to investigate homogeneous freezing, sulphuric acid seed aerosol is typically injected into the chamber (Figure 1). By starting the expansion the gas temperature decreases and therefore the relative humidity rises whereby water condenses at the sulphuric acid droplets. They then grow until they are almost pure water drops. First ice particles appear at lower temperatures by homogeneous freezing. The ice particles then rapidly grow in size at the expense of the remaining droplets (Wegener-Bergeron-Findeisen process) with the result that at the end of the experiment only ice particles are left inside the chamber.

During these expansions, the aerosols, droplets and ice particles are monitored by a number of instruments. For the calculation of homogeneous ice nucleation rates the measurements of an optical particle counter (welas, PALAS GmbH) are used. The

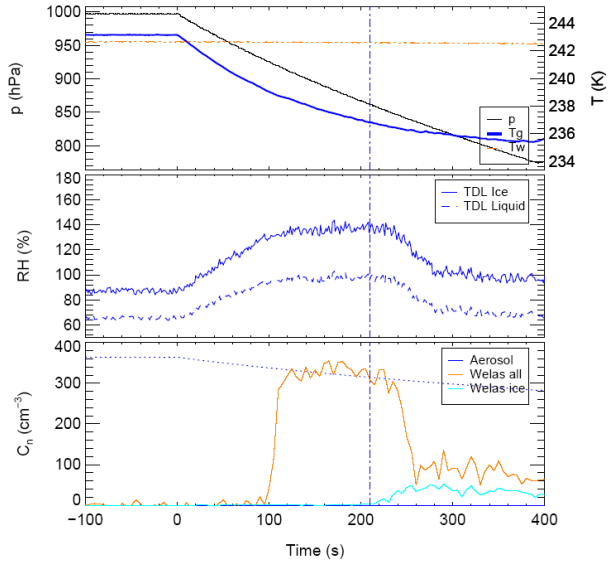

Figure 1. Data time series of a typical AIDA homogeneous droplet freezing experiment.

instrument detects the size of the resulting droplets and the number concentration of droplets and ice particles during the expansion. With these values homogeneous ice nucleation rates in supercooled water droplets can be calculated.

On the base of the new and improved data set we hope to achieve a more accurate fit of classical nucleation theory parameters. In addition, these new homogeneous ice nucleation results from the AIDA cloud chamber facility will be compared with homogeneous ice nucleation rates derived from other experiments like the cold stage where a droplet ensemble can be examined (Di Natale, 2012) or the Paul trap where single droplets can be studied by levitating them in an electrodynamic balance (Duft and Leisner, 2004; Rzesanke *et al*, 2012).

Fog is a major processing and removal agent of ambient aerosols. Enhanced secondary organic aerosol (SOA) production has been reported during fog events and there is a growing understanding that SOA formed via this aqueous processing can contribute significantly to ambient aerosol loading apart from traditional gaseous SOA.

The present study which was carried out during winter of 2012-13 in a heavily polluted city of Kanpur situated in Indo-Gangetic plane of India, focuses on identification and quantification of this aqueous processing of the ambient aerosols by natural fog. Although many smog chamber studies have been carried out to understand this aqueous processing and formation of SOA but often these studies were carried out in conditions not representative of complex ambient system and since very few ambient studies were reported till now so there is a need to evaluate what is happening in real ambient condition to properly understand this complex process.

During this campaign from 24 Nov, 2012 to 10 January, 2013, 12 fog events were captured from 20 Dec to 10 January and termed as foggy period while remaining as non foggy period. Foggy period typically showed very high RH and low temperatures than non foggy period with the highest RH (~95%) and lowest temperature (~3°C) occurring during actual fog events. We had deployed an array of instruments during this campaign for real time measurement of aerosol physicochemical properties – High Resolution Time of Flight Aerosol Mass Spectrometer (HR-ToF-AMS) for measurement of size resolved chemical composition of non refractory submicron aerosol, Scanning Mobility Particle Sizer (SMPS) for size distribution of submicron aerosol, Cloud Combination Probe (CCP) to measure fog droplet size distribution and liquid water content (LWC), Cloud Condensation Nuclei counter (CCN) to measure droplet forming potential of ambient aerosols, PM1 sampler and fog water collector, Vaisala RH & T sensor. This is the first time AMS is used in India and to our knowledge AMS has never used so extensively in ambient foggy condition before.

Average aerosol loading during foggy period was 104±44 μg/m^3, much higher than that of non foggy period which was 70±43 μg/m^3, but during actual fog events the loading was lowered to 85±23 μg/m^3 indicating overall aerosol removal by fog. Overall aerosol composition during both the period was dominated by organics which constitutes about 70% of total AMS mass followed by Nitrate, but during foggy period Sulfate was found to be increased many fold.

AMS and SMPS measured aerosol mass compared well. An average aerosol density of 1.3 g/cc was assumed for conversion from SMPS measured number to mass based on the measured aerosol chemical composition of 70% organics and 30% inorganic. Droplet size distribution and LWC revealed that every fog events consists of multiple cycles of dense and thin periods with highest LWC as high as 0.160 g/m^3 and average droplet size of 25±4 μm during densest periods.

HR-ToF-AMS measured aerosol O:C ratio was also analyzed to understand the real time variation in ambient organic aerosol oxidation level. Noticeable differences for the diurnal average values of O:C ratio between foggy and non foggy period are found. Although in both the period diurnal O:C ratio was higher around noontime typically representing photochemical activity but during foggy period the days were mostly hazy with very little and weak Sunlight, so fog processed aerosol may have retained their already oxidized products. During foggy period, night to early morning O:C ratio was 0.54±0.05, higher than that of non foggy period 0.43±0.03, clearly indicating enhanced oxidation activity, despite the fact that oxidized organics are preferentially scavenged by fog. Biomass burning activity doesn't seem to contribute much during any of the period as m/z = 60, 73 signals of AMS spectra which are the markers of biomass burning aerosol, remain low and almost the same. To our knowledge this is the first reporting of real time evolution of ambient oxidation level under foggy condition. AMS also showed that mode size of all the species specially organics and sulphate had shifted to a higher diameter during foggy period an indication of aging and mass addition via secondary production.

During foggy period the acidity of ambient aerosol which is measured by H^+ concentration was almost twice as high as non foggy period, mainly due to enhanced sulphate production. Although during actual fog events the acidity was lowered because of enhanced removal of sulphate which normally associated with larger droplets. Total organics from both the period showed very good correlation with aerosol acidity.

Presenting author email: schwarz@icpf.cas.cz

Aerosol mass size distribution is an important factor that influences aerosol behavior both on local and global levels. The content of water soluble ions is the most important factor controlling hygroscopicity of aerosol particles. Hygroscopicity influences the dependence of particle size on relative humidity and therefore it is a substantial parameter for particle deposition in lungs, particle – cloud interactions, aerosol optical effects etc. Therefore, the size distribution of PM and water soluble ions was studied in two Central European capitals – Prague and Vienna both in summer and winter.

The measurements were done at an urban background site (Suchdol) located in the residential area in NW suburbs of Prague on the campus of the Institute of Chemical Process Fundamentals (ICPF) at 285 m a.s.l. The road with traffic density 10-15000 car per day is located in about 200m from the site. The closest house is placed about 30 m from the site. The sampling point was about 4 m above ground, on the roof of a sampling container. The sampling period was from 27th June to 7th July 2012, and from 6th to 15th February 2013. 11 samples were obtained in summer and 9 in winter. Each sampling took 23 hours.

The Vienna urban site was located on the roof of Faculty of Physics about 35 m above ground, close to the inner court of the building. The building is located in downtown Vienna but the roads next to the building have low traffic densities. The Vienna sampling period was from 17th to 30th July 2012, and from 14th to 30th with 9 samples in summer and 12 in winter. Each sample in Vienna took 23 hours except the weekend samples. Those two samples took 71 hour each.

The instrument used for size selective sampling followed by ion chromatography analysis of samples was a small deposit area cascade impactor (SDI) that has 12 stages and 11 l/min flow rate. The cut diameters of the stages were 0.041, 0.087, 0.15, 0.23, 0.34, 0.52, 0.73, 0.99, 1.5, 2.4, 4.2, and 8.0 µm (Maenhaut et al. 1996). The samples were extracted using 30 min ultrasonic bath and 1 hour shaking and analyzed using Dionex 5000 system both for cations and anions in parallel.

PM mass size distributions were determined using a Berner rotational cascade impactor with a flow rate of 25 l/min and calculated cut diameters of the stages 0.016, 0,032, 0.065, 0.13, 0.25, 0.5, 1, 2, 4, 8 µm.

The results we obtained on mass size distributions of mass and water soluble ions exhibit common basic features of ambient aerosols in Central Europe. E.g., mass size distributions in winter were dominated by a fine mode (see an example in Fig. 1). Sulfates and ammonium were almost exclusively present in the fine mode, fine nitrates were mostly low in summer (see an example in Fig. 2) due to high summer temperatures, but they had always a distinct coarse mode. Normal size distributions of ammonium and sulfates were often almost identical in summer due to low nitrates.

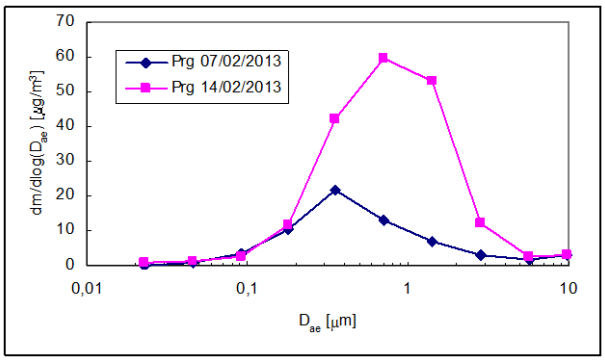

Fig. 1: An example of mass size distributions in Prague in winter

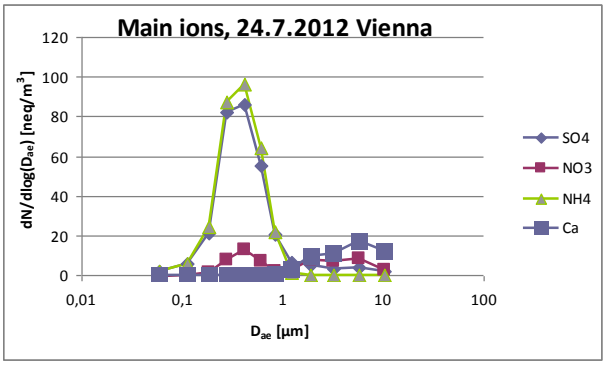

Fig. 2: An example of mass size distribution of ions in Vienna in summer.

[3]Environmental Department, Municipality of Thessaloniki, Paparigopoulou 7, Thessaloniki 54630, Greece
[4]Faculty of Applied Sciences, Delft University of Technology, Delft 2628-BL, The Netherlands

Keywords: PM, number size distribution, SMPS, nucleation events

Thessaloniki is a densely populated coastal city of northern Greece suffering from high concentrations of atmospheric particulate matter (PM). Previous studies have investigated the concentration levels, the chemical composition of PM, as well as the size distribution of particle mass concentrations and the relationship with PM mass, photochemical pollutants and meteorological parameters over the city (Voutsa *et al*., 2002; Petrakakis *et al*., 2007; Siakavaras *et al*., 2008; Terzi *et al*., 2010).

In this paper we report the characteristics of local and regional particle nucleation and growth events observed during the summer period. The measurements were carried out at Eptapyrgio: one of the urban background stations of the Municipality Air Quality network of Thessaloniki. A Scanning Mobility Particle Sizer (TSI, Model 3034) was employed to measure the size distributions of the particles having diameters in the range of 10-487 nm. An Integrating nephelometer (TSI, Model 3563) was also employed to measure the light scattering coefficient of the particles. $PM_{2.5}$ samples were collected on filters using a sequential sampler (Met One Instruments) for chemical characterization of the particles. Gaseous pollutants (CO, NO_x and O_3) and meteorological parameters (wind speed, wind direction, temperature and RH) were also recorded during the measurements. The experiments were conducted from 10 June to 20 July 2012.

Nucleation events were classified in 5 categories based on their intensity (Dal Maso *et al*., 2005). Almost 50% of the days exhibited new particle formation. More specifically, 11% of the days were classified as class Ia events, 16% as class Ib, and 21% as class II. Days that exhibited no clear particle formation patterns and thus were considered as undefined accounted for 34% of the total number of measurement days, whereas days that showed no events accounted for the rest 18%.

During the nucleation event of the 18th of June the apparent growth of the particles started locally at the lower detection limit (10 nm) at ca. 11.00 am and evolved until the end of the day to a particle size of 100 nm at a growth rate of 6.9 nm/h (cf. Fig. 1a).

At 7 days nucleation started at particle sizes around 20 nm. This is the case at the 19th of July where nucleation started at a remote site and particles were transported to the measuring site (Fig. 1b). Particles where detected at a size of 18 nm at 11:00 am and evolved until 15:00 pm to a size of 4 nm at a growth rate of 4.5 nm.

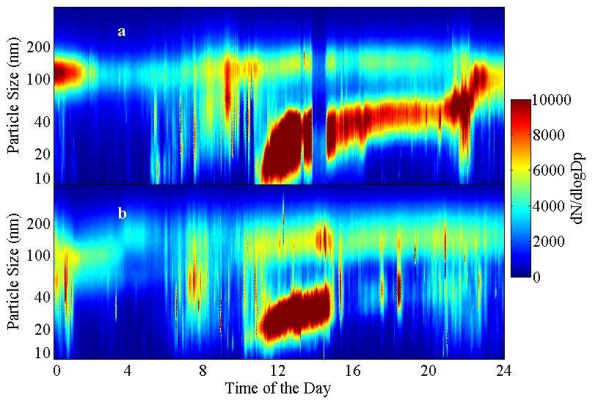

Figure 1. Typical number size distributions for a local particle formation and growth event on 18 June 2012 (a) and a regional particle formation and growth event on 19 July 2012 (b) at Eptapyrgio. On this day nucleation was transported to the site.

MEASUREMENT CAPABILITIES OF THE POLAND-AOD NETWORK

A.Strzalkowska[1], P. Makuch[1], P. Pakszys[1], O. Zawadzka[2], P. Markuszewski[1],T. Zielinski[1], T. Petelski[1], K. M. Markowicz[2], I. Stachlewska[2], A. Ponczkowska[1], M. Wichorowski[1]

Kaywords: POLAND-AOD, MICROTOPS, Volcano

The Poland-AOD research network was created in November 2011. The main purpose of this project are measurements and analysis of the optical properties of aerosols and radiative balance of the atmosphere. The network is composed of several laboratories such as the EUSAAR Sopot Station in the Institute of Oceanology Polish Academy of Sience, the University of Warsaw Radiative Transfer Laboratory, the Geophysical Obesrvatory in Belsk and the EUSAAR SolarAOT in Strzyzow. In spite of the fact that the network was officially established in November 2011, measurements were carried out under an unwritten cooperation at all four stations. The joint management of measurements gives a number of excellent results but the connection into one nationwide network offers many new opportunities.

The network was established to carry out work and develop climatology of the atmospheric aerosol optical properties and validation of inverse methods to determine the optical thickness and single scattering albedo from satellite data of MSG-9, as well as ground-based observations. Other tasks include modeling and experimental study of aerosol direct effect or transformation of the optical properties of aerosols based on contaminant transport models (NAAPS, GEM-AQ).

At each station measurements are made with the same equipment. The basic measuring devices are Multi-Filter-Rotating Shadowband Radiometer MFR-7 and Microtops photometers. Pyranometers and MFR-7 measure the radiation streams. The radiative balance at the upper boundary of the atmosphere is determined by the SEVIRI detector on satellite MSG-9. As one of the few networks POLAND-AOD makes measurements in the Baltic Sea. It is possible thanks to S/Y Oceania which belongs to IO PAS. During the research cruises measurements of the total scattering and back scattering coefficient are performed with use of the TSI Nephelometer. On S/Y Oceania scientists also uses AE-31/MAGEE Aethalometer to research concentration of soot and laser particle counter CSASP-100 and TSI Condensation Particle Counter for concentration and size distribution of aerosol particles.

Measurements are automatically collected from all stations of the network. Than the data are saved on a server located at the University of Warsaw Radiative Transfer Laboratory. The data are recorded on three levels. Level 1.0 is the raw data, at level 1.5 data are cloud-screened and at level 2.0 the data are quality-assured. All the research results are published on http://www.igf.fuw.edu.pl/meteo/stacja/PolandAODdata.php. The page is updated every minute.

In 2010 the European airspace was closed [1] because of the explosion of the Eyjafjöll volcano in Iceland. That gave an idea to measure optical properties of volcanic ash over Poland in these days. The observations were performed between 16 and 18 April at four Poland-AOD stations and in these case the measurements were not made only with Microtops sunphotometers. Instruments such as ceilometers and aerosol LIDARs also played a very important role. All analyses were supported with satellite data from MODIS, data analyses from AERONET and models such as FLEXOART or HYSPLIT. An indirect effect of volcanic aerosols on climate is through their influence on microphysical cloud properties [2]. That was the reason of combined LIDAR measurements with measurements which was made by the ceilometer.

Due to the presence of high cloud cover over the period between 16 and 18 April 2010 the remote sensing of the atmosphere over the region of central Europe was very difficult, especially on 16 April. AOD value ranged between 0.12 and 0.4 during the considered period and it was the highest on 16 April. Analyses of the optical properties of volcanic ash are difficult because they require knowledge about the particle size distribution, refractive index and particle shape. In order to simplify this problem uses the properties of desert dust particles according to the Optical Properties of Aerosol and Cloud Data Base [3].

Aerosol characteristics during dust storm in Middle East and South-Western Asia

F. Subhan[1], K.Alam[1,2]

[1]Institute of Physics & Electronics, University of Peshawar, Peshawar,25120, Pakistan
[2]Higher education commission (HEC), Pakistan
Keywords: AOD, SSA, Radiative forcing, MODIS,AERONET.
Presenting author email: khanalamso@gmail.com

Aerosol optical and radiative properties were analyzed during dust storm in March, 2012 over Middle East and South-Western Asia using moderate resolution imaging Spectroradiometer (MODIS) and aerosol robotic network (AERONET) data. The aerosol optical depth (AOD) values were found maximum on 18th March in Kuwait, Bahrain, Qatar, and Saudi Arabia and were 4.948, 4.414, 4.283, and 4.999, respectively. The AOD values were also found maximum on 19th March in Oman, Arabian Sea, and Iran and were 4.552, 5, and 5, respectively. The dust storm spread over Pakistan and passed through Multan, Faisalabad, and Lahore. The maximum AOD values on 20th March were found to be 2.14, 2.63, and 2.66 over Multan, Faisalabad and Lahore, respectively. The aerosol volume size distributions were maximum during dusty days and minimum in non-dusty days in Lahore as shown in Figure.1.

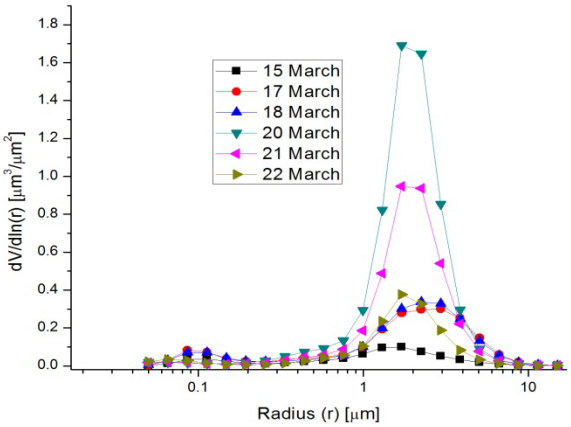

Figure.1. Aerosol volume size distribution during dust days (20-21 March) and non-dusty days (15,17,18,22 March)

The single scattering albedo (SSA) increases as wave length increases implying that SSA is wavelength dependent and increases rapidly with wavelength on the dusty days as compared non-dusty days. This rapid increase in SSA with wavelength revealed that dust particles were dominant and were of larger size as compared to other aerosols particles. The aerosol radiative forcing values at the surface and at top of atmosphere during dusty and non-dusty days were in the range of -64 Wm^{-2} to -260 Wm^{-2} (averaged -137±60 Wm^{-2}) and -20 Wm^{-2} to -105 Wm^{-2} (averaged -48±25 Wm^{-2}), respectively.

Assessment of air pollution sources and implications for human health

Afrim SYLA, PhD Environment and Public health
University of Prishtina- Republic of Kosova
Tel. +377(0)44147473 ; E-mail: afrimsyla2002@yahoo.com

The present environmental situation in Mitrovica, put as in front of the responsibility to act more rationally towards nature and to be more responsible towards the protection of the environment for future generations. The protection lack of environment during the last ten years, as well as the conflict in Kosova as the origin of huge problems regarding present environmental situation in Mitrovica (Kosova). The city of Mitrovica, approcimately 40 km north of Prishtina, was the site of one the largest lead smelters in Europe, known as the Mitrovica Industrial Park.

Three potential sites have been identified by Environmental Deapartament, with the favoured site on the north bank of the Ibar at Bosniak Mahalla. However, a pilot soil survey (using portable XRF) by University of Prishtina at this site revealed very high metal levels (especially Pb) in the soils, and questions were therefore raised about the suitability of this site. Following discussions between Ministry of Environment ,University in Prishtina and Municipality, a series of objectives were identified relating to the three proposed development sites:

1. What are concentrations of Pb and other metals/metalloids in surface and sub-surface soils?

2. Are the Pb concentrations typical or atypical of soil Pb concentrations found elsewhere in Mitrovica city?

3. What is the bioaccessibility of soil Pb to the residents of Mitrovicë/a?

4. What is the source of the lead, and is the source still „active"?

Structural analysis of fine particles using a Time-of-Flight Secondary Ion Mass Spectrometer

Presenting author email: takamia@nies.go.jp

Rapid development in East Asian countries has brought the increase of emission of atmospheric pollutants (Ohara *et al.,* 2007). Gas and aerosol are transported from the Asian continent to the Pacific Ocean in the winter-spring by seasonal monsoon. Since the mixing state and chemical transformation of aerosol particles influence direct radiative forcing (Adachi *et al.,* 2010), individual particle analysis is important. Individual particles have been analyzed by electron probe microanalysis (EPMA) (Tomiyasu *et al.,* 1996), scanning electron microscopy (SEM) (Ault *et al.,* 2012) and transmission electron microscopy (TEM) (Adachi *et al.,* 2010). Recently, time-of-flight secondary ion mass spectrometry (TOF-SIMS) has been introduced to study the structure of aerosol particles (Sakamoto *et al.,* 2008). The TOF-SIMS can analyze the materials located inside the particles by the combination of FIB milling and repeated elemental mapping. We show the structure and chemical composition of fine aerosol particles with diameters of 1 μm collected in the East Asian region.

Sampling was performed at the National Institute of Environmental Studies (NIES) Fukue Atmospheric Observation site (Fukue site; 128.7E, 32.8N) in spring 2011. An Aerodyne quadrupole aerosol mass spectrometer (Q-AMS) was used for the continuous chemical analysis of aerosol. The TOF-SIMS sample was collected on the silicon substrate and was sent to Tokyo for the TOF-SIMS analysis.

Comparison of the Q-AMS measurement results with those of previous studies made at the same location (Takami *et al.* 2005) were similar, suggesting that the particle composition we observed is typical for this site.

Based on the results of TOF-SIMS, we classified the aerosol particles into three types: Type A, sulfate covered with Organic Matter (OM); Type B, soil-containing particles covered by sulfate and OM; Type C, BC and sulfate aggregates covered by OM (see Figure 1). As for Type B, soil was found inside the sulfate and OM was found on the outer surface. In Type C, BC was found at the edge and/or the surface of the sulfate, and formed BC-sulfate aggregates.

During the observation period, the relative abundances of Type A, B, and C particles were 55%, 20%, and 25%, respectively, while in Tokyo, they were 60%, 35%, and 5% (Table 1). More than half of the fine particles were light scattering, in Fukue and Tokyo. These results can be used for the revision and/or constraints of regional and global simulation for the radiative forcing.

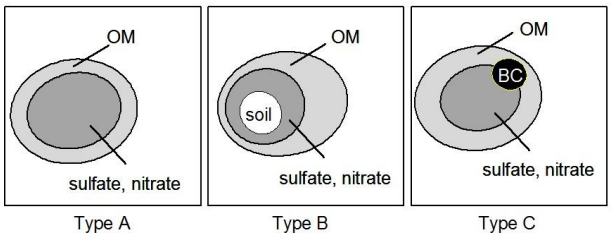

Figure 1 Schematics of the structures of fine particles of Types A to C

Table 1. The relative abundances of each type

	Type A (%)	Type B (%)	Type C(%)
Fukue	55	20	25
Tokyo	60	35	5

Estimating PM2.5 in the Stockholm region from spaceborne AOT measurements

M. Tesche[1] and P. Glantz[1]

[1]Department for Applied Environmental Science, Stockholm University, Stockholm, Sweden
Keywords: PM2.5, aerosol optical thickness, air quality, remote sensing.
Presenting author email: matthias.tesche@itm.su.se

The aim of this study is to deduce surface PM2.5 for the region of Stockholm from satellite observations of aerosol optical thickness (AOT). Previous studies showed the potential for using aerosol observations from space for air-quality monitoring (e.g., Wang and Christopher, 2003; Hoff and Christopher, 2009 and references therein) — especially for tracking the pollution levels of in the air quality index. The present study is based on a previous work by Glantz *et al.* (2009). However, we now intended to obtain an AOT–PM2.5–relationship that is representative for the clean conditions that tend to prevail over the region of Stockholm. Note that it is yet to be explored if such methods can also be applied in a rather clean environment.

Here we use AOT at 555 nm from the MODIS collection 5 Atmosphere and Land product for MODIS–Terra (MOD04_L2, since 1999) and MODIS–Aqua (MYD04_L2, since 2002). AOT is provided with a spatial resolution (pixel size) of 10 km × 10 km. MODIS AOT was checked for reliability by means of a comparison to measurements carried out at the four long–term AERONET stations in Sweden: Gotland, Gustav Dalen Tower, Palgrunden, and SMHI. MODIS AOT was found to be well within the expected uncertainty range of $\pm 0.05 \pm 0.05 \times$AOT. It was also found that periods with AOT larger than 0.2 were scarce.

In the next step, the spaceborne AOT observations were related to surface measurements of PM2.5 at four in–situ measurement sites in the vicinity of Stockholm: Aspvreten (since 2000), Norr Malma (since 2005), Lilla Essingen (since 2005), and Uppsala (since 2007). These sites are representative for regional and urban background conditions. An AOT–to–PM2.5 relationship was obtained for cases ich which AOT values were available for at least 7 of the 9 pixels around a ground site. We use the binning approach suggested by Wang and Christopher (2003) to account for the wide spread in the data of both in–situ and MODIS observations. Furthermore, the AOT–to–PM2.5 relationship was obtained by using the median values in the respective bins of 0.05 AOT rather than the mean values. This approach reduces the impact of extreme values to the final outcome. Measurements of meteorological parameters (i.e., relative humidity, wind speed and direction) were available at the in–situ stations. Additional AOT–to–PM2.5 relationships were determined for cases in which the individual meteorological parameters showed values above and below their median values, respectively. These measurements were used to investigate possible effects of the meteorological situation on the median AOT–to–PM2.5 relationship and to properly assess the error of the PM2.5 retrieval. Note again that few cases occurred for which the PM2.5 concentration exceeded values of 30 μg m^{-3} or AOT was larger than 0.45. Hence, the obtained AOT–to–PM2.5 relationship is representative for relatively clean conditions.

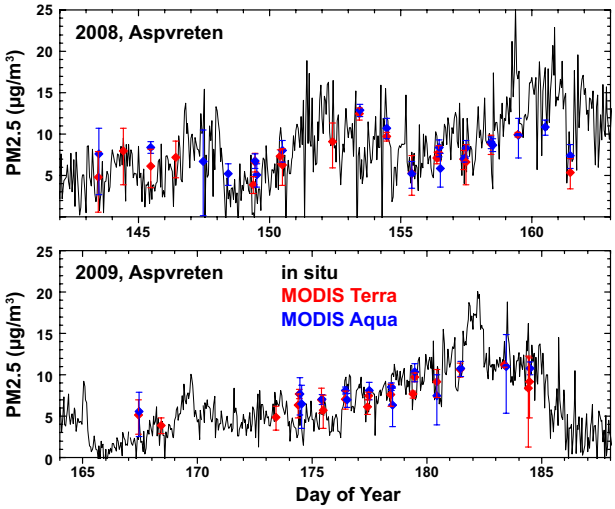

Figure 1: Retrieved (diamonds and error bars) and measured (black line) PM2.5 concentration at Aspvreten for selected time periods in 2008 and 2009.

Figure 1 presents PM2.5 time series for two selected periods in 2008 and 2009. PM2.5 as retrieved from MODIS observations agree with the surface measurements and follows the variation that occurred during the respective time periods.

Note that the AOT–to–PM2.5 relationship is established based on an assumption of homogeneous aerosol conditions within the planetary boundary layer (PBL) and an absence of elevated aerosol layers. While these conditions are widely given for the Stockholm region, future developments will focus on how seasonal differences in PBL development influence the retrieval of PM2.5 from satellite observations.

Keywords: aerosol extinction, hygroscopic growth, CALIPSO, Zeppelin station.
Presenting author email: matthias.tesche@itm.su.se

Aerosols play an important role in the Earth's climate system. This is especially relevant for the vulnerable and clean Arctic, where even slight changes in aerosol size or concentration can have large effects on cloudiness and the radiative budget. To assess aerosol microphysical and optical properties, in–situ measurements are performed at Mt. Zeppelin, Svalbard, since the early 1990s (Ström *et al.*, 2001). However, in–situ measurements are usually performed with dried aerosol samples whose particle size distribution, refractive index, or extinction coefficient can vary significantly during different ambient (i.e., humid) conditions. Arctic aerosols were also found to be highly sensitive to relative humidity (Zieger *et al.*, 2010). Microphysical models are used to transform the measured properties of the dried aerosol sample to values that are representative for ambient conditions. Such numbers are needed for a reliable assessment of aerosol optical properties.

In this study we try to reconcile particle light extinction coefficients derived from humidifying dry in–situ measurements at Zeppelin station and ambient observations with the lidar aboard the Cloud–Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) satellite (Winker *et al.*, 2009). The high overpass rate of polar–orbiting satellites over the Svalbard region favors a systematic comparison of continuous ground–based in–situ measurements and spaceborne lidar observations. Previous studies revealed that high correlation in aerosol properties can be expected for distances of up to 500 km over water (Kovacs 2006). However, for this study we only considered overpasses at distances of less than 360 km from the ground site at Svalbard.

The present study focuses on measurements performed in 2008. A comparison of ambient extinction coefficients measured by CALIPSO with humidified extinction coefficients from the in-situ measurements could be performed for 57 suitable cases — mostly during winter and spring. Clouds, low aerosol load, and a strong solar background (i.e., low signal–to–noise ratio in the spaceborne lidar measurements) inhibit comparisons during summer.

Figure 1 summarizes the findings of this study. On the whole, humidified extinction coefficients from ground-based in–situ measurements and ambient extinction coefficients from spaceborne lidar measurements were found to agree within a factor of one to five with a majority of the values not exceeding a factor of two. This is a surprisingly good finding when considering the efforts necessary to come up with comparable quantities. CALIPSO extinction coefficients are generally larger than the ones derived from the humidification of in–situ measurements. Is has been observed previously, that extinction coefficients measured with lidar are larger than the ones obtained from in–situ measurements (e.g., Masonis *et al.*, 2002).

In the future we will expand this study to the entire CALIPSO data set that currently spans six years.

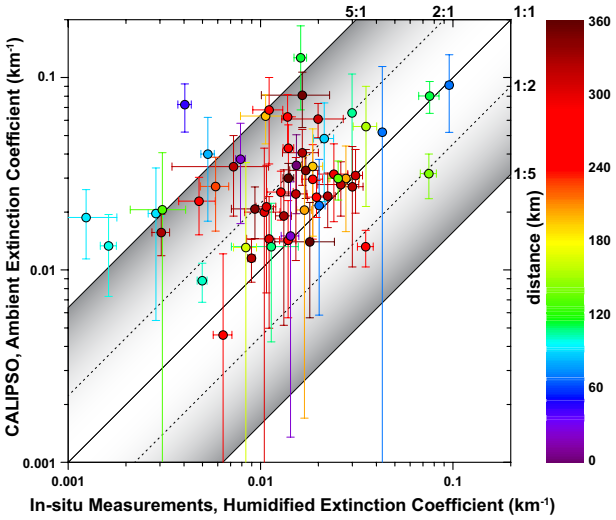

Figure 1: Comparison of the humidified extinction coefficient calculated from in–situ measurements at Zeppelin station with the ambient extinction coefficient extracted from CALIPSO overpasses for 57 suitable cases. The color coding describes the distance of the CALIPSO observation from the ground site. Error bars represent the standard deviation from averaging over 5 hourly nephelometer data points and 9 30–m CALIPSO height bins between 250 and 760 m, respectively. Ratios of 1:1, 1:2, and 1:5 are marked by solid and dashed lines as well as the shaded area.

Investigating the Formation of H_2SO_4 from ion-induced Oxidation of SO_2

N.T. Tsona[1], N. Bork[1,2] and H. Vehkamäki[1]

[1]Department of Physics, University of Helsinki, Helsinki, 00014, Finland
[2]Department of Chemistry, University of Copenhagen, Copenhagen, 2100, Denmark
Keywords: Sulphuric acid, molecular clusters, ion-induced nucleation.
Presenting author email: narcisse.tsonatchinda@helsinki.fi

Atmospheric aerosols are very important in human life. They participate in the formation of cloud, acting as cloud condensation nuclei. Aerosols particles are either emitted directly to the atmosphere or produced by nucleation of gas-phase species. It is therefore fundamental to understand the formation of aerosols in order to predict climate. However, the mechanism of nucleation is not fully relatively understood.

Sulphuric acid (H_2SO_4) has been identified as an important precursor for the formation of atmospheric particles (Kulmala *et al* (2006)). It interacts strongly with bases, water, and various organics in the atmosphere and forms stable molecular clusters. Understanding the mechanism of nucleation is closely related to understanding the atmospheric production of H_2SO_4. H_2SO_4 is mostly from SO_2 oxidation by OH radical, catalysed by UV light. Recently, to complement the UV-induced mechanism, a new synthesis mechanism involving ions was found (Enghoff *et al* (2008)).

It was found that SO_2 reacts rapidly with e.g. O_2^-, O_3^-, and CO_3^- (Möhler *et al (*1992)) to form atmospherically relevant ions. Due to the low oxidation state of its sulfur atom, SO_2 is seemingly an important species in the production of ions relevant to aerosol science. Thereby, we have investigated the oxidation reaction of SO_2 by SO_4^-, detected in the atmosphere at relatively high concentration by Ehn *et al* (2010).

We used a density functional theory calculation to determine structures and formation energies of relevant species for our reactions. The reaction rates were determined using the transition state theory and all the calculations were performed at T=298.15 K and p= 1atm.

Results

Upon collision between SO_2 and SO_4^-, a $SO_2.SO_4^-$ cluster is formed and an oxidation subsequently occurs inside the cluster. The stable oxidation intermediate, $SO_3SO_3^-$, is formed with ca. 8 kcal/mol Gibbs free energy gain This means that the formation of $SO_3SO_3^-$ is a likely process at standard conditions. The energy gained by forming $SO_3SO_3^-$ might induce its decomposition into SO_3 and SO_3^-, but the decomposition reaction is endothermic by ca. 18 kcal/mol (Fig. 1). However, $SO_3SO_3^-$ is a long-lived species and may collide with abundant atmospheric species like O_2. The set of reactions

$$SO_4^-(H_2O)_{0\text{-}1} + SO_2 \rightarrow SO_3SO_3^-(H_2O)_{0\text{-}1}, \quad (R1)$$
$$SO_3SO_3^-(H_2O)_{0\text{-}1} + O_2 \rightarrow SO_5^-(H_2O)_{0\text{-}1} + SO_3, \quad (R2)$$

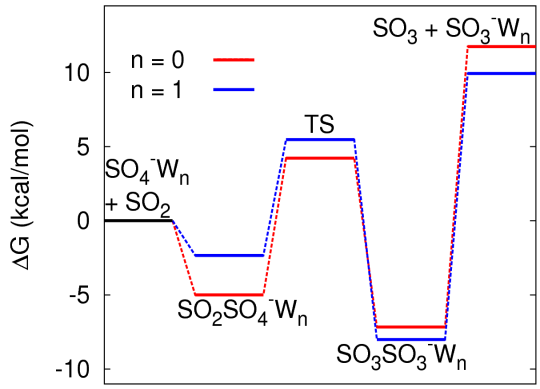

Figure 1. Free energy surface of SO_2 reaction with SO_4^-. The reaction forms a stable intermediate, $SO_3SO_3^-$, likely stable towards decomposition to SO_3 and SO_3^-. "TS" denotes transition state.

follows, where O_2 molecule induces evaporation of SO_3, while stabilizing SO_3^- as SO_5^-. The dehydrated products of reaction R2 is formed with ΔG=1.5 kcal/mol. The presence of water destabilizes the products by ca 3 kcal/mol. SO_3 easily hydrates in the atmosphere and is detected as H_2SO_4, while SO_5^-, detected in the atmosphere by Enh *et al* (2010) has been part of a complete study by Bork et al (2012).

Introduction

Atmospheric aerosol particles play an important role in climate, air quality and human health.

In Portugal, extended time series on the chemistry and morphological parameters of atmospheric aerosol particles as well as on their seasonal dependency are still scarce and mostly confined to the North of the country.As part of a wider project on aerosol composition and distribution in Southwestern Iberia, in this study we compare aerosols collected in two intensive field measurement campaigns carried out in August 2011 and February 2012.

Experimental

In order to determine aerosol particle chemical and morphological properties, two sampling modes were adopted at the sampling site located on the roof of the Évora Geophysics Center:

- Active sampling:

Particles were collected on TEM grids by a cascade impactor and a vacuum pump with nominal particle diameter cut-offs at 1, 0.65, 0.45 and 0.25 µm. The samples were subsequently analysed by VP-SEM+EDS to obtain morphological and chemical compositional data.

- Passive sampling:

Particles were collected using a modified version of the aerosol passive sampler Type A “flat plates” by Ott and Peters (2008). The air could freely flow and particles were deposited by gravitation. The sampler was placed at the top of a university building about 15m above ground level. Sampling was performed weekly to account for the slow gravitational settling of particles.
Single particles automated analysis was performed using a HITACHI 3700N VP-SEM interfaced with a Bruker 5010 XFlash EDS and QUANTAX and automatic ESPRIT software.

The particles were classified into 9 chemical and mineralogical classes and into 4 morphological classes.

Results

Figure 1 shows an example of the relative % of the most abundant aerosol classes during two periods: 18-21 August 2011 and 14-21 February 2012. The relative amount of dust-related aerosols (quartz + silicates), increases generally with particle size. Dust aerosols seems to be more abundant in the larger grain-sizes and during the summer campaign, probably due to the incidence of desert storm episodes.

The sulphate concentrations are very different for the 2 set of samples in Fig. 1, with much higher % in summer suggesting a stronger sea salt contribution. It has to be noted that in winter campaign almost 50% of the smaller particles could not be attributed to one of the main chemical classes (Other). The majority of particles assigned to this *other class* did not display a EDS spectrum. On the other hand, the presence of organic and biological particles (with a low EDS signal also due to the C stub support) is to be expected if one takes into account the widespread use of wood as fuel for domestic heating and cooking is common in Évora especially during winter time.

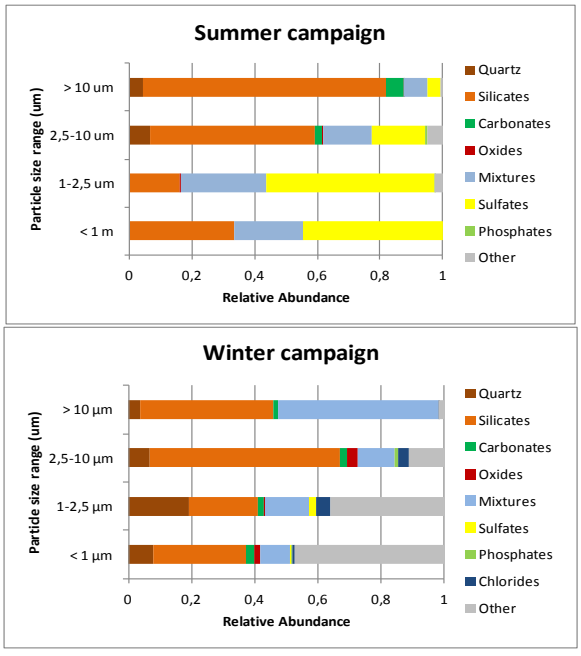

Figure1. Aerosol sampling periods: 18-21 August 2011 (top); 14-2 February 2012 (bottom)

Aerosol pollution is one of the main problems in the urban environment, because of the negative health and environmental impacted of particulate matter.

In cities, aerosol particles can arise locally (e.g. resuspended dust caused by traffic or soot from heating) or from distant sources (e.g. sea salt or Saharan dust). In this work we studied the possible distant source areas of the aerosol detected in Debrecen using backward-trajectory modelling.

In the center of Debrecen aerosol samples have been collected regulary in two size fractions: PM10-PM2.5 (particles with aerodynamic diameter between 2.5 and 10 μm) and PM2.5 (particles with aerodynamic diameter < 2.5μm) since 1993 twice a week. The aerosol concentration is measured by gravimetry and the elemental composition (for Z >13) is determined by Proton Induced X-ray Emission (PIXE) method at the macro-PIXE chamber in the IBA Laboratory of Atomki. By today the database contains more than 1200 sampling days and ~ 65.000 concentration data.

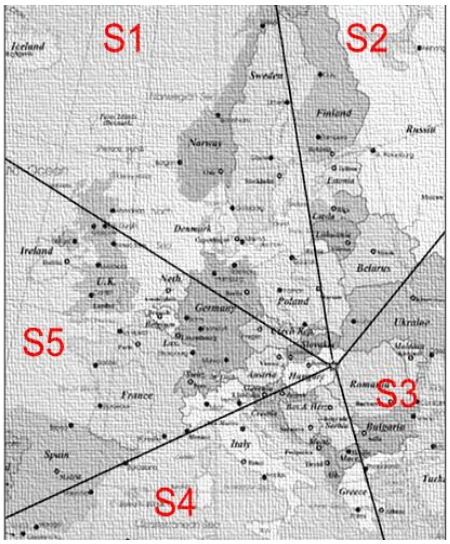

Figure1: Five sectors used to the classification the backward trajectory

The NOAA-HYSPLIT model was used to determine the spread of the aerosol particles. The backward trajectories were calculated for 72 hours periods at three different heights. We investigated what kind of aerosol composition is representative for the different European source areas. In a previous study (Borbély-Kiss *et al*, 1999) five sectors were assigned according to the most frequent wind directions (Fig1). Each trajectory has been classified to one sector. The origin of the air mass on high or low pollution levels were studied too. 513 days were found in the investigated period (1993-2006) when the sector was univocal.

Table1: Average concentration in the five sectors and the percentage contribution

	S1	S2	S3	S4	S5	Sum
events	89	58	127	88	151	513
PM10	30.9	29.8	35.7	42.5	28.8	33.3
PM2.5	18.1	16.9	19.6	23.2	17.0	18.9
>50 μg/m^3	23	15	39	42	40	159
% to sector	26%	26%	31%	48%	26%	

Table1 shows the number of events (row 1) when the body of air originated from the given sector and average aerosol concentration in both size fractions in μg/m^3 (row 2 and 3). The number of days when the measured PM10 concentration exceed the 24-h air quality limit (50 μg/m^3) are also included in the table. The ruling air mass trajctory directions are east-west. 70% of the high polution level episodes air masses originated from Southern and Eastern Europe.

Correlation analysis and receptor modelling (EPA PMF) were applyied to identify elemental fingerprints of the five sectors. This way we could separate local sources (for example road dust: high Mn and Pb content, bimass burning: K and Zn) from remote sources. In the case of NW Europe (S1) Al, Fe, Mn, Cl and Pb showed strong correlation with each other ($r > 0.7$, $p < 0.01$), which could be connected to iron mining and metallurgy. For NE Europe (S2) K, Si, Ca and Fe correlated with each other, which could be attributed to plastic industry. For SE (S3) Europe strong Br/Pb correlation were characteristics, which could aries from waste burners. In the case of Southern Europe (S4) sources attributed to Cr mining, mettallurgy and Saharan dust intrusions could be identified.

Measurements of black carbon using the Transmissometer

A.H. Tremper[1], D.C.Green[1] and G. Fuller[1]

[1]Environmental Research Group, King's College London, London, SE1 9NH, UK

Keywords: black carbon, elemental carbon, transmissometer, aethalometer
Presenting author email: anja.tremper@kcl.ac.uk

Quartz and teflon coated glass fibre filters were exposed in London as part of a PM_{10} mass measurement monitoring programme prior to the commencement of routine EC/OC measurements and prior to the implementation of the Low Emission Zone (LEZ). Analysis of these filters is designed to allow an assessment of tailpipe EC/BC emissions reductions brought about by the LEZ. The Transmissometer (Magee, 2007) offers a very cost effective method of measuring black carbon (BC) concentration on filter samples using a similar technique to that used in the Aethalometer (Magee, 2005). Various methods are available to correct aethalometer measurements for filter loading effects, (Virkkula et al., 2007; Park et al., 2010) but these methods do not directly apply to the transmissometer. Instead an empirical method was tested to correct for filter loading effects using the relationship between transmissometer BC and elemental carbon (EC) concentrations measured using a Sunset Labs Instrument.

Filters were exposed daily at the North Kensington (NK) urban background site, Marylebone Road (MY) traffic site and Earls Court Road (ECR) traffic site. After mass analysis, these filters were analysed using the Transmissometer. A subset of quartz filters, from NK and MY, were analysed for BC using the transmissometer before thermal analysis for EC by Sunset. These EC measurements were used to calculate the corrected transmissometer BC measurements with the generalised least squares method using XGenline (NPL, 2010). Various fitting methods of the calibration curve were tested. Subsequently time series of corrected BC measurements with a known uncertainty were produced to assess changes in the concentration due to the LEZ.

Two short time periods in 2006, during which thermal EC/OC measurements were available at KC and MY, were used to evaluate the transmissometer BC concentrations. Transmissometer BC from $PM_{2.5}$ filters and PM_{10} agreed well as most of the BC can be found in the smaller size fraction.

Comparing the transmissometer BC concentrations from the PM_{10} filters with the EC concentrations recorded by thermal analysis at MY, it is noticeable that the corrected BC is significantly lower than the thermal EC at higher concentrations (Fig. 1). This is not the case for NK, were concentrations are generally much lower (Fig. 2).

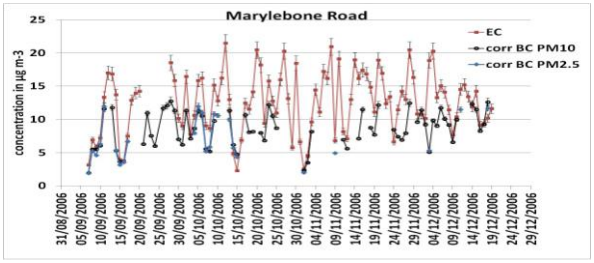

Figure 1: Conc. of thermal EC and corrected BC in PM_{10} and $PM_{2.5}$ filters at MY (all in µg m^{-3})

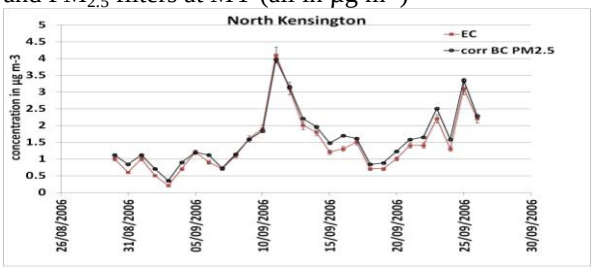

Figure 2: Conc. of thermal EC and corrected BC in PM_{10} and $PM_{2.5}$ filters at KC (all in µg m^{-3})

Overall the corrected transmissometer BC offers an opportunity to extend time series at sites with low EC concentrations – see Fig.3.

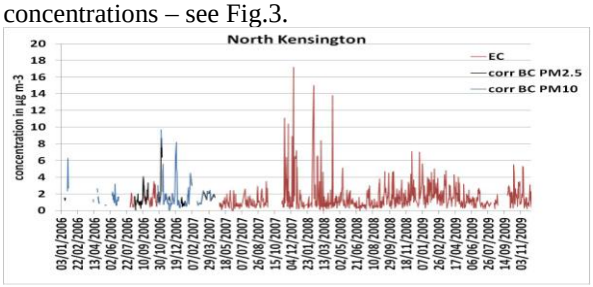

Figure 3: EC and corrected BC in PM_{10} and $PM_{2.5}$ filters at KC between 2006 and 2009 (all in µg m^{-3})

Effect of organics and their hygroscopicity on cloud condensation nuclei (CCN) activity

Deepika Bhattu and Sachchida Nand Tripathi*

Department of Civil Engineering, Indian Institute of Technology, Kanpur, Uttar Pradesh, 208016, India

Keywords: supersaturation, organics, hygroscopicity, size-resolved composition
*Presenting author email: snt@iitk.ac.in

Aerosols play a significant role in the Earth climate system directly by absorbing and scattering sunlight, and indirectly by acting as cloud condensation nuclei (CCN). Higher concentration of CCN in the air parcel results in small cloud droplets, thereby affecting the cloud radiative properties. This leads to reflection of incoming shortwave and cooling the Earth's surface (Twomey, 1974).

Aerosols are the complex mixture of organics, inorganics, BC and dust. The water uptake capacity of inorganics, single organic component are well understood and while the properties of their mixtures need further studies (Petters and Kreidenweis, 2007). Understanding the activation properties of the ambient aerosols need the size and mixing state resolved chemical composition, which is not possible with the present level of instrumentation.

Several studies examined the contribution of aerosol parameters like, size distribution and chemical composition or hygroscopicity, to CCN activity using Köhler theory. It has been found that performance of CCN closure study depends on how well the chemical composition mainly organics and mixing state of aerosols is treated. Various studies have tested different assumptions regarding mixing state of aerosols using chemical composition from AMS (both size resolved and bulk) (Cubsion et al., 2008). It appears that the closure ratio improves as the distance from the source region increases because the particles become more internally mixed and less size dependent.

We conducted measurements of CCN, aerosol size distribution and chemical composition at SS = 0.2-1% at the Indian Institute of Technology Kanpur, India, in November, 2012. The main goal of this study is to investigate the effect of organics and their hygroscopicity on cloud condensation nuclei activity. CCN closure study was carried out on the basis of size distribution measured through Scanning Mobility Particle Sizer (SMPS) and chemical composition from Aerodyne HR-ToF-AMS, using simple Köhler theory at five different supersaturations (0.2, 0.4, 0.6, 0.8, 1%). The size dependence of the chemical composition and the mixing state (internal and external) are accounted in various ways. During the sampling period, CCN concentration ranged from 1500-5000 #/cc at lower SS (0.2%) while at medium SS (0.4-0.6%) it ranges from 3000-15000 and at higher SS (0.8-1%) varies from 5000-20000. The total aerosol (CN) concentration varied from 7000 to 34000 #/cc. Diurnal variation in the activation fraction (CCN/CN) is observed with maxima in day time (1200-1800 hrs). In addition, both CCN and CN concentration decreased during day time due to expansion of boundary layer due to solar heating. Due to higher CCN loading, SS depletion correction has been applied throughout the sampling period (Lathem and Nenes, 2011).

Preliminary results show that differences in the $CCN_{predicted}$ and $CCN_{measured}$ decreases with the increase in SS. For example, closure ratio improved from 180 % to 50% as the SS increases from 0.2% to 1.0%, when aerosols were assumed to be internally mixed and composed of inorganics and insoluble organics. This can be attributed to less sensitivity of smaller sized particles to chemical composition. This over-prediction can be reduced by considering day time and night time aerosols separately during closure study. It has also been observed that O:C ratio increases from 0.3-0.6 during the day time due to photochemical activity and oxidation of organics, thus increasing the activation fraction. The effect of organics on CCN activity is examined using an effective hygroscopicity parameter through "κ-Köhler theory" (Petters and Kreidenweis, 2007).

Estimation of source apportionment using the UNMIX model of ambient $PM_{2.5}$ in Seoul area, Korea

Yeong-Jin Jeong, Tae-Ho Lee, and InJo Hwang
Department of Environmental Engineering, Daegu University, Gyeongsan, Gyeongbuk, 712-714, Korea

Keywords: air quality, $PM_{2.5}$, source apportionment, UNMIX, Seoul
Presenting author email: ihwang@daegu.ac.kr

Many countries recently have developed and carried out policies to control air pollutants, focusing their effort on establishing new environmental guidelines as well as in evaluating the pollution sources more accurately. Therefore, one of these efforts was to survey the physicochemical properties of atmospheric particulate matter (PM) and thereby, quantitatively understand to what extent the specific pollution sources affect the adjacent regional atmosphere (Yi and Hwang, 2013). The Seoul (capital of Korea) has severe air pollution problems, and a variety of governmental policies, such as expansion of the use of liquefied natural gas and low-sulfur fuels and movement of industrial sources out of the city, have been implemented to improve urban air quality. The objective of this study was to estimate the $PM_{2.5}$ composition at the sampling sites by surveying concentration trends after analyzing the mass concentration of $PM_{2.5}$ samples and the elements, ions, and carbon in $PM_{2.5}$. UNMIX was applied to identify the existing sources and apportionment of the PM mass to each source. These results suggest the possible role for maintain and manage ambient air quality of Seoul, and achieve reasonable air pollution strategies.

The ambient $PM_{2.5}$ samples were collected at 9 sampling sites (Hwagok, Guro, Banghak, Hyoje, Dongdaemun, Sinsa, Guui, Yongin, and Ui) in Seoul area. $PM_{2.5}$ samples were collected using Partisol 2300 (Thermo, USA) from September 2008 to March 2010. The samples were collected on Teflon, nylon, and quartz filters every 6 days. These filters were used for analysis of elemental, ionic species, and EC/OC by ICP, IC, and TOT method. The UNMIX model was used to develop source profiles and to estimate their mass contributions.

The five sources were identified as soil, secondary aerosol, vehicle/road dust, Ca related, and industry/oil/biomass burning. The average contributions of all the sources identified during the sampling periods were showed in Figure 1. The result of the UNMIX modeling showed that the source were apportioned by industry/oil/biomass burning 11.5 % (2.97 $\mu g/m^3$), Ca related 2.2 % (0.57 $\mu g/m^3$), vehicle/road dust 37.3 % (9.62 $\mu g/m^3$), secondary aerosol 39.5 % (10.20 $\mu g/m^3$), and soil 9.5 % (2.46 $\mu g/m^3$), respectively. Figure 2 shows comparison of source contributions between UNMIX and PMF model in the Hyoje sampling site. In the case of industry/oil/biomass burning and secondary aerosol source contributions of the PMF result showed slightly higher than the UNMIX result. On the other hand, in the case of vehicle/road dust and soil source contributions of the UNMIX result showed slightly higher than the PMF result.

Keywords: Arctic aerosol, on-ship measurement, biogenic emissions, heavy metals
Presenting author email: udisti@unifi.it

The Arctic Glacial Sea is one of the world regions more affected by the impact of the present positive climate forcing. The consequent feedback processes, involving relevant variations of marine and coastal eco-systems (including large changes in extension and thickness of the annual and permanent sea ice and in the permafrost superficial structure) constitute a serious issue for the wild life and the human settlements at the high latitudes.

The atmospheric aerosol is one of the main components of the Earth climate system through the interaction of the particles with solar and Earth radiation, the cloud formation and the changes in superficial albedo. Although these effects are well known, large uncertainties affect not only their quantitative evaluation but also the sign of the variation (positive or negative climate forcings). This lack of knowledge especially affect the Polar Regions, were just a relative little number of monitoring stations is operative. Besides, data on the chemical composition of aerosol in the open sea are very scarce.

In order to contribute to fill this knowledge gap, an intensive sampling campaign was carried out in the sea area between Norway and Svalbard Islands (Norwegian and Greenland Seas) in the framework of the AREX 2011 oceanographic cruise aboard Oceania ship.

In the period June 20th – August 12th 2011, 79 12-h PM10 samples for ionic and metal composition (Teflon filters) and 42 24-h PM10 samples for Elemental and Organic Carbon fractions (EC and OC, respectively) on quartz filters were collected. The sampling devices (low volume sequential samplers with PM10 sampling heads) were located in a platform 7-m high over the ship deck in the bow section, in order to minimize the contamination risk from ship engine emissions. The very low values measured for heavy metals and EC fraction, possibly used as fuel combustion markers, suggest that the contamination levels could be considered negligible.

One half of each Teflon filter were analysed for inorganic and selected organic anions and inorganic cations by a three-ion chromatograph system. The remaining half was used for metal determination by SF-ICP-MS after mineralization with HNO_3 + H_2O_2 in microwave oven.

Here we report the spatial distribution of the most significant aerosol components along longitudinal (Tromso – Svalbard Islands) and latitudinal (east-to-west route in the Norwegian Sea and along the western side of the Svalbard Island) transects.

In particular, the atmospheric concentrations of secondary marine aerosol (sulphuric acid and methanesulphonic acids (MSA) from phytoplanktonic emissions) was plotted as a function of the ship position in order to attempt to figure out a possible relationship between biogenic aerosol and changes in the source strength as a function of time and marine area (figure 1).

From a temporal point of view, non-sea-salt sulphate and MSA show two sharp maxima in June, in phase one with each other, while lower contribution of biogenic emission are recorded in the filters collected in July. On the other hand, no clear trend along coastal to open-sea transects is evident. Higher MSA concentrations (up to 120 ng/m^3) were measured near the Norwegian coast, along the Tromso-Svalbard route, and in the south-west coastal areas of the Svalbard Island, while the lowest values (few ng/m^3) were found in the open-sea at north-west of the Islands

Spatial and temporal distribution of sea spray components (Na, Mg, chloride), N-cycle compounds (nitrate and ammonium salts), dust markers (Ca, Al, Fe, Mn, Ti) and selected heavy metals possibly coming from anthropic emissions were measured. C-cycle secondary aerosol components (OC fraction, light-chain carboxylic acids) were also determined in order to gain information on the possible contribution of the gas-to-particle conversion of volatile organic compounds (VOCs) in constituting a significant part of the aerosol formation nuclei.

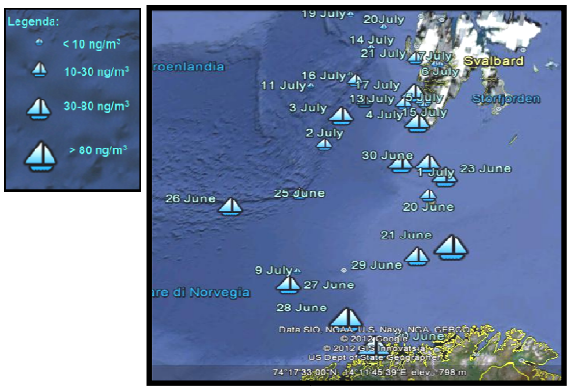

Figure 1. Spatial distribution of MSA in PM10 aerosol.

Keywords: aerosol concentration, source apportionment.
Presenting author email: ulevicv@klt.mii.lt

Atmospheric aerosols have critical effects on human health and the global radiation balance. The magnitude of these effects remains largely unknown due to uncertainties in carbonaceous aerosol sources, transformations, and atmospheric lifetime. **AEROLIT** will provide long-term, comprehensive measurements of carbonaceous aerosol composition at urban, rural, and coastal sites in Lithuania.

AEROLIT couples state-of-the-art measurements (aerosol mass spectra, stable isotope ratio measurements, and organic molecular markers analysis) with source apportionment factor analysis techniques using the multilinear engine to provide a quantitative assessment of the factors affecting Lithuanian air quality. Measurements will be simultaneously performed at coastal, rural, and urban sites. The **AEROLIT** project consists of five Work Packages (WPs) that will be completed over the study period (Fig. 1):

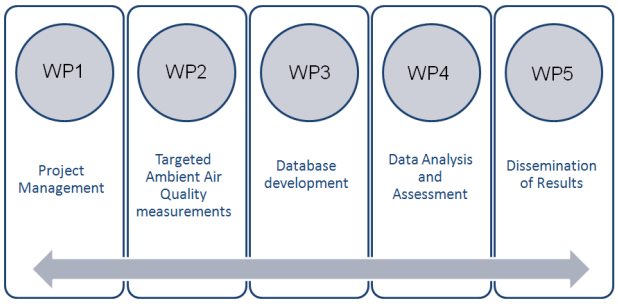

Figure 1. Research associated work plan.

The principal measurements to be performed are:
a) Long-term online aerosol mass spectrometry using an aerosol chemical speciation monitor (ACSM) and a quadrupole aerosol mass spectrometer (Q-AMS).
b) Long-term filter sampling with a High-Vol sampler at 3 sites: Offline analysis of aerosol collected on filters using high-resolution aerosol mass spectrometry (HR-AMS), the new compound-specific TAG-AMS (thermal desorption aerosol gas chromatography-AMS) technique (Williams *et al*, 2006) and isotope-ratio mass spectrometry (IR-MS).
c) Optical measurements of black carbon (BC) using a 7-wavelength aethalometer.
d) A subset of the filters collected in (b) will be analyzed for ^{14}C (modern/fossil carbon) and monosaccharide anhydrides (tracers for biomass combustion).

An example of the **AEROLIT** approach is given in Figure 2, where a pilot study of a biomass burning pollution event from long-range transported aerosols was investigated.

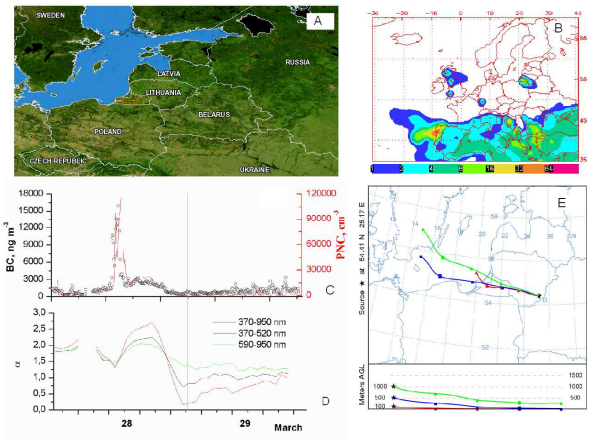

Figure 2. Active fires detected on 28-29 March, 2012 during high BC concentration event: (A) by the MODIS Rapid Response System, (B) NAAPS Smoke surface concentration (ng m^{-3}), (C,D) BC aerosol and particle number concentration and (E) 2-days air mass backward trajectories to Vilnius (at 100, 500 and 1000 m AGL) during the event of wildfires.

Previous results about aerosol source characterization in Lithuanian sites can be found in Garbariene *et al* (2012) and in Ulevicius *et al* (2010). **AEROLIT** brings together leading air quality and pollution researchers with the following goals:
• Identify and quantify the processes and sources governing spatial and temporal PM concentrations at urban, rural, and coastal locations in Lithuania.
• Classify and quantify carbonaceous aerosol in terms of emission mechanism (primary vs. secondary), source geography (local vs. regional vs. trans-national), and source/precursor class (natural vs. anthropogenic, modern vs. fossil carbon).
• Conduct targeted chemically resolved organic aerosol and related molecular-marker measurement campaigns in urban, rural and background sites for source apportionment.

This work was supported by the Lithuanian-Swiss cooperation programme ”Research and development“ project **AEROLIT** (Nr. CH-3-ŠMM-01/08).

Keywords: aerosol optical properties, aerosol origin sources. remote island.

Presenting author email: avalenzuela@ugr.es

During the last decades an enormous effort has been done to determine the effects of aerosols on climate. However, due to their large spatial-temporal variability and the different mixtures between aerosol types, there are still significant uncertainties in understanding the aerosol optical and microphysical properties.

The aerosol optical properties in origin, as issued by the sources, are conditioned by the potential changes during the path of the air masses as well as by the local aerosol properties at the reception site. A possibility in order to minimize the effect of the local aerosol is placing the measuring stations in remote locations far from the potential influence of local aerosol sources. Measurements taken at small islands are valuable because local sources are generally negligible, and medium and long-range transport, together with aerosol aging processes, play a relevant role, thus providing information on aerosol properties over a relatively large scale.

Backward trajectory analysis is a widely used technique in order to relate the air masses origin with the aerosol optical properties at the receptor site (e.g. Pace et al., 2006).

In this work air masses over Alborán Island (35.95º N, 3.03º W) from June 2011 to January 2012 were analysed by means of back-trajectories using HYSPLIT model. The aerosol radiative properties have been classified taking into account sun-photometric measurements and the air mass history. The aim is to classify columnar aerosol properties according to the potential aerosol origin sources. The air masses classification method identifies as a potential aerosol source that region which the difference between the height of the air mass and the height of the boundary layer is minimum.

Optical and microphysical aerosol properties were simultaneously retrieved from sun-photometric measurements (CIMEL CE-318) according to the methodology described by Olmo et al. (2008). The instrument provides solar extinction measurements at 340, 380, 440, 670, 870 and 1020 nm, and sky radiance measurements at 440, 670, 870 and 1020 nm using the almucantar and principal plane configurations.

From the air masses classification three broad geographical sectors have been identified: Sector A (Mediterranean sea and Europe Centre), Sector B (North Africa), and Sector C (Atlantic Ocean and Iberian Peninsula).

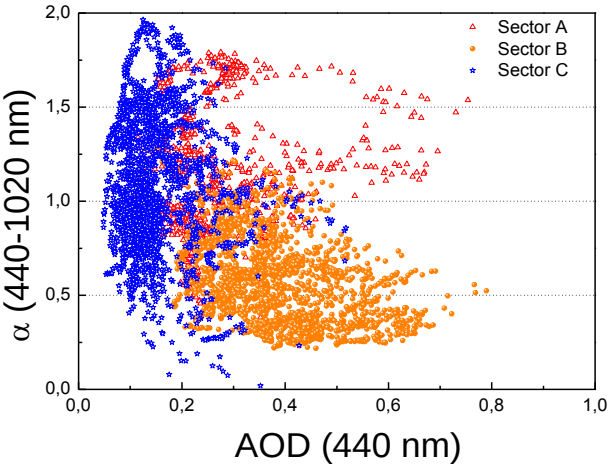

Figure 1. The Angstrom exponent (440-1020) versus AOD (440 nm) for each origin sector.

Figure 1 shows three main groups of particles corresponding to the three origin sectors. Although the values for sector B (African air mass) showed typical high aerosol optical depth (AOD) linked to low Angstrom exponent (α) (coarse particles) a small group of observations showed α values higher than 1, indicating also a contribution of fine particles during desert dust events. An important number of observations for sector C were concentrated in a range with AOD values below 0.2 and α value mainly concentrated in a region between 0.5–1.0 likely related to marine aerosol. The observations corresponding to the sector A contain points with AOD values in the range 0.2-0.8 and α mainly above 1, typical of fine mode aerosol from urban/industrial activities or biomass burning.

A LUR model for NO_2 and BC to assess exposure of schoolchildren to traffic-related air pollution at their home address

Martine Van Poppel[1], Evi Dons[1,2], Luc Int Panis[1,2]

[1]VITO - Flemish Institute for Technological Research, 2400 Mol, Belgium
[2]Hasselt University, 3590 Diepenbeek, Belgium

Keywords: Black Carbon, NO_2, LUR, traffic.
Presenting author email: martine.vanpoppel@vito.be

To assess the health impact of traffic related air pollution on schoolchildren, the HEAPS study (Health Effects of Air Pollution in Antwerp Schools) was performed.
The HEAPS study comprises the biomonitoring of 130 children (aged 6-12) from 2 schools by measuring oxidative stress, inflammation and cardiovascular markers and simultaneous air quality monitoring.

To assess the exposure of the children, air quality measurements were performed at the school locations, at a selection of 40 home locations and while in transport. In addition the land use regression (LUR) technique was applied to model exposure to BC and NO_2 at all 130 home locations. BC and NO_2 measurements were performed at 8 home locations simultaneously during 5 consecutive weeks resulting in 40 home locations sampled. Monitoring was performed in two seasons: spring and autumn. NO_2 was monitored using diffusive sampling tubes resulting in a weekly average. BC was measured using µ-Aethalometer (AethLabs), resulting in 30 min time profiles and a weekly average. NO_2 was measured at 40 and an additional 13 locations simultaneously in each season. In addition, NO_2 and BC measurements were performed during the entire monitoring campaign at two school locations and at an urban location of the AQ monitoring network. The data of the last location were used to rescale BC and NO_2 concentrations that were measured consecutively.

Three categories of potential variables are included in the LUR: land use (CORINE land cover), traffic variables (e.g. traffic densities, road length, number of heavy duty vehicles), population density (addresses). To build the LUR model, the method as described by Henderson et al. (2007) was applied. For both pollutants a LUR model was set-up for spring, autumn and a yearly average.

Significant variables for both models (NO_2 and BC) in spring are traffic load (50m), heavy duty traffic (100 m) and road length (1km). At short distance (50 m and 100m), traffic characteristics are important for the variability of both pollutants. At a larger distance also the total number of roads affects the pollutants concentrations, probably as a proxy for urbanization. The BC model also includes the intensity at the nearest busy road (>10,000 vehicles) and the NO_2 model includes also nature with a negative estimate.

The LUR for autumn includes an additional variable 'number of address within 50 m'. This can be explained by additional sources of household heating, that are only relevant in the cold season.

Model validation was performed using leave-one-out cross-validation. Results for spring are presented in Table 1.
The paper will present the LUR results for spring, autumn and yearly average. Significant variables will be discussed and model validation will be presented.

Table 1: Results of model validation (spring)

	Conc. Modelled ($\mu g/m^3$)	Conc. Measured ($\mu g/m^3$)	r	IA	NMSE
BC	1.55	1.59	0.63	0.77	0.05
NO_2	28.1	28.2	0.90	0.94	0.01

The Košetice observatory (49°35´ N, 15°05´E, 534 m a.s.l.) is operated by the Czech Hydrometeorological Institute (CHMI) and was established in 1988 as a station specialized in air quality monitoring at the background scale. The observatory is involved in GAW/WMO (Global Atmosphere Watch), EMEP/ECE (Co-operative Programme for Monitoring and Evaluation of Long-range Transmission of Air Pollutants in Europe) and ICP-IM (International Co-operative Programme on Integrated Monitoring).

The monitoring program includes meteorology, solar radiation, air chemistry, precipitation chemistry, hydrology, surface water chemistry and soil analysis. More detailed information is available in (Váňa *et a*l. 2007, 2009).

The basic measurements of atmospheric aerosols were implemented within the National Imission Network (operated by CHMI) since the start of the observatory. At the beginning, mass concentrations of total suspended particles (TSP) were monitored. In 1996, monitoring of PM_{10} concentrations started according to the European legislation. The recent studies have concluded that fine particles ($PM_{2.5}$) are more hazardous in terms of mortality on cardiopulmonary diseases and lung cancer (Pope et al., 2002). Measurement of $PM_{2.5}$ started at Košetice Observatory in 2004.

Thanks to its well selected location and long-term homogeneous data series, Košetice Observatory has been included into several European projects. In regards to atmospheric aerosols, the first of them was EUSAAR (European Supersites for Atmospheric Aerosol Research), an EU-funded I3 (Integrated Infrastructures Initiatives) project carried out in the FP6 framework of the specific research and technological development programme "Structuring the European Research Area - Support for Research Infrastructures" in the period 2006-2011. The EUSAAR aerosol activities are continuing within more widely composed EU FP7 project ACTRIS (Aerosols, Clouds, and Trace Gases Research Infrastructure Network).

Advanced aerosol measurements have been carried out in close co-operation with the Institute of Chemical Process Fundamentals (ICPF). Continuous sampling of dry particle number size distributions using a Scanning Mobility Particle Sizer (SMPS, TROPOS) started in 2008 with 5 min time resolution covering particle size range from 9 to 900 nm (Asmi et al., 2011). One year series of aerosol hygroscopicity data had been collected between 2008-2009 using a Humidity Tandem Differential Mobility Analyzer (HTDMA, ICPF) with one hour time resolution. $PM_{2.5}$ OC/EC measurement has been implemented since 2009 with 6 days sampling frequency on 2 quartz-fiber filters (Putaud et al., 2010). Since October 2011 (within ACTRIS), a carbon honeycomb denuder developed within EUSAAR had been installed upstream the filters. The OC/EC content in the samples has been determined by thermal-optical analysis at CHMI Central Laboratories in Prague-Libuš using the OC/EC Sunset Lab Dual Analyzer. Charring correction has been done by laser transmission monitoring.

Special attention to the climatological effects of atmospheric aerosols is devoted in The CzechGlobe project operated by Global Change Research Centre AS CR at the co-located station Košetice (ACTRIS) – Křešín u Pacova (ICOS). The measurements of optical properties of the atmospheric aerosol started in 2012 as the first of this type in the Czech Republic. The aerosol scattering coefficients at three wavelengths have been determined by an integrating nephelometer (TSI 3563). The aerosol absorption coefficients at seven wavelengths have been gathered using an aethalometer (AE-31, Magee). All parameters have been determined on dry aerosol particles, the measurement methods closely follow ACTRIS recommendations, and the results will be used for the extension of the Czech participation within ACTRIS.

The authors gratefully acknowledge funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement n° 262254 and a project of Czech Science Foundation P209/11/1342. This work is an output of the CzechGlobe Centre that is being developed within the OP RDI and co-financed from EU funds and the State Budget of the Czech Republic (Project: CzechGlobe – Centre for Global Climate Change Impacts Studies, Reg. No. CZ.1.05/1.1.00/02.0073), of the National Infrastructure CzechCOS/ICOS (LM2010007) and institutional support (RVO:67179843).

Source apportionment of carbonaceous PM2.5 with ^{14}C analysis in Nagoya, Japan

F. Ikemori[1, 2] *, K. Honjyo[1], M. Yamagami[2], T. Nakamura[3]

[1] Graduate School of Environmental Studies, Nagoya University, Nagoya 464-8601, Japan
[2] Nagoya City Institute for Environmental Sciences, Nagoya 457-0841, Japan
[3] Center for Chronological Research, Nagoya University, Nagoya 464-8601, Japan
Keywords: radiocarbon, PM2.5, biomass carbon, fossil carbon.
Presenting author email: ikemori@nagoyakankaken.net

Radiocarbon (^{14}C) is a powerful tracer for estimating the source apportionment of carbonaceous compounds because ^{14}C can be used to discriminate between modern and fossil carbon. There are many studies of PM using ^{14}C in Japan, however studies with ^{14}C analysis for annual and long-range transport from Asian continent are few. We measured ^{14}C concentrations of total carbon (TC) in PM2.5 in Nagoya to investigate the source apportionment of carbonaceous compounds and the long-range transport from Asian continent.

Sampling of PM2.5 was conducted in Nagoya, Japan. Nagoya is located almost at the center of Japan (latitude 35°18'N, longitude 136°91'E), has a temperate climate (average temperature of 16.6 °C), over 2.2 million inhabitants and is one of the major cities in Japan. We carried out daily sampling of PM2.5 for 23.5 h using FRM-2000 from April 2003 to March 2004 at an urban site in Nagoya. 173 samples were collected for a year. Organic carbon (OC) and elemental carbon (EC) were analyzed by the IMPROVE thermal/optical reflectance (TOR) method with carbon analyzer (Sunset Lab). $^{14}C/^{12}C$ ratio was measured with an AMS ^{14}C system at Nagoya University. The samples for 3-11 days were pooled, because it required more than 1 mgC per 1 measurement in order to measure $^{14}C/^{12}C$ ratio with sufficient accuracy. Biomass carbon (BC) and fossil fuel carbon (FC) were calculated by the previous method (Takahashi *et al*, 2007).

The changes of pMC and OC/EC are shown in Fig. 1. Especially in spring, pMC and OC/EC show similar seasonal variations. It is suggested that the change of pMC is not influenced by primary sources (e.g. diesel, industry, etc.) but by other sources (e.g. secondary generation from volatile organic compounds (VOC), long-range transport, etc.).

The concentrations of FC and BC are shown in Fig. 2. BC concentration shows variations similar to OC in spring. Backward air mass trajectories were calculated during the sampling period in spring to identify the source region of high BC concentrations because the air mass flows from the Asian continent in spring. The air mass came from Siberia when OC and OC/EC have high values especially 5-1 and 6-1 (Fig. 2). However the result of 6-2 that has lower OC and BC concentration than 5-1 or 6-1 showed that the air mass came from various regions. In Siberia, large forest burning happened in 2003. High BC concentration in 5-1 and 6-1 is influenced by this forest burning in Siberia.

BC and FC show high concentrations in fall to winter. Some reports say that open burning of agricultural biomass and dry vegetation might be the dominant sources of biomass-derived aerosols. It is considered that biomass burning is important contributor to total carbon (TC) in fall to winter, because daily concentrations of K^+ which is a known tracer for biomass burning s how good correlation with BC. In addition, it is considered that fossil-origin carbon from primary sources is important contributor to TC, because daily concentrations of NO_3^-, NO_x and CO which are known the tracers for primary sources (e.g. diesel, industry, etc.) show good correlation with FC. The high BC and FC concentrations were due to atmospheric stability, because the velocity of the wind showed reverse variations for BC and FC.

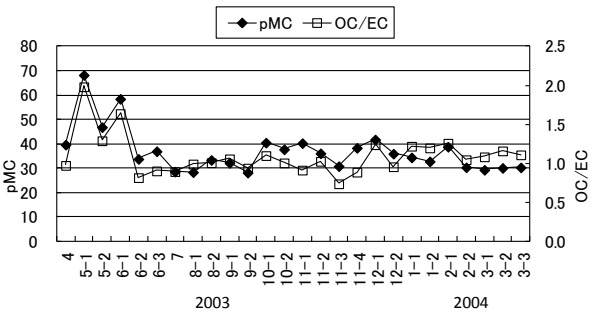

Figure 1. The changes of pMC to OC/EC.

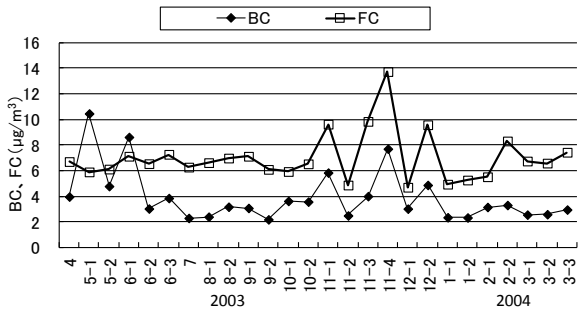

Figure 2. The variations of BC and FC concentration.

Presenting author email: perola@iq.usp.br

The Brazilian Amazon region has been intensively affected by deforestation and biomass burning, resulting in increased impacts on our climate and environment with adverse effects on health (Alves *et al*, 2011).

Moreover, studies have documented that one of the components that may be responsible for the observed health effects are organic particulate matter, mainly carcinogenic and/or mutagenic compounds such as polycyclic aromatic hydrocarbons (PAHs) (Boneta et al., 2009).

The objective this study was to identify and to quantify the PAHs in the particulate matter smaller than 10µm (PM_{10}) in filter samples collected in Porto Velho, located in the northern state of Rondonia, region of deforestation and human occupation in the Amazon.

The PM_{10} samples were collected during the dry season (July - October/2011) using high-volume sampler (Figure 1). Subsequently, the samples were extracted with dichloromethane and fractionated in different classes of organic compounds. The PAHs were analyzed by gas-chromatography-mass spectrometry.

Figure 1. The PM_{10} samples were collected using high-volume sampler in Porto Velho, Amazon region.

PM_{10} average mass concentration in the samples collected were 27.3 µg/m³ (Figure 2). The majority of the PM_{10} concentrations did not exceed the limit established by the World Health Organization (WHO) (50 µg/m³).

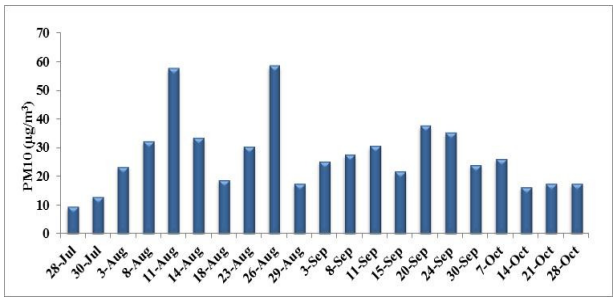

Figure 2. Concentrations of PM_{10} collected in Porto Velho.

The results showed that the anthracene, indene[1,2,3-c,d]pyrene and benzo[g,h,i]perylene were the most abundant compounds among those analyzed. Benzo[a]pyrene, a highly mutagenic and carcinogenic compound, has been identified (Figure 3).

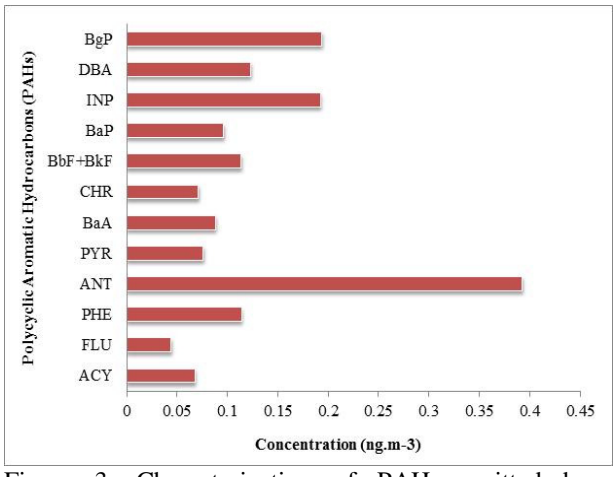

Figure 3. Characterization of PAHs emitted by biomass burning in Porto Velho.

Optical and chemical characterization of biomass burning aerosols

J. Vasilescu, L. Marmureanu, A. Nemuc, C. Talianu, L. Belegante
National Institute of R&D for Optoelectronics, Magurele, Ilfov, RO 77125, Romania
Keywords: mass spectrometer, lidar, optical and chemical properties
Presenting author email: jeni@inoe.ro

The aim of this study is to characterize biomass burning organic aerosols (BBOA) detected during the EMEP summer campaign (07 June - 18 July 2012) at Magurele site (44.35 N, 26.03 E) near Bucharest, Romania, using collocated instruments.

Chemical composition and size resolved distribution of submicronic non-refractory aerosols at ground level have been evaluated using a C-TOF aerosol mass spectrometer (AMS) model (Allan et al, 2003). The long range transported aerosols have been studied using a multiwavelength Raman lidar system, which perform vertical measurements in the frame of EARLINET (Pappalardo, G., 2010) since 2008. The lidar system provides backscatter coefficients (1064, 532, 355 nm), extinction coefficients (532, 355 nm) and linear particle depolarization ratio (532 nm) of aerosols between 0.8 and 10 km altitude (Radu et al, 2010).

The long range transported aerosols cases were confirmed by Hysplit- Hybrid Single Particle Lagrangian Integrated Trajectory Mode (Draxler et al, 2012) and MODIS (Moderate Resolution Imaging Spectroradiometer) global fire maps.

Even though the instruments usually measure different air samples, AMS at the ground level and Lidar the vertical profile, on particular meteorological conditions the lofted layers sensed by lidar could be also detected by AMS after downward mixing. We identified 16 cases of biomass burning aerosols at ground level during this campaign. On 11th of July 2012 both AMS and lidar systems sensed BBOA. The air masses traveled from the West of Europe, where high density of forest fires has been showed by MODIS fire map.

The time series of 355 nm wavelength range corrected signal from lidar measurements show a distinct smoke layer at 2.5 km (Figure 1), which is mixing within the planetary boundary layer during the night of 11 July 2012. The plume, descending from 2.5 to 1.5 km, is characterized by extinction related Angstrom exponents (355/532 nm) between 2.2 and 1.7 and lidar ratios between 35 and 55, typical for smoke (Muller D. et al, 2005).

According to AMS measurements on 11 July 2012, main species at ground level are organics, nitrate, sulfate, and ammonium as can be observed in Figure 2. The organics concentrations represent around 40% from the total mass of the submicronic aerosols (Figure 2). The wood combustion marker *f60* values (ratio of m/z 60 to total organics) indicate the presence of BBOA (Cubison et al., 2011) after 18:00 UT, approximately 36 hours old. The age of BBOA was estimated by both *f44* (ratio of m/z 44 to total organics) and *f60* values and by Hysplit back trajectories. The smoke marker decreases by a factor of 2 between 18:00 and 14:00 next day, while the f44 increases from 0.15 to values around 0.25.

Using the synergy of AMS, lidar data and model the presence and age of BBOA was confirmed.

Keywords: boreal aerosols, chemical composition, hygroscopic properties
Presenting author email: alfo4ka@rambler.ru

Organic aerosols (OA) along with the elemental carbon (EC) and inorganic ions strongly contribute to direct and indirect aerosol effects on climate. Boreal forests in Eurasia are a major source of primary organic aerosols (POA) directly emitted from the surface to the atmosphere and secondary organic aerosols (SOA) formed from gaseous precursors in the atmosphere. In order to evaluate and understand the influence of aerosols on climate change in the Artic and Northern Eurasia, long-term observations of the OC, EC and ion content of aerosols in the boreal zone are needed.

In this work we present continuous measurements from April 2010 to June 2012 conducted at Zotino Tall Tower Observatory in Central Siberia (ZOTTO, 60º N, 89º E), Russia . The quartz fiber filters were analyzed for organic and elemental carbon by thermal-optical instrument (SunSet lab.). The Nuclepore filters were analyzed for major anions and cations by ion chromatography (Dionex, ICS-1100). With help from high time resolution CO and light absorption results and HYSPLIT back trajectories calculations, the filter samples were separate to episode samples and non-episode samples.

The aerosols chemical composition were clearly different between episode and non-episode samples, and between winter and other three seasons. The winter episodes associated with elevated concentrations for most of species were usually related to anthropogenic pollution, the air masses during such episodes had passed over the central Siberian region around Omsk and Novosibirsk – a heavily industrialized area. During spring and fall, a number of samples exhibited high K+, and oxalate levels, indicating an impact from biomass burning. In addition a notable episode with extreme high Na, Cl, and Mg were observed for the samples collected between 20 to 24 December 2010, which may result from long range transport of sea salt.

In the aerosol chemical mass closure calculations, six aerosol types were considered. Organic matter (OM) contributed by far the most to the PM mass; it accounted for about 60-70% of the average PM mass. Followed by Secondary Inorganic Aerosols species (SO4, NH4, and NO3), more than 30% of PM mass. OM contribution to PM mass was lower in winter than that in the other three seasons, while EC, Ammonium and Nitrite show higher contribution in winter. The mean PM mass attribution to the different aerosol types Zotto during non-episodes periods were similar to those for the 2007 campaign at the forested site of Hyytiälä, Finland. EC and Nitrate were more important and Ammonium was clearly less important at Zotto, though.

Key issues are the hygroscopic growth of boreal aerosol particles and their activation as cloud condensation nuclei (CCN). Water soluble organic carbon compounds typically account for ~50% or more of total OC (Timonen, 2011) but their impact on aerosol water uptake and cloud formation are not fully characterized. In this study the mass-based hygroscopicity measurements under sub-saturated conditions at 5-99% RH (FDHA, Mikhailov et al., 2013) were used to characterize CCN and hygroscopic properties of the boreal aerosols. It was shown that aerosol water uptake is basically controlled by concentration of inorganic ions in the aged particles.

Measured concentrations of polycyclic aromatic hydrocarbons in urban air are the outputs of mixed emissions from various sources. Because of the carcinogenic and mutagenic properties of the inhalable size particulate PAHs, various methods for source apportionment have been reviewed to extract source specific profiles.

Positive Matrix Factorization has been widely used to apportion the source of pollutants recently, as one of the advanced receptor modelling tools. There are some difficulties to extract site representative profiles because of the uncertainties caused by transport and removal mechanisms between sources and receptors. However, the fact that there are similar extracted source profiles from different continental locations support the existence of source specific profiles (Christie et al., 2012).

Application of PCA to the UK PAH Network sites by Mari *et al* (2010) and Brown and Brown (2012) identified that urban PAH including benzo(a)pyrene was associated with metallurgical industry emissions, domestic solid fossil fuel combustion for heating, and traffic influence. However, common fuel usages between the domestic and industry sector sometimes make it difficult to separate the two specific source profiles and quantify each contribution.

An example of the results shown in Figure 1 is a decomposition of a known industry influenced urban particle-bound PAH dataset into an industry factor with sporadic emission, and a domestic combustion origin with notable seasonality. The latter profile strongly explained by cyclopenta(c,d)pyrene and anthanthrene, was consistent with a factor profile extracted from another dataset which domestic combustion is known to be prevalent.

Known local emission characteristics of combined PAH with seasonal variation made it possible to distinguish between domestic fuel combustion origin and industry influence. The largest contribution to the particle associated PAH and BaP was from traffic exhaust and solid fossil fuel combustion, respectively across UK urban areas.

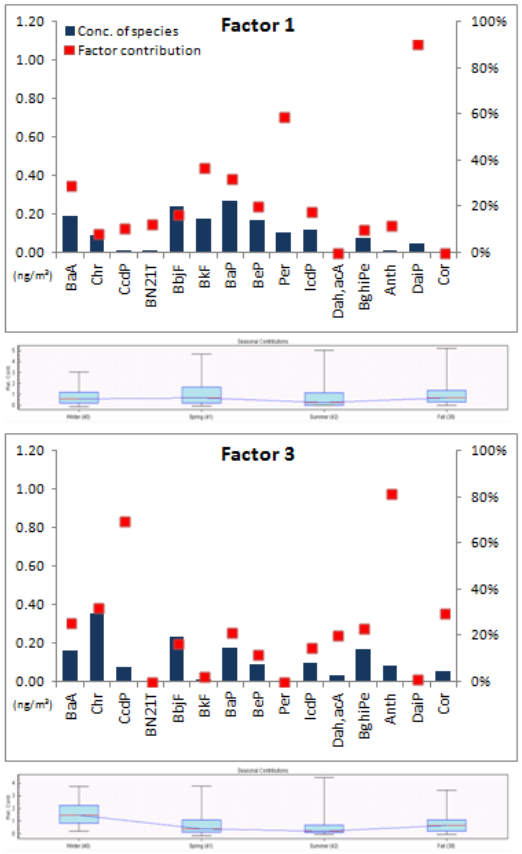

Figure 1. Extracted two factor profiles from known industry sites.

Keywords: $PM_{2.5}$, ions, roadtunnel, urban.
Presenting author email: marcelovieira@model.iag.usp.br

The megacity of São Paulo is facing recurring problems regarding the degradation of air quality, with intense vehicular emissions accounting for a substantial part of this situation. The São Paulo vehicle fleet is quite diverse, containing old and new vehicles powered with gasol (gasoline with 20 - 25% ethanol), hydrated ethanol, CNG (compressed natural gas) and diesel. This fact, coupled with the changing fleet profile (addition of flex-fuel engines), increases the complexity of emissions and physical and chemical processes that involves aerosols.

In order to understand the limiting factors for the formation of aerosol in the atmosphere of São Paulo, in particular the participation of the major inorganic ionic species (sulfate, nitrate, ammonium and chloride), measurements campaigns were carried inside an urban road tunnel (Jânio Quadros) and in the surrounding region (Parque do Povo).

The campaign used two particle samplers (Tupiniquim - AFG model, and Partisol - automatic dichotomous model - Thermo Fischer), The samples were collected in May, 2011 with distinct sampling intervals, for the inner region the sampling period was divided into: (i) 8:00 to 14:00, (ii) 14:00 to 20:00, and (iii) 20:00 to 08:00 of the next day; and for the external region: (i) 08:00 to 20:00 and (ii) 20:00 to 08:00. Besides the particle samplers, two impinger systems for ammonia measurements were employed.

The soluble ions analysis of the fine and coarse particulate matter were performed by chromatographic system Methron 850, and ammonia measurements (in acid medium like ammonium ion) were performed using a flow injection system with gas diffusion and contactless conductivity detection (FIA-GD-C4D).

The results indicated that the median concentration of NH_3 inside the road tunnel (TJQ) was approximately four times higher than in the external region (PP). The mean concentration for the $PM_{2.5}$ major ions (SO_4^{2-}, NH_4^+, NO_3^-) were 2.42±1.45, 1.14±0.71, 0.80±0.52 μg m^{-3}, respectively, for the outside region and 3.27±1.76, 1.27±0.69, 0.76±0.53 μg m^{-3} for the road tunnel. The total mass concentration for fine particulate matter in the inner region was 41.2±10.8 μg m^{-3} and 29.2±17.9 μg m^{-3} for the PP region.

Regarding the representativeness of inorganic species, a simulation from the equilibrium model Isorropia II (Figure 1) attributes 20%, at least, of the total $PM_{2.5}$ mass for the samples collected in the surrounding region. Nonetheless, a maximum of 25% was attributed for the inner region. To verify the relation between the ionic species, a multiple regression analysis was calculated considering the NH_4^+ ion as a dependent variable and the major ionic species, temperature and relative humidity as independent variables. The regression indicated an increase of the adjusted determination coefficient by adding the chloride ion for the external region. However this increase is not observed for the road tunnel which indicates that ammonium ion has no association with this species in an environment with high sulfur oxides concentrations. A greater dependence of thermodynamic variables was observed in the road tunnel, whose slope coefficient for temperature was, β_T = -0.11, with significance level of 5% ($p < 0.05$).

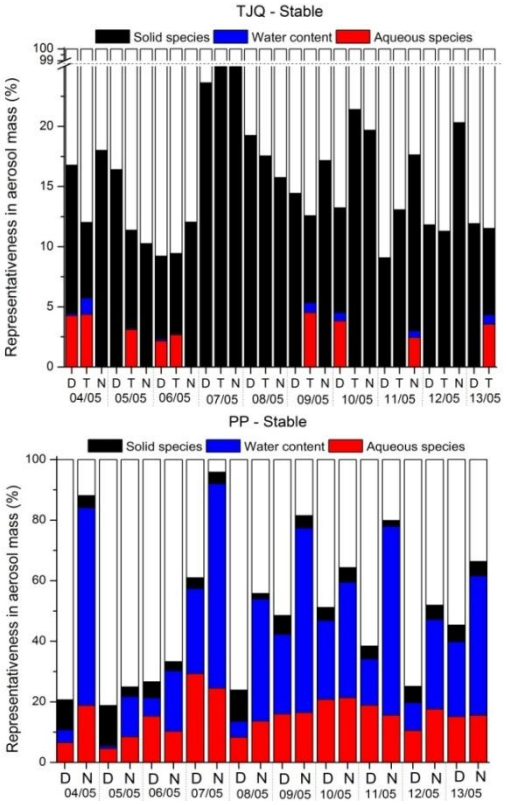

Figure 1. Distribution of solid and aqueous species and water content in the fine particulate matter. This simulation was performed using the ISORROPIA II equilibrium model for $PM_{2.5}$ sampled inside the Jânio Quadros road tunnel (upper graph - TJQ) and surrounding region (lower graph - PP).

Determination of alkyl phenols in atmospheric aerosols by gas chromatography–ion trap mass spectrometry

M. Visentin, M.C. Pietrogrande,

Department of Chemical and Pharmaceutical Science, University of Ferrara, Ferrara, I44121, Italy
Keywords: biomass burning, wood combustion markers, GC/MS/MS analysis, PM chemical characterization
Presenting author email: vsnmrc@unife.it

In recent years there is increasing interest in atmospheric emissions from biomass burning, one of the largest sources of accumulation mode particles globally.

Specific molecular markers have been identified for tracing biomass combustion, in particular carbohydrates (predominately levoglucosan and other anydrosugars) produced by thermolysis of cellulose and hemicellulose and alkoxyphenols, as thermally decomposition products of lignin, one of the main components in wood. As the basic structure of lignin derives from p-coumaril, coniferyl and synapil alcohols, its burning releases in atmosphere molecules similar to their precursors, such as p-coumaric acid, vanillin, vanillic acid, acetovanillone ferulic acid, syringol, syringaldehyde, syringic acid and acetosyringone.

Different kinds of woods contain different percentage of the three monomers, so that their combustion releases different amounts of alkoxyphenols: diagnostic ratios of syringic/vanillic acids (S/V) and cinnamic/vanillic acids (C/V) have been proposed to identify emissions from specific plant tissue combustion, i.e., hard woods (oak, beech and walnut) or soft woods (conifers) and grass and soft plant tissues (Kuo *et al*, 2011).

GC–MS is the most widely applied technique for the characterization of organic aerosols since it provides multi-residue methodologies for the simultaneous analysis of several compounds with excellent separation efficiency, sensitivity and high number of species analyzed. Due to their high polarity, lignin phenols have to be converted into volatilizable and stable derivatives: trimethylsilyl derivatives are produced by using BSTFA (N,O-bis(trimethylsilyl)-trifluoroacetamide) as silylation reagent (Pietrogrande *et al*, 2011).

Due to small concentration of alkoxyphenols in environmental samples, very sensitive analytical methods like GC/MS/MS are needed. The present paper describes a gas chromatography tandem mass spectrometry method using an ion trap system, as a further development of the pervious GC/MS method (Pietrogrande *et al*, 2013), providing the low detection limits and the high reproducibility required by environmental monitoring.

All the compounds were monitored in multiple reaction mode (MRM). For each target analyte the precursor ion and collision-induced dissociation (CID) voltage were carefully selected to optimize CID efficiency to produce daughter ion(s) and minimize interference during the analysis. The MS detection conditions for each target compound are listed in Table 1.

Five-point calibration curves were prepared to quantify the target analytes in the concentration range of 0.2ngm^{-3} to 5ngm^{-3} using standard solutions. The limits of detection (LOD) of the proposed method were determined by three times the signal to noise ratio S/N (Table 1).

Table 1: MS/MS detection parameters for each target compound: precursor and parent ions. Comparison between sensitivity (LOD) of MS/MS and MS detection procedures.

Analyte	Precursor ion (*m/z*)	Parent ions (*m/z*)	MS/MS LOD (ngm^{-3})	MS (SIM) LOD (ngm^{-3})
Catechol	254	239, 166	0,76	1,24
Syringol	196	153, 181	0,51	0,94
Pyrogallol	239	133, 151, 211	0,45	3,53
Vanillic acid	267	223, 225	0,58	1,82
p-Coumaric acid	293	253, 255, 223	1,75	4,56
Syringic acid	297	243, 233, 219	0,57	3,26

As expected, compared to MS detection operating in the selected ion monitoring (SIM) mode, the MS/MS method is characterized by higher specificity and sensitivity due to the effective exclusion of interfering matrix compounds.

The applicability of the developed method to air quality monitoring was verified by application to $PM_{2.5}$ filters collected under different seasons (summer vs. winter) in different sampling sites (urban vs. rural) in the Emilia Romagna region (Northen Italy).

This work was financially supported by the “Supersito” project of the Regional Agency for Prevention and Environment of the Emilia-Romagna Region (ARPAER).

Seasonal variations of organic carbon with different volatility at suburban site

Petr Vodička and Jaroslav Schwarz

Institute of Chemical Process Fundamentals of the AS CR, Prague, Czech Republic
Keywords: Organic carbon, OC fractions, Volatility, Ambient aerosol, Seasonal variations, Central Europe
Email: vodicka@icpf.cas.cz

The instrument for analysis of elemental and organic carbon (EC and OC) yields also additional information about volatility of individual OC fractions. Depending on the temperature protocol used, it is possible to distinguish and quantify pyrolitic carbon (PC) and OC1 to OC4 fractions (OC1 being the most and OC4 the least volatile one). This work characterizes diurnal trends of OC fractions at Prague suburban site during various seasons throughout the year.

Measurements of OC fractions were done by the field OC/EC analyzer (Sunset) provided with PM2.5 cyclone inlet. Sampling frequency was 2 hours. Thermal-optical analyses were performed by a modified EUSAAR2 protocol (Cavalli *et al*, 2010) that takes about 15 minutes. Fractions of organic carbon were taken in the following temperature ranges - OC1: <200°C, OC2: 200-300°C, OC3: 300-450°C and OC4: 450-640°C. OC_{total} = OC1+OC2+OC3+OC4+PC. One year data series was collected at Prague-Suchdol urban background station (50°7'36.473" N, 14°23'5.513" E, 277 m ASL) between September 2009 and August 2010. Over 3400 measurements were carried out for each OC fraction in this work.

In many studies published so far, various sources of carbonaceous particles had been mentioned during summer and winter seasons (e.g. Aurela *et al*, 2011). While in winter there is a significant impact of household heating, the influence of secondary OC of both anthropogenic and biogenic origin prevails in summer. Results of this study are in-line with these findings.

The highest concentrations of the most volatile OC1 fraction were found during wintertime (Fig. 1) with diurnal afternoon minima in all seasons. However, after looking at diurnal variations of $OC1/OC_{total}$ ratios during all seasons (Fig. 2), there is well visible the largest proportion of OC1 fraction during summer afternoons, and it corresponds to formation of secondary organic aerosols (SOA). Therefore, it can be assumed that the important part of summer suburban afternoon SOA is formed mainly by the most volatile components of OC. Other OC fractions were studied by a similar way as OC1 fraction and preliminary conclusions from one year measurements of individual OC fractions at Prague-Suchdol site show the following:

- The suburban environment is mainly the source of the most volatile OC1 fraction (especially during the night). It implies that the OC1 fraction is main part of anthropogenic emissions in wintertime and, in contrast to the less volatile fractions (OC2, OC3), it is also most affected by the thinner boundary layer.
- Secondary organic aerosols are the most probable summer source of OC1 fraction being formed mainly during afternoon hours.
- During interpretation of results it is necessary to pay attention to temperature profile of used protocol. For example, OC2 has both the lowest temperature step and absolute concentrations.

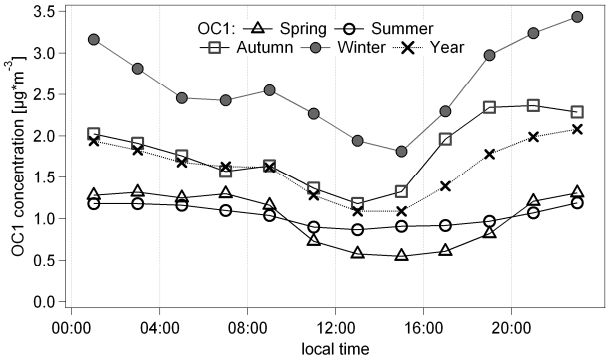

Fig.1. Diurnal cycles of OC1 concentrations averaged according to seasons.

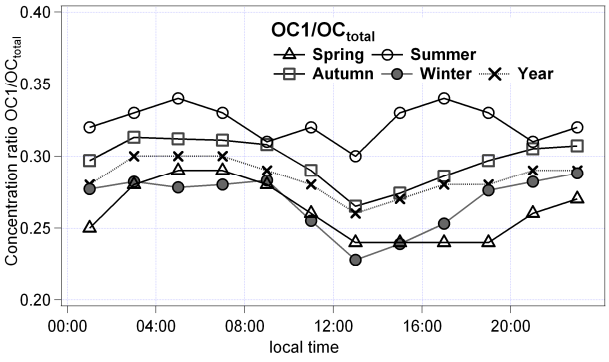

Fig.2. Diurnal variations of $OC1/OC_{total}$ ratio averaged according to seasons.

Ionic composition of PM_{10} and $PM_{2.5}$ in the area of Thessaloniki, Northern Greece - Estimation of secondary inorganic aerosols and sea spray contribution

D. Voutsa[1], C.Samara[1], E. Manoli[1], E. Gounari[1], D. Lazarou[1], P. Tzoumaka[2]

Presenting author email: dvoutsa@chem.auth.gr

Ionic constituents represent a significant component of atmospheric particles (Putaud et al., 2010). Thessaloniki, Greece (40°62´E, 22°95´N) is a densely populated city suffering from high concentrations of airborne particulate matter. Previous studies at urban sites of the city indicated that ionic species were major components of PM_{10} (Voutsa et al., 2002; Terzi et al., 2010). However, there, there are no data available for PM2.5 fraction.

The aim of the present study was to investigate the ionic composition of both PM_{10} and $PM_{2.5}$ in the Major Area of Thessaloniki, Northern Greece. For this purpose, PM_{10} and $PM_{2.5}$ fractions were collected from an urban-traffic (UT) and an urban-background (UB) site. At both sites, PM_{10} and $PM_{2.5}$ samples were concurrently collected during the warm and the cold months of the year (July-Sept 2011 and Febr-April 2012). Sampling was carried out according to EN12341 and EN14907 using Low Volume Samplers operating at constant flow rate 2.3 m^3/h. PM_{10} and $PM_{2.5}$ fractions were collected on Φ 47 mm Teflon filters (Zefluor^{TM} membranes, Pall 2μm). Each sampling had a 24-h duration starting at 00:00. Ionic chromatography has been employed for the determination of water soluble ions (NO_3^-, SO_4^{2-}, Cl^-, Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}).

The average concentrations of ions associated with PM_{10} and $PM_{2.5}$ are shown in Fig. 1.

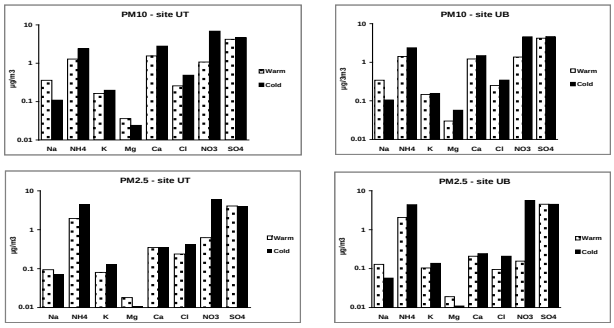

Figure 1. Average concentrations of ions associated with PM10 and PM2.5 at two sampling sites

The PM_{10} fractions of ions were almost similar at the two sampling sites. The $PM_{2.5}$ fractions of Ca^{2+}, Cl^- and NO_3^- (in summer) were higher at the UT site. Mg^{2+} and Ca^{2+} were mainly associated with the coarse fraction whereas NO_3^- and SO_4^{2-} with the fine fraction. Higher concentrations of NO_3^-, NH_4^+ and Cl^- were observed during winter. This trend is probably due to higher NO_x emissions during winter as well as to loss of nitrate or chloride ammonium during summertime. Moreover, K^+ exhibited higher concentrations during winter probably due to emissions from the increasing residential wood burning in the area.

Average contributions of ionic species to total PM_{10} mass were 25% at UT and 32% at UB. The corresponding contributions to total $PM_{2.5}$ mass were 30% and 43% at UT and UB, respectively. Sulfate was the predominant PM_{10} ionic constituent, followed by NO_3^-, Ca^{2+} and NH_4^+. The main ion in $PM_{2.5}$ was also SO_4^{2-}, followed by NH_4^+, NO_3^- and Ca^{2+}.

Secondary inorganic aerosol (SIA) calculated as the sum of non-sea salt of SO_4^{2-}, NO_3^- and NH_4^+ exhibited similar concentrations (~10% μg/m^3) at both sites. This may indicate common origin and removal processes, suggesting that SIA dynamics are more linked to regional processes than to local sources. The average contributions of SIA to $PM_{2.5}$ mass were 35% at UT *vs.* 45 % at UB. The corresponding contribution to PM10 mass was 20% at UT *vs.* 29% at UB. At both sites the concentration of SIA was almost two folds higher in winter. Similar SIA concentrations and temporal variation was also reported by other investigators (EEA, 2012; Squizzato et al., 2012). The sulfur oxidation ratio (SOR) showed that sulfate is photochemically oxidized in the atmosphere from its precursor SO_2. The nitrogen oxidation ratio exhibited higher values at the UB in cold period suggesting favorable conditions for gas conversion processes.

The marine contribution was calculated as the sum of Na^+ concentration and sea salt fractions of Cl^-, Mg^{2+}, K^+,Ca^{2+}, and SO_4^{2-}. The sea spray contribution to particulate matter on a mass basis was low (<2%) similar to the reported values from other Mediterranean coastal areas (Querol et al., 2008; Terzi et al., 2010; Eleftheriadis et al., 2011). The low $PM_{2.5}/PM_{10}$ ratio of sea spray showed the predominant coarse grain size of marine constituents.

Data and Methods

Aerosol particles were investigated at the Geophysics Center of Evora (CGE, 38.57°N, 7.91°W, 290 m a.s.l.) for more than 1 year. The sampling period was usually 1 week. The particulate matter was collected on Aluminium stubs coated with carbon adhesives inserted into a modified version of the aerosol passive sampler Type A "flat plates" by Ott and Peters (2008).

The elemental analysis was done using an HITACHI VP-SEM interfaced with a Bruker EDS QUANTAX automatic ESPRIT software as well as FEI QUANTA 200 FEG. The conditions for SEM were as follows: 20 kV accelerating voltage; 10 mm working distance; 120 mA emission current; 70 mA probe current.

About 1000 particles were analysed for each sample and particle size and elemental composition was determined. Based on a set of rules the elemental composition of each particle was transformed into 8 chemical classes. Additional the particles were separated into 3 classes according to their size.

Trajectories were calculated with the HYSPLIT model (Draxler and Hess, 1998) in order to support the interpretation of the data. 10 days backward trajectories were calculated between 500 m a.s.l. and the top of the boundary layer, with a vertical spacing of 100 m and for every hour. Subsequently the location of the points along the trajectory path which are inside the boundary layer were determined and a source region (e.g. Africa, Europa, Atlantic Ocean) was assigned.

Results

Figure one shows the time series of the 8 chemical classes for the largest sampled particles (2.5 – 10 µm). Over the whole period silicates were predominant with an abundance of about 50%. Sulfates vary over time between almost 0% and 30%.

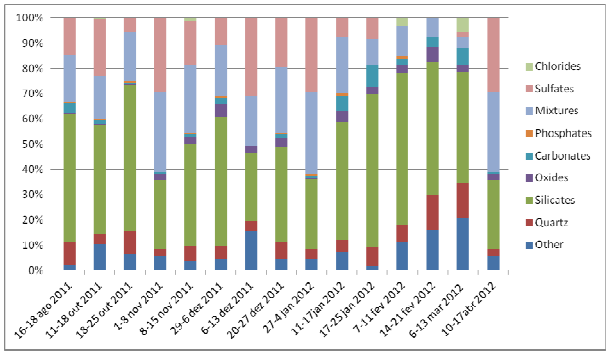

Figure 1. Time series for the chemical composition of deposited particles with diameters between 2.5 and 10 µm.

Identification of parameters influencing the variability of particle number size distributions in Europe - a multi-site study

Clemens von Bismarck-Osten[1], Stephan Weber[1]

[1] Institute of Geoecology, Climatology and Environmental Meteorology, Technische Universität Braunschweig, Langer Kamp 19c, 38106 Braunschweig, Germany
Keywords: number size distribution, cluster, multiple regression, prediction
Author email: c.von-bismarck-osten@tu-bs.de, s.weber@tu-bs.de,

Three years of aerosol measurements from four European cities were analysed to identify and quantify the parameters influencing the particle number size distribution (NSD) at different measurement sites (Copenhagen, Helsinki, Leipzig, London). A 'triple-site' approach was established with data from a roadside, an urban background and a rural measurement station, which were available for each city. The NSD measurements were conducted over a diameter size range of 8 to 700 nm.

Average hourly total number concentrations varied between 3.300 cm^{-3} (Copenhagen rural) and 23,000 cm^{-3} (London roadside). Highest variability on the diurnal course was found for the roadside sites and on the seasonal course for the rural sites.

A first identification of the influencing parameters was found using correlation analysis pointing out wind speed, wind direction, temperature, shortwave downward solar radiation, daytime and season as most dominating factors. These were then quantified using a multiple linear regression approach with a partially non-linear treatment of input data documenting the highest influence for daytime (45%) followed by wind direction (18%), season (12%), wind speed (11%), temperature (8%) and solar radiation (6%) on average.

The variation of influence between the different cities are analysed and discussed. Subsequently NSDs were modelled using the regression approach in order to verify how well the parameters are capable of 'explaining' the actual NSD, showing best performance for roadside NSD with correlation coefficients between 0.65 and 0.8 (average COD of around 0.2 to 0.3, Fig.1) and with correlation coefficients of 0.5 to 0.6 only limited performance for the rural sites (COD of around 0.3 to 0.4 on average).

Finally the data was classified into a limited number of characteristic cluster size distributions using unsupervised and semi-supervised cluster analysis approaches. After a first source assignment of each cluster (e.g. on the basis of daytime and seasonal occurrence, wind sector, mean diameter or total number concentrations) the main information about the influence of the local (meteorological) conditions on the particle number size distribution can be derived. This way the main connections and interactions between the ambient environment and particles are reduced and compressed to a manageable minimum which makes it easier for a near-future forecasting of particle number size distributions.

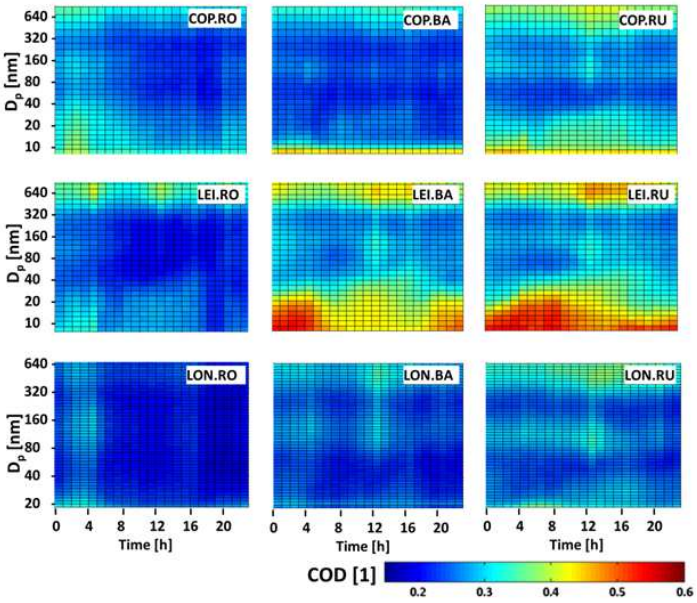

Fig.1: *Coefficient of Divergence (COD) for comparison of modelled and measured number size distribution. The smallest values indicate the highest conformity at a specific daytime and per particle size; the highest values indicate heterogeneous conditions. RO represents the roadside measurement site, BA the urban background and RU the rural site within Copenhagen (COP), Leipzig (LEI) and London (LON).*

Vertical aerosol stratification above the Caribbean Sea near Barbados

B. Wehner[1], F. Ditas[1], H. Wex[1], I. Serikov[2], A. Wiedensohler[1], and H. Siebert[1]

[1]Leibniz Institute for Tropospheric Research (TROPOS), 04318 Leipzig, Germany

Keywords: aerosol layers, aerosol profiles.
Presenting author email: birgit@tropos.de

Shallow cumulus clouds are widespread in the trade wind regions and play an important role for the vertical transport of moisture, momentum, and heat as well as for the earth's radiation budget. The influence of aerosol particles on the formation and life cycle of these clouds is controversially discussed in the literature.

Therefore, one major topic of the CARRIBA (**C**loud, **A**erosol, **R**adiation, and Tu**R**bulence in the trade w**I**nd regime over **BA**rbados) campaigns in November 2010 and April 2011 was to investigate the temporal and spatial variability of aerosol particles near the Caribbean Island Barbados (Siebert et al., 2012). More than 30 research flights with the helicopter-borne platform ACTOS have been performed in that region.

For measuring the total particle number concentration a commercial CPC (model 3762, TSI Inc., St. Paul, USA) has been implemented on ACTOS to measure the total particle number concentration N with a time resolution of 1 s. The aerosol particle number size distribution (PNSD) from 6 nm to 2.5 µm was measured using an SMPS (designed by TROPOS) and an OPC (Model 1.129, Grimm Aerosol Technik, Ainring, Germany) with a time resolution of 120 s. Furthermore, ACTOS contains various instruments to measure cloud properties and thermodynamic parameters, such as temperature, humidity and 3D-wind vector. Continuous measurements of a Raman-Lidar located at Deebles Point at the East Coast of Barbados were also used to detect distinct aerosol layers.

Results

Figure 1 shows the profile of potential temperature Θ, specific humidity r and particle number concentration N measured on April 18, 2011. In the well-mixed sub-cloud layer (SCL < 500 m) Θ, r, and N are nearly constant. Above that height N increases slightly except for a short dip due to a cloud contact in around 700 m. Between 800 and 1200 m N reaches its maximum of this profile of ~ 1000 cm^{-3} and decreases above to values between 400 and 600 cm^{-3}. Above the SCL, the profile of N can be divided into strongly separated aerosol layers: e.g. Layer 1 from 800 to 1200 m and Layer 2 from 1200 to 1700 m.

Figure 2 shows PNSDs measured below 500 m (SCL), in Layer 1 (800 – 1200 m), and Layer 2 (1200 – 1700 m). The shape of the individual PNSDs is similar but the number concentration is highest in Layer 1 corresponding to the profile of N.

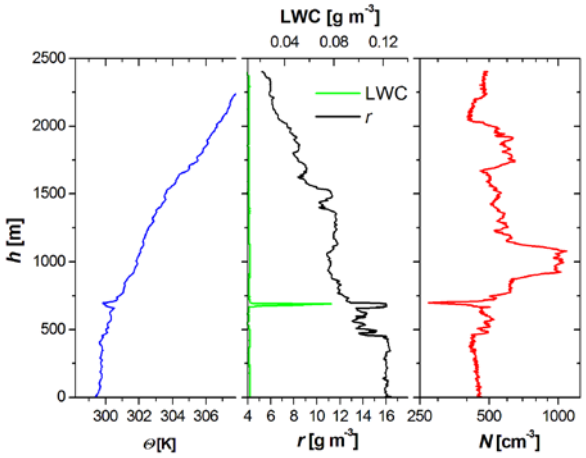

Figure 1. Vertical profiles of potential temperature Θ, specific humidity r and particle number concentration N measured on April 18, 2011 by ACTOS.

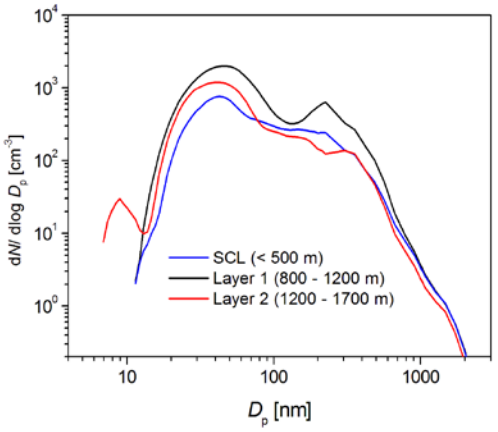

Figure 2. Particle number size distributions in selected layers: SCL (below 500 m), Layer 1, and Layer 2 on April 18, 2011.

The existence of such narrow aerosol layers has been observed on several days throughout the campaign. Obviously there are no efficient mixing processes to balance such concentration gradients immediately. The continuous Lidar data will be used to detect aerosol layers during the day and may give some information about their optical properties.

This work was supported by the Deutsche Forschungsgemeinschaft (SI 1534/3-1 and WE 1900/18-1).

Methods and limits of unipolar charged aerosol inversion

Z.N. Wei[1], L. Knobel[1], H.-J. Schmid[1]

[1]Chair of Particle Technology, University of Paderborn, Paderborn, Germany
Keywords: inversion, unipolar charger, electrical mobility, particle number size distribution
Presenting author email: zhongning.wei@uni-paderborn.de

The Scanning Mobility Particle Sizer (SMPS) is in widespread use for measuring the airborne particle size distributions and concentration which is electrical mobility based sizing techniques. In such a device the particles are classified according to the electric mobility. As a result after investigations an electrical particle mobility distribution is giving. But multiple charges per particle can result in particles of two different diameters but having the same electrical mobility. Therefore it is impossible or not easy to get the particle number size distribution directly. Thus the methods of conversion from electrical mobility particle distribution to particle size distribution are used extensively.

A NanoScan SMPS will be used for analytic unipolar charged nanoparticles. A patented unipolar charger charges more nanoparticles than bipolar charger, in other words, the bipolar charger has a lower charging efficiency, e.g., as pointed out in Wiedensohler (1988), over 90% of 10 nm particles would be neutral and could not be efficiently. Compared to the bipolar charging has the unipolar charging a higher charging efficiency (Tippayawong et al., 2011). Additionally the unipolar charger eliminates the need for radioactive material, which has less health risks and more regulations.

In a NanoScan a conditioner will be used in order to remove larger particles which could not be measured. Thus an electrical mobility particle distribution for the rest particles will be given by the TSI software. The measured mobility particle distribution for particles which are probably to have multiple charges and which can result in particles of two different diameters but having the same electrical mobility must be corrected and then the conversion from electrical mobility particle distribution to particle size distribution will be with the inversion routines calculated. But by the unipolar charger is the correction method encountered to limit, e.g. a lower resolution, lack of accuracy information for the larger particles. So we need to analysis and determine limits of the resolution and the size limit. And then these limits will be expected and quantified.

Furthermore we present the theory of a data inversion algorithm for the SMPS measurement. As pointed out in Stratmann et al. (1996), to convert from particle mobility distribution into particle size distribution, i.e. to calculate the number concentration of particles in size bin, a linear equation has to be solved. Where, the number of mobility bins, the number concentration in mobility and size bins and the probability of the particles to carry *n* elementary charges (or the charge number per particle) must be known. Namely the particle number size distribution will be calculated from the raw data, the measured electrical particle mobility. This method is called multiply charged inversion. If the unipolar charge distribution is principally known, it will be possible to obtain the particle number size distribution. The idea of this numeric method is under the assumption with a given number of sampling points of this particle number size distribution.

Investigation of behavior of environmental background radioactivity (aerosols and gases) is one of the main tasks when solving problems of low dose effects. It also useful for investigation of electrical properties of atmosphere and climate global change forecasting, because of air radioactive aerosols and gases and their balance regulate the surface layer of atmospheric plasma. The main purpose of this work was to investigate temporal and spatial dynamics of α-radioactive aerosols in the ground atmosphere. The general distinctions of this investigation are: 1) synchronous measurements of characteristics of α- and β-radiation fields and volumetric activity of atmospheric radionuclides (radon isotopes and their aerosol decay products (DPs)) at one point; 2) parallel measurements at different heights up to 35 m; and 3) high time resolution of data series. Such approach allowed getting more informative data to reach the purpose of the work.

The long-term experiment was performed at Tomsk Observatory of Radioactivity and Ionizing Radiation (TORIR). Instrumental equipment included: scintillation detectors of α- and β-radiation (ATOMTEX, Republic of Belarus) installed at series of heights (0.1; 1; 5; 10; 25 and 35 m); radon isotopes and DPs radiometers (EQF 3200, SARAD, Germany; RRA-01-03, Russia; Ramon-01, Kazakhstan) and automated devices for radon (RFD) and thoron (TFD) flux densities measurements (Fig. 1). In order to determine the degree of external factors influence the monitoring of meteorological, actinometrical and atmospheric-electrical values was performed via automated information measuring system.

In accordance with simplify radon and PDs transport model (only turbulent diffusion) in air the vertical distribution of their concentrations follows exponential law and decrease with height. Results of experiment with help of scintillation α-detectors showed inverse dependence (Fig. 2), i.e. increasing of α-radioactive aerosols concentration with height.

The results of numerical simulation of radon isotopes and their DPs transport in ground atmosphere with using complex model (turbulent diffusion, moving under the influence of vertical wind, removal by gravity and precipitation) showed that turbulent diffusion coefficient and vertical component of wind velocity are the most important factors, which influence vertical aerosols distribution. But only when wind blows upwards (from ground surface) we can observe such inverse situation in vertical distribution of radioactive aerosols.

Because of α-active aerosol (radon isotopes and DPs) concentration is direct (by radioactive complex decay low) related with β-active aerosol concentration (DPs), the experimental check of vertical distribution for β-radioactivity in air was also applied. The results (Fig. 2) revealed different dependences of flux density from height for α- and β-radioactivity in air.

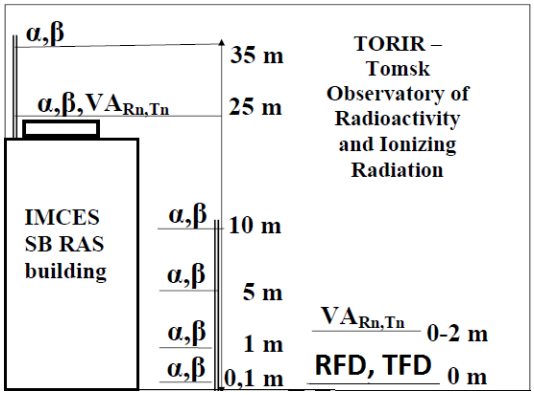

Figure 1. The scheme of experiment in Tomsk

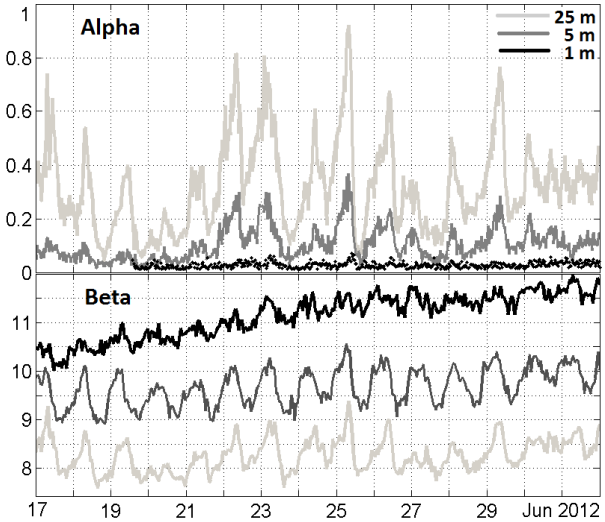

Figure 2. Temporal dynamics of α- and β-radiation flux densities in units of $m^{-2}s^{-1}$ at different heights

Detail discussion of behavior of α-radioactive aerosols in ground atmosphere during 2011–2013 and influencing factors are presented in the report.

The role of condensable vapours in atmospheric new particle growth and shrinkage

L.-H. Young[1], P.-S. Cheng[1], Y.-J. Liou[1], S.-H. Lee[2], V.P. Kanawade[2] and T.-C. Hsiao[3]

Presenting author email: lhy@mail.cmu.edu.tw

New particle formation (NPF) is a key process that increases the number of aerosols in the atmosphere. It is characterized by a sudden burst of new particles of a few nanometres and subsequent growth to sizes of tens of nanometres. The latter growth is commonly considered as an irreversible process. However, particle shrinkage can occur due to the evaporation of the condensed species if the involved processes are reversible (Zhang *et al.*, 2012). To date, there are only a few observations of new particle shrinkage and thus still poorly understood.

In a multi-site NPF study in subtropical central Taiwan (Young *et al.*, 2012; Young *et al.*, 2013), 10-1000 nm particle number size distributions were measured with SMPS (GRIMM Model 5.500) in an urban (U), coastal (C), mountain (M) and downwind (D) area. The sampling campaigns were conducted during a cold and a warm season. Among the identified 14 NPF events, there were five particle shrinkage events during which the grown particles shrank back to sizes of ~10 nm, thereby creating a unique "arch-like" shape in the size distribution contour plot (Figure 1). The new particle growth and shrinkage rates (GR and SR), and their corresponding condensable vapour (C_v) and H_2SO_4 proxy (P) concentrations, and particle volume loss (VL) were estimated.

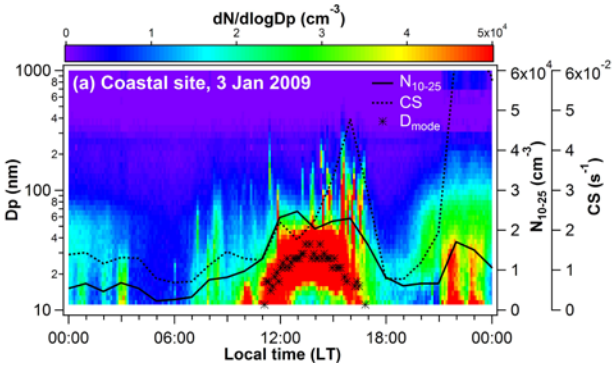

Figure 1. An example of new particle growth and shrinkage observed on the 3 January 2009.

Table 1 shows the GR, SR and GR-to-SR ratio, while Table 2 gives the C, P and VL for the five particle shrinkage events. As shown, the GR ranged from 7.4 to 17.3 nm hr^{-1}, whereas the SR ranged from 5.1 to 7.6 nm hr^{-1}. The SR-to-GR ratios were all above 0.44 indicating the SR were slower than the GR. The C of 1.69-6.59×10^8 cm^{-3} were required to explain the particle growth, whereas the P of 1.72-7.79×10^7 cm^{-3} were estimated to be produced under the observed atmospheric conditions. The P-to-C ratios were all below 0.22, suggesting that H_2SO_4 alone were not sufficient for the new particle growth. The VL on the 3 January 2009 and the 7 September 2010 were above 90%, indicating near complete evaporation. On the remaining three days, the VL were between 18% to 38%. These results clearly show that a notable fraction of the prior condensed chemical species evaporated from the particle phase to the gas phase. Bzdek *et al.* (2012) recently showed that sulfate contributed to 41-46% new particle growth, whereas NO_3^-, NH_4^+ and organics contributed to the remaining 54-59% growth. In particular, some of the latter chemical species are known to be semi-volatile and, as such, they have the potentials to evaporate off the new particles under favorable conditions.

Table 1. Growth rate (GR), shrinkage rate (SR) and SR-to-GR ratio during the new particle shrinkage events.

Date	Site	GR (nm hr^{-1})	SR (nm hr^{-1})	SR/GR

Evolution of *n*-Alkanes in PM samples collected in São Paulo, Brazil (2000-2010)

P.C. Vasconcellos[1], Sofia Caumo[1] and J.B. De Andrade[2]

[1]Departmento de Química, Universidade de São Paulo, 05509-000, Brazil
[2]Departmento de Química Geral e Inorgânica, Universidade Federal da Bahia, Salvador, 40170-290, Brazil
Keywords: organic aerosols, n-alkanes in the atmosphere, biomass burning emissions, vehicular emissions
Presenting author email: perola@iq.usp.br

N-alkanes determination is interesting to study the origin and fate of atmospheric aerosols (Alves, 2008). They are ubiquitous in urban, continental or marine samples. They can be derived from both biogenic and anthropogenic sources which can be differentiated based on their *n*-alkanes distribution. Their relatively low reactivity and volatility make them interesting tracers of both atmospheric transport and particle origin.

Samples were collected for over ten years (from 2000 to 2010). All measurements were done in the campus of the University of São Paulo (SPA) using high-volume sampler (PM_{10}) and in 2000, total suspended particles (TSP). Samples collected during winter time (2000, 2002, 2003 2008, 2010) were collected in intensive campaigns (n=10-15 samples, in each campaign). Two extensive sampling (all over the year) were done collecting 26 samples (2001-2002) and 33 samples (2003-2004), those collected every 15 days. In the total, over 150 samples were analyzed.
Winter samples (Figure 1) were collected aiming to study the period with strong events of air pollution. Total *n*-alkanes concentrations presented variations ranging from 32 ng m^{-3} (PM_{10}, 2003) to 103 ng m^{-3} (TSP, 2002).

Colder and drier months (June to September) favored the pollutants accumulation. Besides, biomass burning plumes are often observed arriving of the vicinities from May to November to this site.

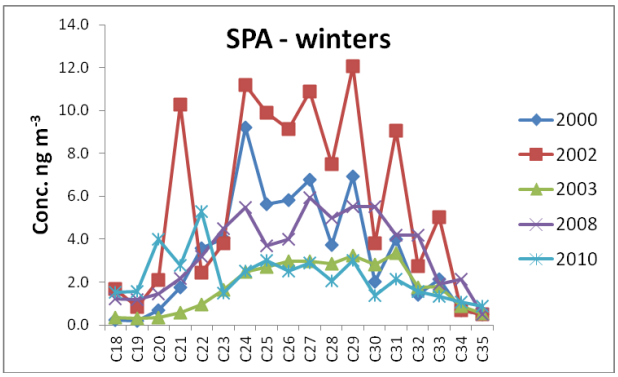

Figure 1. *N*-alkanes concentrations in the samples collected in the wintertime.

The relative contribution of biogenic emissions is assessed by wax normal alkanes index (Figure 2). In the average, considering all samples, the anthropogenic sources (biomass burning) were responsible for over 80% of these *n*-alkanes (higher than C_{25}) emissions.
The carbon preference index (CPI), a diagnostic parameter close to 1 indicated also the strong contribution of anthropogenic contaminants in PM coming from vehicular emissions (Vasconcellos *et al*, 2011).

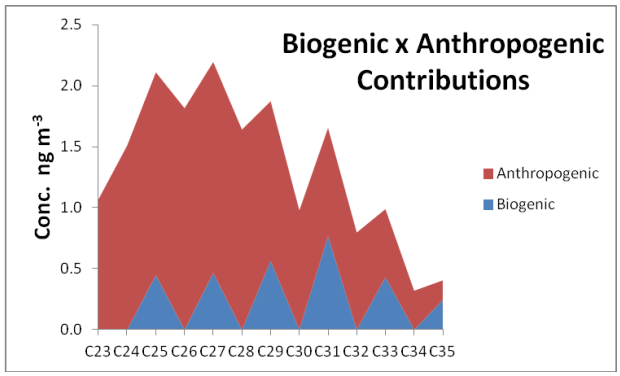

Figure 2. Relative contributions of the sources of *n*-alkanes.

In the extensive campaign (2003, Figure 3) where samples were collected all over the year, samples collected during the summer and fall campaigns presented the highest concentrations, differently of particulate matter concnetrations (higher in the wintertime).

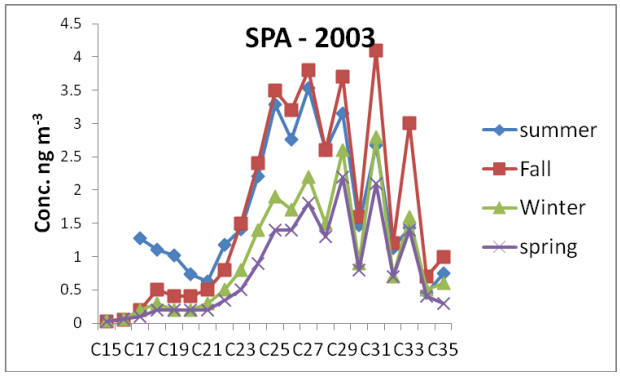

Figure 3. *N*-alkanes concentrations of the samples collected in the extensive campaign (2003).

In general *n*-alkanes lower than C_{25} (anthropogenic emission) were less abundant than those higher, emitted by biogenic (tropical vegetation) and by anthropogenic sources (sugarcane burning).

Presenting author email: zikova@icpf.cas.cz

Health aspects of ultrafine aerosol particles in urban environment have been studied extensively in recent years (Salma *et al.*, 2011; Putaud *et al.*, 2010; Qian *et al.*, 2007 etc.). Three main sources of the ultrafine particles have been defined – traffic, biomass burning, and atmospheric nucleation. However, the diurnal changes in intensities of individual sources are of considerable extent, similarly to the scale of variations in particle number concentrations due to meteorological phenomena.

In order to quantify the variability in all the aspects mentioned above, to reveal differences and similarities, as well as common or specific features, we compared different properties of particle number size distributions in three cities (Budapest, Prague and Vienna) that belong to the same region, type of climate, and are of comparable size. The three cities are situated in Central Europe in a relatively narrow band oriented in parallel with one of the prevailing wind directions that is NW in the region.

Number size distributions of atmospheric aerosol particles were determined over the mobility diameter range from 10 to 1000 nm in each of the three capitals for a one-year-long period. We derived and compared particle number concentrations in various size fractions, their diurnal and seasonal variations, and frequencies of new particle formation events.

Annual median particle number concentrations for Budapest, Prague and Vienna were 10.6×10^3, 7.3×10^3, and 8.0×10^3 #/cm^3, respectively. Differences may be related to the different pollution levels of the cities, and/or to the different measurement environments and local conditions (Borsos et al., 2012).

Furthermore, it has been found that contributions of the cumulative concentrations of particles smaller than 100 nm in diameter to the total number concentration were 80%, 84% and 74% for Budapest, Prague and Vienna, respectively. Thus, in each of the cities, the particles under 100 nm contribute decisively to the total number concentrations.

Diurnal variations of submicron particles larger than 100 nm, exhibited similar shape for all the cities (Fig. 1). The diurnal pattern with a peak at about 8 AM and another maximum at about 9 PM was related to the time-activity pattern of inhabitants and regional influences (traffic, heating etc.).

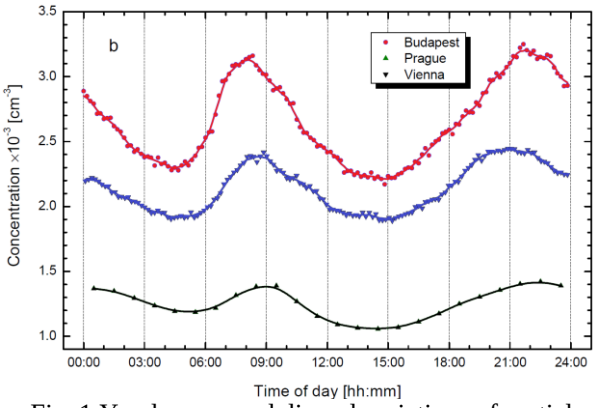

Fig. 1 Yearly averaged diurnal variations of particle number concentrations in Budapest, Vienna and Prague (particles between 100 and 1000 nm in diameter).

The structure of the diurnal variation for ultrafine particles (smaller than 100 nm in diameter) was similar to those in sizes between 100 and 1000 nm with an exception related to the position of the second peak. That peak was shifted from late evening to afternoon. This can be due to daily cycling in meteorological parameters, due to the character of the measurement site, and mainly due to the presence of new particle formation and subsequent growth in urban environments.

Keywords: silica, coating, CCN activation
Presenting author email: Maryam.dalirian@itm.su.se

Insoluble particles, e.g. mineral dust, silica and soot, can act as CCN if they acquire some deliquescent material. Extensive data and theories on CCN activation of completely soluble and insoluble particles exist but the CCN activation of coated particles has been investigated less. In this study laboratory measurements were conducted on CCN activation of insoluble silica particles coated with soluble species. The experimental results were compared to the theoretical calculations using the framework introduced by Kumar *et al.* (2011b).

Measurements

Particles with insoluble core and soluble coating were generated and analyzed in this study. Fumed silica was used as the insoluble particle. Three different kinds of species were used as soluble coatings: ammonium sulphate, sucrose and a protein (bovine serum albumin known as BSA). The fractions of soluble species were 5%, 10% and 25% of total particulate mass in the original aqueous solution, which was atomized and dried to yield the mixed particles. Particle number distribution measurements were conducted using a scanning mobility particle sizer (SMPS). Size-resolved CCN activity was carried out using the Scanning Mobility CCN Analysis (SMCA) and the structure of atomized particles from aqueous suspension was defined by transmission electron microscopy (TEM).

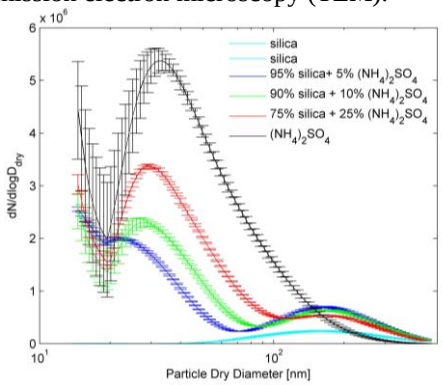

Figure 1: SMPS data for number size distributions of silica particles coated with $(NH_4)_2SO_4$.

Theory

κ-Köhler theory (Petters & Kreidenweis, 2007) was used to estimate the critical supersaturation of soluble particles. Critical supersaturation of pure silica particles, on the other hand, were calculated using the FHH adsorption theory (Sorjamaa and Laaksonen, 2007; Kumar *et al.*, 2009 & 2011a). For mixed soluble and insoluble particles a shell-and-core model (Kumar *et al.*, 2011b) was used in the calculations.

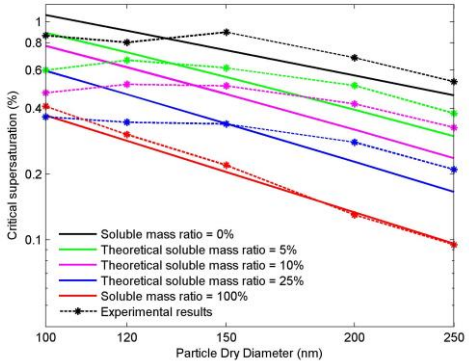

Figure 2: Calculated and experimental critical supersaturations for silica + sucrose particles

Conclusions

Pure and mixed particles of silica and soluble compounds (AS, sucrose and BSA) were generated. Morphology of silica and BSA agglomerates changed with particle size, while $(NH_4)_2SO_4$ and sucrose were spherical. The mixed particles resembled pure silica agglomerates. For pure soluble components the results were in good agreement with k-Köhler theory and for pure silica reasonable agreement was observed with adsorption theory, but deviation from the size-dependence was observed. The reason of these deviations could be e.g. uncertainty in the adsorption parameters and the effect of changing particle morphology with size. Mixed particles had reasonable agreement with the framework by Kumar et al., but shell-core model failed to reproduce the size-dependence of the CCN activation, probably due to the complex particle morphology.

Biomass burning represents one of the largest sources of particulate matter in the atmosphere and can significantly perturb local air quality, meteorology and the earth's radiative balance (Bond et al., in press). Due to the relatively short atmospheric lifetimes, these effects are most acutely felt on regional scales and can have a significant effect on quality of life and the hydrological cycle. However, many of its predicted effects are very poorly constrained. The lifetime and properties of these aerosols are strongly dependent on their composition and injection height, which are turn are highly dependent on the burn conditions.

The South American Biomass Burning Analysis (SAMBBA) field campaign took place in Brazil in September and October 2012, towards the end of the dry season when biomass burning is typically at its peak. This was a collaborative project between a number of UK and Brazilian institutes and featured a comprehensive suite of state-of-the-art instruments on board the UK Facility for Airborne Atmospheric Measurements (FAAM) BAe-146 large research aircraft, based in Porto Velho, in the state of Rondonia. Aerosol instrumentation included an Aerodyne Aerosol Mass Spectrometer (AMS), Single Particle Soot Photometer (SP2), Scanning Mobility Particle Sizer (SMPS), Particle Soot Absorption Photometer (PSAP), Cloud Condensation Nuclei Counter (CCN), Passive Cavity Aerosol Spectrometer Probe (PCASP) and Nephelometers. In conjunction with other measurements, such as inorganic gases, VOCs, optical spectrometers, lidar and dropsondes, a comprehensive characterisation of the composition and dynamics of smoke plumes could be obtained, which can in turn be used to inform and validate models that attempt to simulate the emissions and impacts of these fires based on satellite data.

During the campaign, 19 sorties were performed and a number of different fires were characterised, along with regional hazes, background aerosols (in both the boundary layer and free troposphere) and 'clean' areas dominated by biogenic emissions. Very different aerosol compositions were found depending on the exact burn conditions. As an example, flight B737 sampled a large forest fire in a remote area of Rondonia, which was principally smouldering in nature, whereas B742 sampled fires in an agricultural area of Tocantins, which were principally flaming. The B742 case showed a larger mass concentration of black carbon (up to 50 µg m^{-3} instead of 5 µg m^{-3}), whereas organic matter concentrations were similar (up to 5 mg m^{-3}). Relationships were also found between different fractional mass spectral markers commonly used in the AMS, specifically *f*44 (oxygenated organics) and *f*60 (anhydrous sugars such as levoglucosan). The relationship between these markers changed between the two cases, although these were both within the range of previously published works (figure 1).

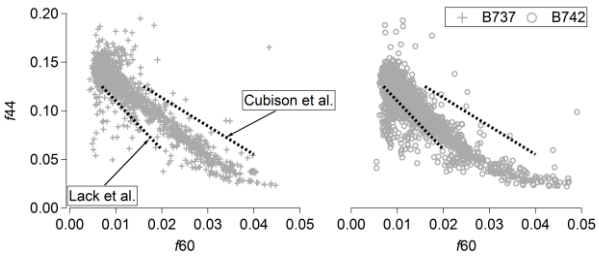

Figure 1: Relationship between *f*44 and *f*60 for a smouldering wildfire (B737) and flaming agricultural fires (B742). The dotted lines correspond to the relationships reported by Lack et al. (2012) and Cubison et al. (2011)

Further results from this campaign will be presented and discussed, quantifying the properties of aerosols under the various conditions. As well as differences in the plume characteristics with burn type, also of interest are the transformations during plume age. The intended applications of these data (e.g. to modelling activities) will also be discussed.

Fine aerosol particles have been studied in the last years due to their important role in several atmospheric processes and effects on climate and human health. New particle formation events are observed all over the world both in polluted and clean, background air. Similarly, in Hungary NPF events can be detected in polluted cities like Budapest (Salma *et al* (2011), Borsós *et al* (2012)) as well as in rural air at K-puszta (Yli-Juuti *et al* (2009)). Our former results showed that at K-puszta new particle formation (NPF) can be frequently observed, the number of NPF events peaked in spring and autumn (September) per each year.

In this work we summarize our results on the particle formation at K-puszta station between Nov. 2008 and Dec. 2012. The size distribution of the particles between 3-800 nm is evaluated. On the basis of DMPS spectra the classification of particle formation events is carried out according to the recommendations of Yli-Juuti *et al* (2009). The event classification is studied with respect to the seasonal variation and the frequency of the particle formation event types (event, non-event and unclassified) is also discussed.

Figure 1. Event classification statistics (2012), K-puszta.

Generally, our four year statistics on new particle formation (NPF) shows that winter is the most inactive period. In contrast the number of NPF events was found to be the highest in spring and in autumn as presented for 2012 (Figure 1). As a consequence of the above-mentioned seasonal variation of the NPF events, the frequency of the nucleation mode (3-25 nm) was the highest during spring and autumn (Figure 2). On the other hand, in winter the accumulation mode (100-800 nm) showed the highest, while in spring and summer the lowest frequency. This seasonality is also shown by the "typical" seasonal number size distributions. This means that in spring the freshly formed particles, while in winter the aged particles characterize the aerosol size distribution.

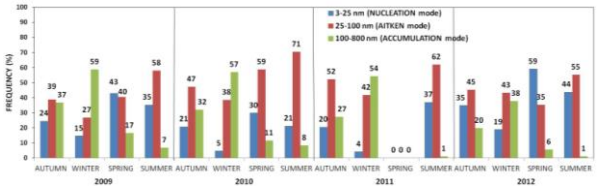

Figure 2. The seasonal frequency of the maximum concentrations in different particle modes (2009-2012).

The growth rate (GR) of the freshly formed particles is also calculated (Hirsikko *et al* (2005), Yli-Juuti *et al* (2009)). Our results on four-year data showed the high variability of particle GR with no significant seasonal variation at K-puszta. The rates were estimated between a few and 14 $nmhr^{-1}$ except some days with higher GR (between 16.5-18.41 $nmhr^{-1}$). The average GR was 5.85 $nmhr^{-1}$. On the other hand, the formation intensity of new nucleation mode particles (smaller than 25 nm) is also estimated. The calculation is based on the method considering the change of the particle number concentration in each size modes per unit time. The average formation rate for 10 nm particle size range was found between 0.33-46.31 particles $cm^{-3}sec^{-1}$.

The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement n° [262254], [ACTRIS]; and TÁMOP-4.2.2.A-11/1/KONV-2012-0064 (The project is realized with the support of the European Union, with the co-funding of the European Social Fund).

A two-year dataset of almost continuous Black Carbon (BC) content measurements by a Magee AE31 7-wavelenghts aethalometer (370 to 950 nm) near a crude oil pre-treatment plant in South Italy (Agri Valley, 40.33°N, 15.92° E, 582 m a.s.l) has been analyzed. Since 1996 an intense crude-oil extraction together with a pre-treatment activity has been carried out at the site with continuous and controlled combustion processes and smoke emissions.

A suitably implemented algorithm has been applied to the aethalometer data in order to analyse absorption coefficient spectral dependence and to reduce the error in UVPM detection (Esposito *et al.*, 2012). BC and UVPM data have been compared to some organic compounds concentrations (Benzene, Toluene, Methane, Non-Methane Hydrocarbons) routinely measured at the same site and for the same period by ARPAB (Basilicata region environmental protection agency).

Recurrent trends have been searched for on a wide temporal scale (two-years diurnal cycles/ seasonal pattern, summer and winter) by applying the statistical Lomb-Scargle periodogram technique to the entire data-set. This is a powerful technique to be applied for frequency analysis of not equally-spaced data to obtain reconstructed spectra on both seasonal and annual basis (Hocke *et al*., 2009). These spectra can be considered as representative of background emissions to be compared with much intense emissions taking place in shorter periods (few days to few weeks) during the year (Pavese *et al*., 2012).

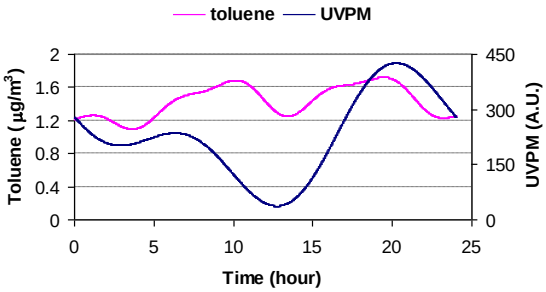

Figure 1: Reconstructed spectra of toluene and UVPM "typical day" as obtained by Lomb-Scargle periodogram for the two-year database.

As an example, reconstructed spectra of toluene and UVPM "typical day" from two-years concentrations data are shown in Figure 1. The differences observed can suggest different dynamics in aerosol formation and/or in adsorption processes onto atmospheric particles.

On the contrary, considering an episode of intense emissions (March, 8th- 19th 2011), UVPM and toluene time behaviours show similar patterns, as reported in Figure 2, highlighting the necessity to study emissions on different time-scales.

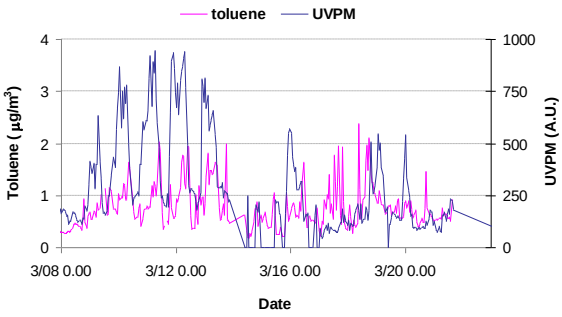

Figure 2: Temporal variation of toluene concentrations and UVPM hourly mean values for the period march 8th - 19th 2011.

To complete this study, an analysis of meteo-climatic parameters such as solar radiation, wind intensity and prevalent direction, has been carried out to verify if and when these parameters contribute to a major/minor agreement among combustion products time patterns.

This work was supported by "Osservatorio Ambientale della Val d'Agri" in the framework of the project "Integrated model for environmental matrix" and by ARPAB.

Keywords: wood-burning, photooxidation, AMS, SP-AMS
Presenting author email: joel.corbin@env.ethz.ch

Wood-burning stoves, used worldwide for heating and cooking, can be an important atmospheric source of primary and secondary aerosols. Current legislation restricts only the primary aerosol emissions of such stoves, which include primary organic aerosol particles (POA), ash, and soot. Such legislation neglects the potential formation of secondary organic aerosol (SOA), which may nucleate or condense after the atmospheric oxidation of volatile organic compounds. For example, smog chamber photooxidation experiments have observed wood-burning SOA concentrations up to four times higher than the corresponding POA emissions (Grieshop et al., 2009; Heringa et al., 2011).

To characterize the SOA-formation potential of wood-burning stoves and similar emissions, Keller and Burtscher (2012) have developed a continuous-flow photooxidation reactor for monitoring potential SOA in real-time. The short residence time (seconds) of this chamber allows the time-resolved measurement of potential SOA. However, the small chamber also necessitates higher-than-ambient irradiation conditions.

Here, we present results from high-resolution Aerosol Mass Spectrometer (AMS) and Soot-Particle AMS (SP-AMS) analysis of wood-stove emissions under three different conditions: filtered and photooxidized ("SOA"), unfiltered and photooxidized ("OxPOA"), and unfiltered emissions ("POA").

Figure 1 shows the increase in aerosol oxidation after photooxidation, as measured by the AMS. The figure shows the difference of the normalized SOA and POA organic mass spectra, averaged over multiple burns. High-resolution analysis has been used to identify organic species as C_xH_y (*green*), $C_xH_yO_{z=1}$ (*purple*), or $C_xH_yO_{z>1}$ (*pink*). However, data are presented on a unit-mass scale for clarity. As shown, the relative intensity of CO_x ions was higher for SOA, whereas C_xH_y was higher for POA. The pie charts (inset) summarize all three cases, showing $C_xH_yO_z$ increasing and C_xH_y decreasing, from left to right. For POA, the contribution of hydrocarbons C_xH_y was more than double that of SOA. Also, SOA contained more $C_xH_yO_{z>1}$ relative to OxPOA. Elemental analysis indicated that the shift of H:C and O:C ratios due to oxidation was comparable to, but significantly greater than, observations in Mexico City (Heald et al., 2010).

In these experiments, refractory species (those involatile below 600 °C) were also characterized with an SP-AMS laser equipped on the same AMS. High-resolution SP-AMS analysis yielded similar results to the AMS, with the major spectral change due only to pure-carbon ions (C_x). Detailed AMS and SP-AMS results will be presented and compared.

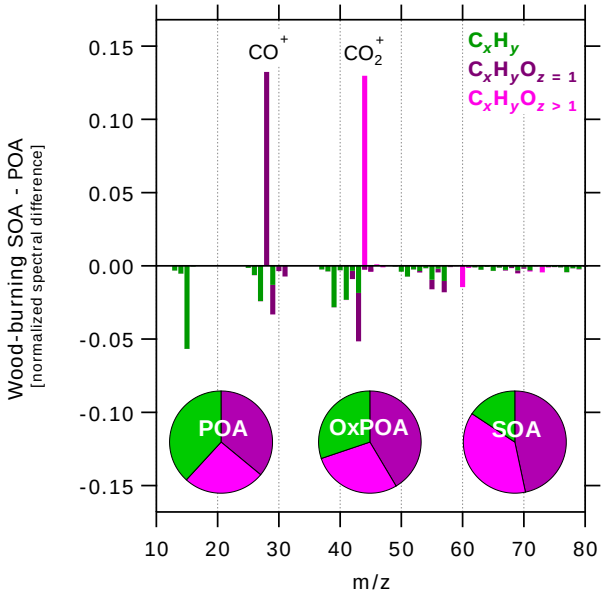

Figure 1. AMS difference mass spectrum for wood-stove SOA minus POA. Inset: pie charts of the organic composition for the three cases.

Presenting author email: maxcherepnev@gmail.com

Extreme weather conditions created in summer in the European part of Russia in 2002 and 2010 and in Siberia in 2004 and 2012 due to forest fires led to the large number of forest and peat fires accompanied by extreme smoke of atmosphere.

Tropospheric aerosol together with greenhouse gases is an important climate-making factor influencing the radiation balance of the Earth. An important mechanism of variations of atmosphere electrical parameters (electric intensity E and polar conductivities $\lambda_{\pm}$) is the change in the number of light ions that are the main charge carriers due to their outflow onto the atmospheric aerosol. Decrease in the number of light ions in their outflow onto aerosol particles should lead to a decrease of $\lambda_{\pm}$ and to an increase of electric field intensity E. Ionization of air molecules in the atmosphere surface layer takes place mainly due to the natural radioactivity.

Based on a joint analysis of the variations of ionizing radiation levels (α-, β-, γ-background) in the atmosphere at heights of 5, 10 m and 25 m and depths of 0.1, 0.2, 0.5 and 1 m in the soil, meteorological and atmospheric electrical parameters in the summer smog due to summer forest fires in Siberia (2012) it was found that an increase of intensively smokiness and related with it decrease of visual range (S_m, Fig. 1, panel 1) and fall of solar radiation flux (I, panel 2) in the visible and UV ranges is followed by a decrease of λ_+ (panel 3) and the level of α-background radiation (panel 4). The clear dependence of β-, γ-background radiation level (panel 5) on S_m was not found.

Analysis of observation data of atmospheric electrical parameters during periods with maximal smog aerosol concentrations in the urban atmosphere surface layer due to long-term forest fires allowed for the first time to find out the effect of daily inversions of the electric field intensity with a changing range of 300 V/m and more in the daytime, of -300 V/m at night (panel 6). The observed effect of daily variations of the electric field in the atmosphere surface layer differs from the known effects by that it was detected in the smog conditions when forest fires covering large areas often for a long time in many regions. The proposed interpretation of this effect does not contradict the well-known diffusion-kinetic model of the ion charge aerosol.

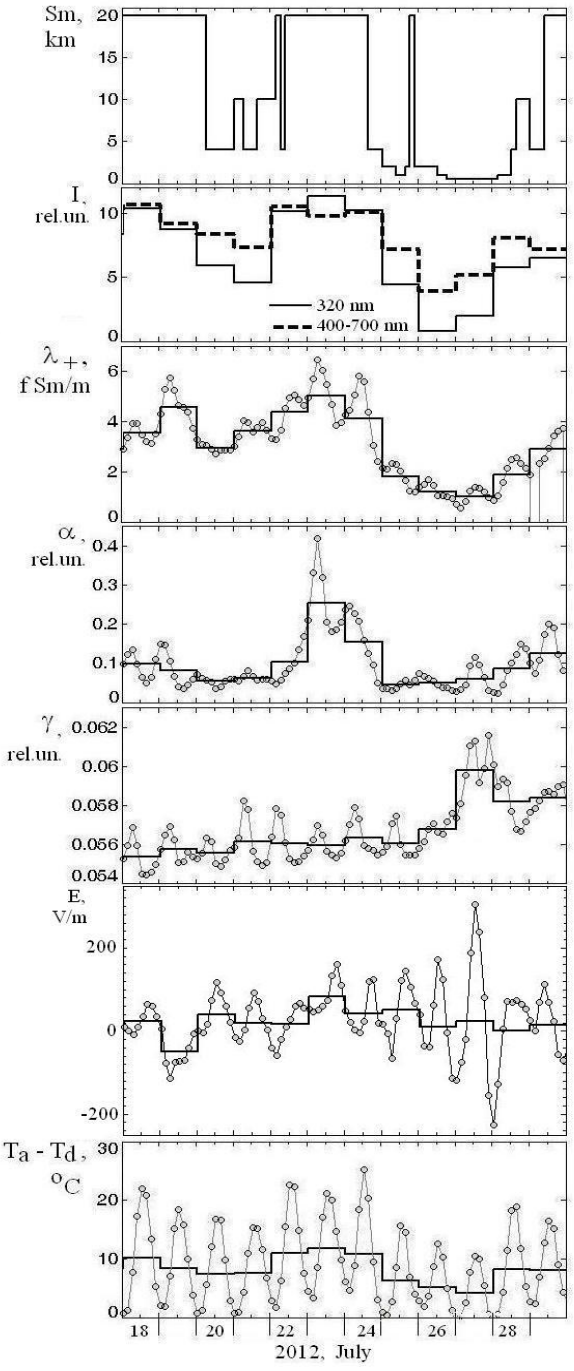

Figure 1. Variations of α-, γ-radiation components and meteorological quantities (S_m, I, λ_+, E, T_a -T_d) during the smog due to summer forest fires

Road tunnels - particle properties, wet and dry conditions

S. Janhäll[1], M. Gustafsson[1], S. Abbasi[2], G. Blomqvist[1], A. Gudmundsson[3], C. Johansson[4,5], M. Norman[5], U. Olofsson[2], B. Sjövall[5]

Keywords: particle, tunnel, road, traffic
Presenting author email: sara.janhall@vti.se

Particulate air pollution in traffic tunnels is often very high due to high emissions and restricted air exchange (e.g. Gëller *et al.*, 2005). Road traffic tunnels have both exhaust and non-exhaust particle sources such as tires, pavement and brakes. In tunnel environments the emissions of ultrafine particles would decrease due to high levels of particle surface area for deposition (Janhäll *et al.*, 2012).

In an on-going research project, airborne particles in one road and one railroad tunnel (Gustafsson *et al*, these proceedings) are characterized regarding concentrations, size distributions and elemental composition in relation to traffic. This abstract show initial project results for the road traffic tunnel, with the aim to characterise and identify the main particle sources to be able to suggest abatement measures.

Particle properties were studied during campaigns in the Söderledstunneln (road tunnel in central Stockholm). The measurements were performed in a small room adjacent to the tunnel and with the inlets mounted within the tunnel from drilled holes, while the road dust load was measured directly at the road surface when the tunnel was closed for maintenance. Dust sampling was made with the VTI wet dust sampler (Jonsson *et al.*, 2008, Blomqvist *et al.*, these proceedings).

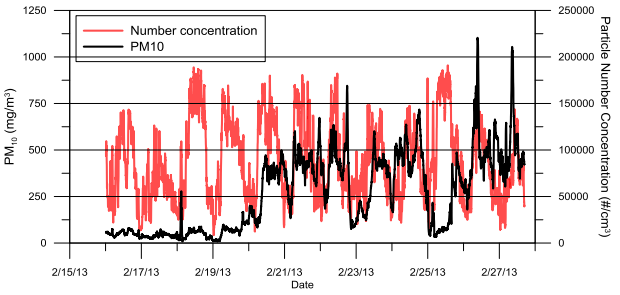

Figure 1.The concentrations of PM_{10} and particle number show the onset of abrasion particle suspension.

Figure 1 shows concentration of PM_{10} and of particle number. Around the 20th of February PM_{10} increase due to drying up of the road surface in the tunnel, while the particle number concentrations are not affected. The size distribution in the size range between 0.5 and 20 µm is shown in Figure 2, where it is clear that the wet conditions give a less pronounced peak as well as very much lower concentrations. Directly before the campaign started, also during wet conditions, samples of the road dust load showed very large levels as compared to road dust load at the surface roads in the same area.

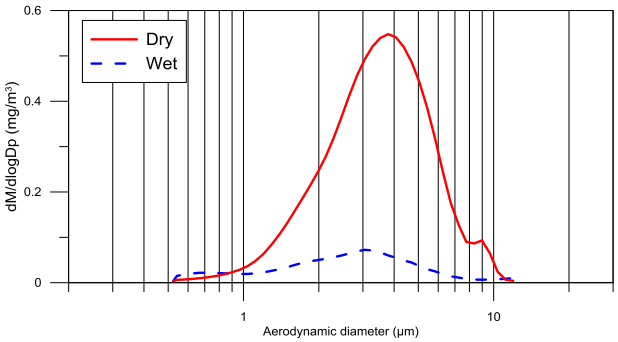

Figure 2. Particle mass size distribution averaged over the first, wet part of the campaign and over the second, dry part of the campaign, respectively.

Further work will describe differences between road and railroad tunnel particle emissions, size resolved particle composition, source apportionment and abatement strategies.

Winter particulate matter (PM10) sources for an Austrian-Slovenian border region.

M. Kistler[1], E.C. Cetintas[1], H. Bauer[1,†] and A. Kasper-Giebl[1]

[1]Institute of Chemical Technologies and Analytics, Vienna University of Technology, Vienna, A1060, Austria
Keywords: local PM10, carbonaceous aerosol.
Presenting author email: magdalena.kistler@tuwien.ac.at

Air pollution by particulate matter derived from biomass burning is recognized as a worldwide problem and is considered from the point of view of scientists and politicians, respectively. Many European regions have difficulties with keeping the internationally, nationally or locally defined limit values. Emission sources may cause pollution across the borders, what makes one-sided reduction policies inefficient. This is true also for residential burning particles, as observed e.g., in Aosta Valley (IT, FR, CH, Finardi *et al.,* 2002).

The following study was set by local authorities of South Austria and North Slovenia in order to develop efficient methods to improve the local air quality. The scientific goal was to obtain a detailed chemical characterization of collected particulate matter, information about its sources and the optimization of methods for assessment of source contributions.

Particulate matter sampling was conducted at four urban and three background stations in Carinthia (AT), South Styria (AT) and Maribor region (SI). PM10 was collected between 29.01.2011 and 28.02.2011 daily (24h), on quartz fibre filters (Pallflex, 150mm), using high volume samplers (~700m³). The particle mass was determined gravimetrically.

Circular filter aliquots (with 10mm diameter) were used for the determination of carbon parameters (organic carbon, OC and elemental carbon, EC) with a thermal-optical method (*Sunset OCEC Aerosol Lab Analyser*), using a EUSAAR2 temperature protocol (Cavalli *et al.,* 2009). Inorganic ions and sugars were analysed using ion chromatography (*Dionex*) with conductivity (ions) or pulsed amperometric detection (saccharides). For this purpose 3 to 5 filter aliquots (10mm) were eluted with extra pure Milli-Q (resistance 18.2 MΩ) water (anions, sugars) or with 12 mM methane sulphonic acid (cations).

HULIS (humic like substances) were determined with a TU Vienna derived method (Limbeck *et al.*, 2005) comprising an NDIR analysis of CO_2 evolved from combustion of water- and alkali-extract treated with appropriate solid phase extraction.

Selected elements including Al were analysed using X-Ray Fluorescence.

Aerosol water content was assessed with thermo-gravimetric method in which the loss of weight of a filter aliquot heated to 100°C in a thermo-balance under nitrogen atmosphere and kept at this temperature for 5 minutes is equivalent to the aerosol H_2O.

Source analysis was performed using a simple macro-tracer approach, describing up to nine main aerosol sources (Puxbaum *et al.,* 2005). This model involves anhydrosugars: levoglucosan and mannosan as specific tracers for wood burning (Schmidl *et al*., 2008, 2011, own unpublished data).

Except for the rural background station in Styria the short-term PM10 threshold value was exceeded between 17 and 20 times during the measurement period. The average PM10 concentration observed for urban sampling points was 60 µg/m³.

The contribution of biomass burning was lowest in the rural background in Styria (22%), and accounted up to 40% in Carinthia (urban background), being the most relevant local PM10 source. Similar significance was observed for secondary inorganic aerosols (ammonium sulphates and nitrates): between 29% (Carinthia, urban traffic) to 48% (Styria rural background). Traffic near locations were characterized by a higher impact of fossil fuel emissions (expected mainly from Diesel engines), mineral dust (carbonates and silicates) and de-icing salt (both from the re-suspension). On the other hand a higher amount of organic secondary aerosols was found at background measurement sites.

This work was conducted with samples collected within the INTERREG IVA SI-AT PMinter project conducted through the Municipality of Klagenfurt, Municipality of Maribor and Styrian Government, in cooperation with Provintial Government of Carinthia, Public Health Institute Maribor, TU Graz and the University of Maribor. Lab work by C. Ramirez Santa Cruz L. Sampaio Cordeiro Wagner, E. Schriener (Institute of Chem. Technologies and Analytics) and S. Lüftl from Institute of Material Science and Technology is gratefully acknowledged.

Keywords: PM_{10}, biomonitors, source apportionment, industry.
Presenting author email: joanalage@ctn.ist.utl.pt

The objective of this study was to assess the air quality and the contribution of emission sources in the vicinity of an industrial area placed in the North of Spain, which is affected by a steelwork, a cement factory and a power plant. For that complementary tools were used:

1) Metal concentrations were mapped in the surroundings of the industrial area using passive biomonitors;

2) Geographic Information System was used to evaluate the relations between the spatial distribution of the elements, contamination factors, land use and topography and to identify the sources and processes associated with the pollutants' formation;

3) PM_{10} was sampled in the industrial area and a temporal database of aerosol species was built to evaluate the seasonal variations of metal concentrations;

4) Receptor models were used to identify and quantify the contributions of the industrial operations to metal concentration in the local ambient air.

The spatial distribution of the chemical elements assessed by the biomonitors showed an increase of Al, Ca, Cl, Cu, Fe, I, Mn, Na, Sb and V in the industrial area. Elements associated with the soil also presented increased concentrations in this area probably due to re-suspension caused by the heavy traffic of trucks (Fig.1).

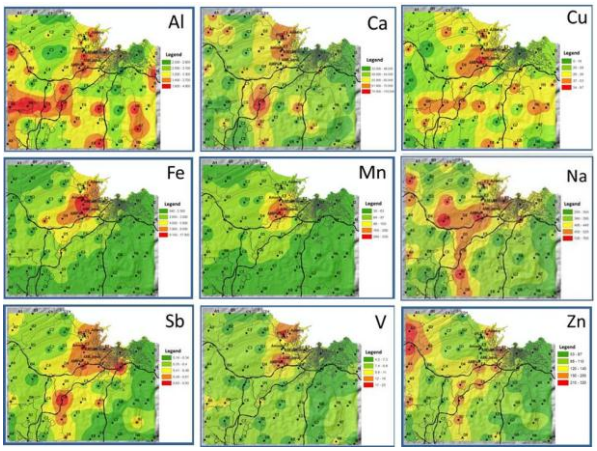

Figure 1. Spatial distribution of the Al, Ca, Cu, Fe, Mn, Na, Sb, V and Zn concentrations measured in the exposed biomonitores.

PMF applied to the PM_{10} compounds identified 7 emission sources. The first source clearly reflected the sea-spray composition, having high shares of Cl and Na, and contributed on average to 22% of the PM_{10} mass. The second source, which contributed on average to 11% of the total PM_{10} mass, was mainly composed of As, Cr, Cu, Ni, Pb, Sb and Zn and was attributed to mixed combustion processes and traffic. The third source contained high percentages of NH_4^+ that derives from gas to particle conversion processes. The contribution of this factor to PM_{10} mass was on average 12%. The fourth factor is made of Br and contributed for 1.8% of the total PM_{10} mass. The fifth source is dominated by NO_3^- and SO_4^{2-} and contributed on average for 19% of the PM_{10} mass concentration. The sixth source carries high percentages of Al, Ca, La, Si, Ti and V and account for 14% of the PM_{10}. These are the major constituents of soil and point out the fingerprint of mineral dust. The seventh factor was associated with steel production as it is defined by Fe and Mn. This source accounted for 21% of PM_{10} mass concentration (Fig.2).

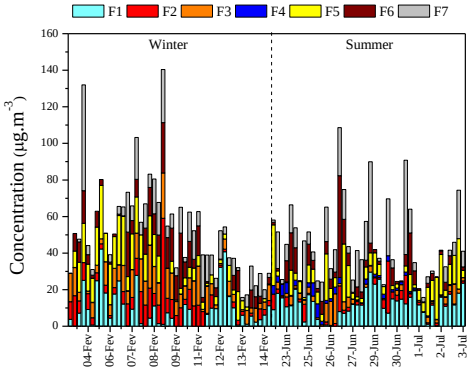

Figure 2. Source contribution for PM_{10} total mass concentration time series (µg.m^3).

This work showed that the use of complementary tools is essential in the assessment of the air quality. Atmospheric particles are usually measured instrumentally. However, particles sampling and characterization is necessarily performed by a limited number of sampling stations due to the associated high costs. As a result, vast areas are not covered by any monitoring system. Therefore, in one hand biomonitoring offers unique advantages - the ability to perform high-density sampling at any spatial scale at low cost and the measurement of a wide range of pollutants. In the other hand, instrumental measurements inform about the absolute air concentrations and the temporal trend of the pollutants.

This work was supported by the Portuguese "Fundação para a Ciência e Tecnologia" under the J. Lage PhD fellowship SFRH/BD/79084/2011. The research leading to these results has received funding from the European Community's Research Fund for Coal and Steel (RFCS) under grant agreement no RFSR-CT-2009-00029.

Relationship between oxidation level and optical properties of secondary organic aerosol

Presenting author email: lambe@aerodyne.com

Brown carbon (BrC), which may include secondary organic aerosol (SOA), can be a significant climate-forcing agent via its optical absorption properties. However, the overall contribution of SOA to BrC remains poorly understood. Here, correlations between oxidation level and optical properties of SOA are examined. SOA was generated in a flow reactor in the absence of NO_x by OH oxidation of gas-phase precursors used as surrogates for anthropogenic (naphthalene, tricyclo[5.2.1.$0^{2,6}$]decane [JP-10]), biomass burning (guaiacol), and biogenic (α-pinene) emissions. SOA chemical composition was characterized with a time-of-flight aerosol mass spectrometer. The mass spectra yielded oxygen-to-carbon (O/C) ratios, used as a measurable surrogate for SOA oxidation level, that ranged from 0.29 to 1.29.

SOA mass-specific absorption cross sections (MAC) and refractive indices were calculated from real-time cavity ring-down photoacoustic spectrometry (CRD-PAS) measurements at 405 and 532 nm and from UV-Vis spectrometry measurements of methanol extracts of filter-collected particles (300 to 600 nm). At 405 nm, SOA MAC values and imaginary refractive indices ranged from $<$0.001 to 0.088 $m^2\ g^{-1}$ and 1.9×10^{-4} to 3.6×10^{-3}, respectively, increasing with SOA oxidation level. SOA light absorption decreased with increasing wavelength, leading to negligible absorption at 532 nm. Real refractive indices (n) of SOA at 405 nm ranged from 1.45 to 1.66 and for a given precursor changed at a rate of $\Delta(n)/\Delta(O/C)$ = -0.055 to -0.11. Comparison with literature studies suggests that under typical polluted conditions the effect of NO_x on SOA absorption is small. SOA may contribute significantly to atmospheric BrC, with the magnitude dependent on both precursor and oxidation level.

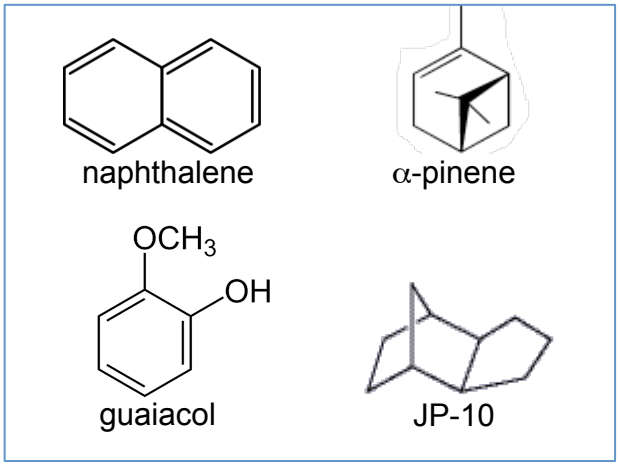

Figure 1: Molecular structures of SOA precursors used in this work.

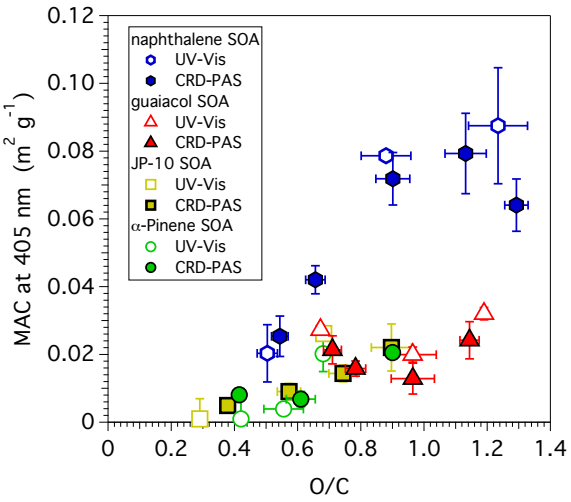

Figure 2: Mass-specific absorption cross sections (MAC) of SOA obtained at λ = 405 nm as a function of O/C ratio. MAC values are calculated from CRD-PAS and UV-Vis spectrometer measurements.

Presenting author email: hanna.manninen@helsinki.fi

Atmospheric ions play an important role in the fair weather electricity. Atmosphere's fair weather condition concerns the electric field and the electric current in the air as well as the air conductivity. On the other hand, atmospheric ions are important for Earth's climate, due to their potential role in secondary aerosol formation. This can lead to increased number of cloud condensation nuclei (CCN), which in turn can change the cloud properties. Our aim is to quantify the connections between these two important roles of air ions based on field observations and existing data archives.

When studying atmospheric electricity, the air ions are essential. Small ions, or charged molecular clusters, carry electric currents in the atmosphere. These small ions are continuously present, and their lifetime in lower atmosphere is about one minute. It's essential to find out a connection between the production rate of cluster ions, ion-ion recombination, and ion-aerosol attachment, and their ambient concentrations, in order to understand electrical properties of air istelf.

Currently, there's an intensive discussion about the connection between the atmospheric electricity and climate change. Recently, changes in atmosphere's electric properties caught new interest, as a possible connection between ionizing galactic cosmic rays, cloud cover and climatic effects was suggested (Carslaw, Harrison and Kirkby, 2002; Kirkby et al. 2011). The most significant factor of uncertainty in climate research is caused by atmospheric aerosols, especially due to small particle effects. Secondary formation of new particles through a process of gas-to-particle conversion, beginning with a few gas molecules colliding to form a cluster of 1-2 nm in diameter, is believed to be the dominant source of aerosol particles in the atmosphere. Some studies suggest that the contribution of air ions is important or even dominant to secondary aerosol formation, whereas other studies show that their role is negligible.

We studied the interactions between atmospheric electricity (air conductivity, electric field, and ambient concentartion of small ions), aerosol particles, and cloud properties. In other words, the correlations and trends in atmospheric ionization, electricity, aerosols, and CCN properties were studied. Most of the work here is based on analysis of already existing data archives, and some new measurements are established as a part of already existing measurement networks. The electrical properties of the atmosphere have been measured over a century now, whereas the longest continuous time series of aerosol particle data available is little over decade old. Tammet (2009) has collected a dataset, which comprises the measurements of atmospheric electric field, positive and negative conductivities, air ion concentrations, and accompanying meteorological measurements at 13 stations, including 7 stations of the former World Data Centre network on Atmospheric Electricity at the Main Geophysical Observatory, St. Petersburg, Russia.

The ongoing field observations of atmospheric aerosols are mainly performed at Hyytiälä SMEAR site, Southern Finland (Station for Measuring Ecosystem-Atmosphere Relations). Hyytiälä provides extensive dataset of measured aerosol particle (physical, chemical, and optical) properties, external and radon radiation, CCN properties, trace gases, meteorological parameters, different flux measurements (micrometeorology), and forest ecology observations. The atmosphere's electricity is measured with the air ion spectrometers (Manninen et al. 2010) to determine air conductivity and with the electric field mills, which measures the strength of atmospheric electric field. The plan is to extend the measurements of atmospheric electricity to the Finnish Meteorological Institute (FMI) site at Pallas, Northern Finland, and to SMEAR site at Järvselja, Estonia. Hyytiälä and Pallas stations are part of ACTRIS (Aerosols, Clouds, and Trace gases Research InfraStructure Network) and GAW (Global Atmosphere Watch) networks.

The lightning activity and ion concentration was also investigated. The lightning flash counter data for Hyytiälä, Pallas, and Järvseljä is collected by FMI. The systematic ground lightning observations are performed with eight ground-based sensors in Finland. The Norwegian, Swedish, and Estonian sensors have been integrated, completing the coverage up to the whole Nordic countries.

The support by the Finnish Cultural Foundation and the Academy of Finland Centre of Excellence program (project no. 1118615) are gratefully acknowledged.

Puijo measurement station has provided continuous data on aerosol-cloud interactions since summer 2006 (Leskinen *et al* 2009). The station is located on top of the Puijo observation tower (306 m a.s.l, 224 m above the surrounding lake level) near the town of Kuopio, Finland. The station is covered by cloud about 15 % of the time, offering perfect conditions for aerosol-cloud interaction studies. With a special inlet setup (total and interstitial inlets) activated and non-activated particles can be measured separately. Continuous twin-inlet measurements include aerosol size distribution (twin-DMPS, 7-800 nm), scattering and absorption. Other continuous measurements include cloud droplet number and size distribution and weather parameters.

We also arrange intensive measurement campaigns every autumn (Puijo Cloud Experiment, PuCE) when the occurrence of clouds is the highest. During these campaigns, extra measurement devices have included aerosol mass spectrometer (AMS), cloud condensation nuclei counter and Hygroscopic Tandem Differential Mobility Analyzer. The AMS has been connected to the twin-inlet system¸ providing data about the chemical composition of activated and non-activated particles (Hao *et al* 2013).

In our current work, we have been analyzing results from PuCE 2010 and 2011 campaigns. During these campaigns, a total of 39 cloud events took place, with a total of 156 hours of in-cloud data. The aim of the research has been the identification of the possible effect of local pollutant sources on aerosol-cloud interactions. The tower is surrounded by residential areas and traffic routes in north, east and south, whereas in west and northwest there aren't any significant sources. Also, two important point sources exist within a few kilometres from the tower, a paper mill and a heating plant.

An example of a cloud event, during which it was possible to pinpoint the effect of local sources, took place on 22.-23.10., 2011. There were several periods with different particle population properties, which also affected the cloud properties to some extent. Here, three of these periods are chosen for a closer inspection.

During the clean period (22.10. 22:00-23.10. 5:45), wind direction was from north and northwest with low total particle and accumulation mode concentrations (fig. 1a). Between 5:45-6:15 on 23.10. wind direction was from northeast where the paper mill is located. Total particle concentration was still low but a pronounced accumulation mode was present. Particle chemical composition during this period was dominated by SO_4 and NH_4. When wind direction shifted to south (23.10. 9:45-13:00), a plume from the heating plant hit the tower. Elevated particle concentration was observed, with a distinguishable accumulation mode, consisting almost entirely of SO_4.

During the pollutant episodes, the size of activated particles was larger when compared to the clean period (fig. 1b). In clean conditions, as small as 100 nm particles activated, whereas during the polluted periods the average diameter for activation was larger. During the paper mill plume, droplet concentration was higher (240 cm^{-3}) with a smaller average droplet diameter (10.9 µm) when compared to the clean period (138 cm^{-3}, 12.2 µm). Unfortunately the cloud droplet probe was frozen during the heating plant plume.

As a conclusion, it is evident that local pollutant sources affect aerosol-cloud interactions. However, it is too early to say if this is only caused by the elevated number concentrations or if the different chemical composition also plays a role. Also, how often these periods take place requires more research and data from forthcoming campaigns.

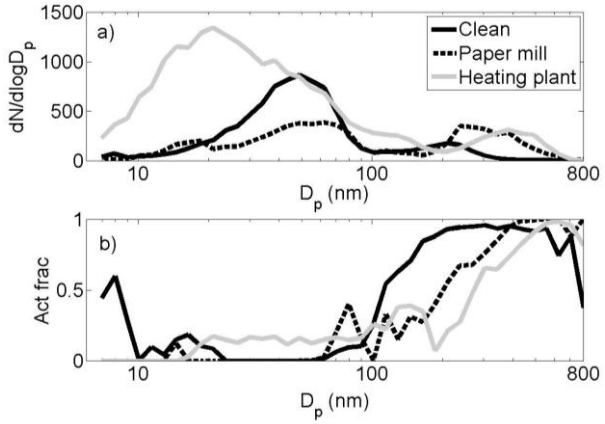

Figure 1. a) Total particle size distributions and b) particle activated fractions vs. size for the different periods during a cloud event on 22.-23.10.2011.

[2]Department of Physics, University of Helsinki, 00014 Helsinki, Finland
[3]Laboratory of Atmospheric Chemistry, Paul Scherrer Institute, 5232 Villigen PSI, Switzerland

Keywords: Neutral sulphuric acid nucleation, new particle formation, Jungfraujoch

Aerosol nucleation from trace vapours is a ubiquitous process in the Earth's atmosphere and has been observed at many different places (Kulmala et al., 2004). It is thought that sulphuric acid is a key species in the formation process of small clusters and particles. A correlation between the particle formation rate and the concentration of sulphuric has been frequently observed during ground-level field campaigns. However, data coverage on the sulphuric acid concentrations at higher altitudes is relatively scarce, although, these regions are very important on a global scale. In addition, it is not clear if and what other compounds (besides water) are participating in the formation of aerosol particles in these regions.

During January and February 2013 the **Nu**cleation, **Cl**oud and **A**erosol **C**haracterization **E**xperiment (NUCLACE) took place at the high alpine research station Jungfraujoch (JFJ) in Switzerland. The JJF station is located at 3580 meters altitude and mainly influenced by free tropospheric air during this time of the year. One of the goals of the NUCLACE campaign was to investigate the role of ions on the formation of new particles. However, in this study we focus on the measurement of the sulfuric acid concentration as well as on the detection of neutral clusters and their composition with state-of-the-art instruments.

For this purpose, two Chemical Ionization Atmospheric Pressure interface Time-Of-Flight Mass Spectrometers (CI-APi-TOFs) were used (Jokinen et al., 2012). Within the inlets of both instruments nitrate primary ions are generated which can ionize neutral sulphuric acid and clusters through a proton transfer reaction or by clustering. The primary and the product ions are detected with a high resolution time of flight mass spectrometer. The combination of these two techniques allows low detection limits (at ppq levels) and the identification of ion species through their exact mass. Although both CI-APi-TOF instruments have the same principle they differ in the design of their ion source. The CI-APi-TOF from the University of Frankfurt utilizes a corona discharge needle (Kürten et al., 2011) while the CI-APi-TOF from the University of Helsinki (Jokinen et al., 2012) utilizes a soft x-ray ion source. In addition, the geometry of the ion drift regions and the inlet geometries differ slightly. Additionally, the operation of the CI-APi-TOFs at JFJ turned out to be challenging due to the low pressure and strong temperature variations inside the building where the instruments were located. Therefore, an intercomparison of the two instruments is important (see figure 1). Furthermore, it turned out that an on-site calibration needed to be performed to take into account the conditions at the measurement site. For this, a calibration unit similar to the one described by Kürten et al. (2012) has been brought to JFJ. With this set-up a known concentration of H_2SO_4 can be generated and measured by one CI-APi-TOF at a time.

We will report on the overall comparison of the two CI-APi-TOFs with respect to the sulfuric acid monomer concentrations. In addition, the instruments will be compared regarding the detection of different neutral clusters. Details about the calibration will also be presented.

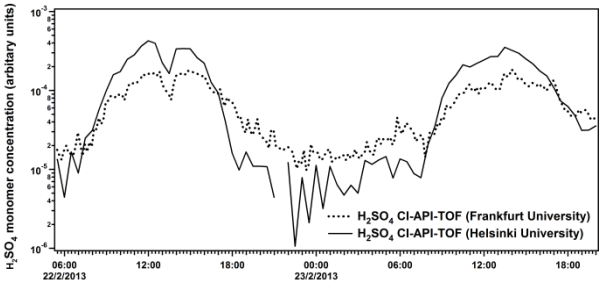

Figure 1. Observed diurnal variation of the sulphuric acid concentration measured by the two CI-APi-TOFs from Frankfurt and Helsinki.

We thank the International Foundation High Altitude Research Stations Jungfraujoch and Gornergrat (HFSJG), which made it possible to carry out the experiments at the JFJ. Also, we thank tofTools team for their support.

Air mass back trajectories and dry atmospheric aerosol mass size distributions in Prague

J. Schwarz[1], L. Štefancová[1] , W. Maenhaut[2], J. Smolík[1], W. Ždímal[1]

[1]Department of Aerosol and Laser Studies, Institute of Chemical Process Fundamentals AS CR, Prague, CZ-16502, Czech Republic
[2]Department of Analytical Chemistry, Ghent University, Gent, BE-9000, Belgium
Keywords: mass size distribution, air mass back trajectories, water soluble ions
Presenting author email: schwarz@icpf.cas.cz

Ambient aerosol size distribution is an important factor influencing aerosol behavior and properties including particle deposition in lungs and aerosol influence on clouds. Both influences are also driven by aerosol hygroscopicity. Cascade impactors used for size resolved determination of chemical composition suffer from changes of ambient RH during sampling. Due to this factor the same particle might be deposited at different impactor stage when it is sampled at noon at 40% RH or in the early morning at 99% RH. Therefore, we used a diffusional aerosol dryer and a 7-stage modified Berner low pressure impactor with a back-up filter (Štefancová et al., 2011) during the heating (shown as "winter" and non-heating season (shown as "summer") campaigns in 2008. The samples were analyzed for water-soluble ions (Cl^-, SO_4^{2-}, NO_3^-, Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}) and water-soluble organic carbon as a main species that influence aerosol hygroscopicity. Due to the drying, the aerosol size distributions were not influenced by the daily variability of ambient relative humidity.

The results cover the measurements from both campaigns (11 "winter" sampling days and 10 "summer" sampling days). The aerosols sampled on individual days were classified based on the connected air mass back trajectories into three classes: sea-influenced aerosol (SIA), continental aerosol (CA), and mixed aerosol (MA) for samples of intermediate origin.

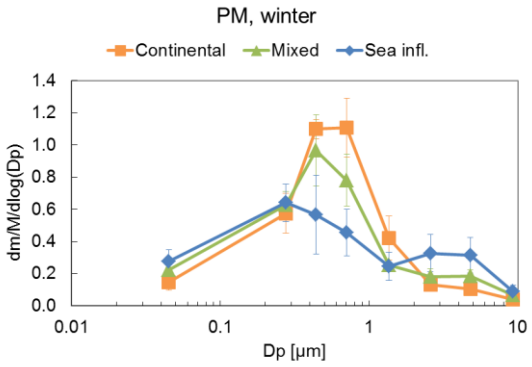

Fig. 1. Average normalized mass size distributions for the PM in the continental, mixed, and sea influenced aerosol samples of the winter campaign.

The differences between CA and SIA were substantial both when looking at the normalized mass size distributions of the particulate matter (PM, Fig. 1) and of the individual species (see an example for SO_4^{2-} in the summer in Fig. 2) and when taking into account

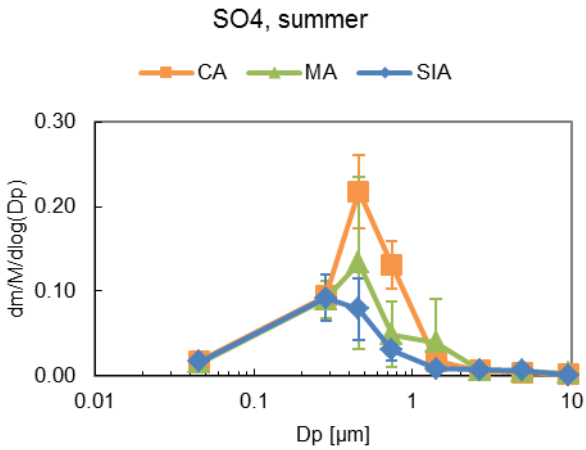

Fig. 2. Average normalized mass size distributions for the PM in the continental, mixed, and sea influenced aerosol samples of the summer campaign.

the absolute concentrations in the fine and coarse size fractions. The shift in the position of fine mode maxima could be explained by the prevailing influence of condensation or droplet mode formation of the accumulation mode particles (Hering and Friedlander, 1982). However, relative humidity profiles along the air mass trajectories could not explain the differences in size distributions in this way. Therefore another reason leading to explanation of the described differences (Schwarz et al., 2012) should be taken into account. As the first hypothesis, we suggest that the differences in average SO_2 concentration fields above Europe could explain our observations if the SO_2 concentration above Western Europe was so low that the diffusional limitation of SO_2 transport into droplets becomes important. This would change size dependence of sulphate formation rate from volume proportional to surface proportional.

Keywords: air quality
Presenting author email: sabine.wurzler@lanuv.nrw.de

In January and February 2013, the poor air quality in many major cities in parts of Asia, such as Peking and Delhi, made headlines worldwide. The high concentrations of air pollutants and the accompanying pictures and effects look very familiar to those, who lived in the area Rhine Ruhr during the fifties and sixties. Notable was, e. g., the smog episode in December 1962, leading to an increase of mortality by 30 %. This drastically increased number of deaths owing to poor air quality made very apparent that something had to be done.

Already the year 1961 marked a turning point in German air quality planning, because of a notable speech of the subsequent chancellor, Willy Brandt, who demanded a change in politics concerning air quality with the catch phrase of blue sky over the Ruhr area. This was the first time that someone so prominently focussed on the combination of air quality, health effects and social justice, turning smoking stacks into something more than just a sign for economic success.

While this single talk did not mean an immediate change in politics and public awareness, it was a popular vision from which future activities could build. These activities included monitoring air quality as well as measures for emission reduction. The awareness of air quality as a challenging problem has grown in the public since then. Now, the blue sky is again visible over the Ruhr area, at least on sunny days. The European Commission has declared the year 2013 as the year of air quality. When comparing today's air quality in Europe to the situation in the past and to the present situation in Asia, this might seem a bit exaggerated at the first glance. But is this true? Are all problems already solved? Therefore, we review the past, present and possible future activities in Germany and Europe and their results for air quality. It can be seen, that the work on clean air includes some success stories. As an example, figure 1 shows the SO_2 concentration in the area Rhine Ruhr from 1964 till 2011. The TSP and PM10 trend from 1968 to 2011 can be seen in figure 2. These figures well illustrate the success stories of air quality measures – as well as some less favourable measures. It can be seen that the general trend shows a clear decrease in SO_2, PM10, and TSP concentrations. Measures like dust separation in industrial facilities, substituting solid fuels in space heating as well as the structural change in the Ruhr area all led to a reduction of SO_2, PM10, and TSP, while the policy of high stacks only led to a change in distribution, causing acidification and eutrophication in ecosystems. Particularly the desulphurisation of power plants since 1977 enhanced the decrease and it can be stated that today the concentrations of SO_2 in Germany are no longer problematic with respect to human health.

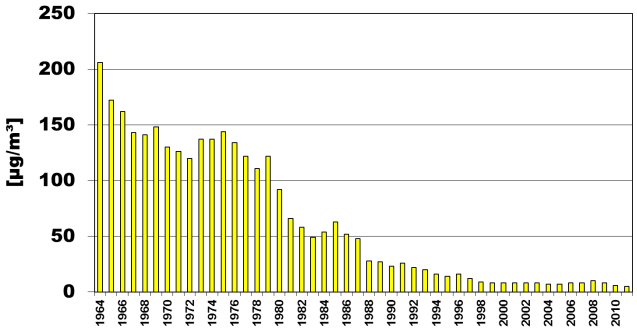

Fig. 1: Trend of annual average SO_2 concentrations in µg/m³ in the area Rhine Ruhr from 1964 to 2011. The highest concentrations correspond to values above 200 µg/m³, the lowest are below 10 µg/m³

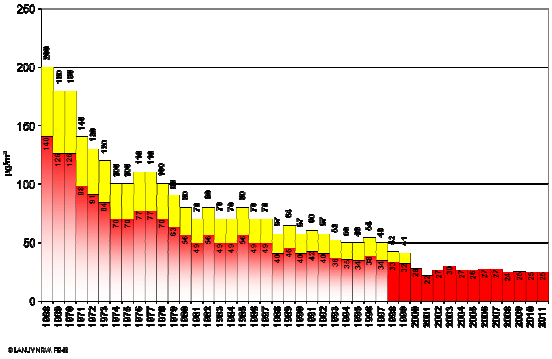

Fig. 2: Trend of annual average total suspended particle (TSP, yellow bars) and PM10 (red bars) concentrations in µg/m³ in the area Rhine Ruhr from 1968 to 2011. The highest concentrations correspond to values above 200 µg/m³, the lowest are below 50 µg/m³

But despite all advances, there are still problems to face. E. g., the high amount of road traffic is a main source for high NO_2 concentrations in cities. The number of PM10 exceedance days is still occasionally too high. Another challenge is the preservation of nature protection areas that can be adversely affected by high depositions of nitrogen, acid, or heavy metals.

Our presentation will give an overview of the last 50 years' challenges, success stories and memorable events as well as a reflection on current and future challenges in the area of air quality planning.

Plenary lecture: Primary Biological Atmospheric Aerosols by Ruprecht Jaenicke

Primary Biological Atmospheric Aerosols

Ruprecht Jaenicke
Institute for Physics of the Atmosphere
University Mainz / Germany

"Quantitative PCR and microscopy revealed that viable bacterial cells represented on average around 20% of the total particles in the 0.25 to 1 µm diameter range … suggesting that bacteria represent an important and underestimated fraction of micrometer-sized atmospheric aerosols". (DeLeon-Rodriguez, *et al*, 2013) Even if that statement covers only a certain situation and a certain part of the troposphere, it clearly shows that primary biological aerosol particles are a major fraction of the atmospheric aerosol.

While most primary particles of the atmospheric aerosol (maritime, mineral, etc) have sources limited to certain regions of the world, like the oceans, the deserts, etc, the primary biological aerosol particles (PBAP) are produced from all available surfaces of the world. The continental biosphere (leaves, animals, dead subjects) is a source for primary biological particles. Since the oceans are full of biological (dead and alive) material, each ejected sea spray particle contains biological material. Rock varnish may contain considerable amounts of organic material which sometimes may be responsible for the gel-like or lacquer-like appearance of the surface. The grey or black films may sometimes consist predominantly of dry cyanobacteria.

Partition	Global emissions (Tg yr^{-1})	Size range	References
PBAP	<10 (dominated by plant debris and fungal spores)	diameter: 4 µm for fungal spores; diameter not specified for plant debris	Winiwarter *et al* (2009)[1]
Biogenic	56 (0-90)	diameter <1 µm	IPCC (2001)[1]
PBAP	78 (includes only bacteria, fungal spores and pollen)	PM_{30}	Hoose *et al* (2010a)[1]
PBAP	186	split equally into the two coarse size fractions: 2.5-5 and 5-10 µm (PM_{10})	Mahowald *et al* (2008)[1]
PBAP	296 (includes only bacteria, fungal spores and pollen)	diameters as above	Jacobson and Streets, (2009)[1]
PBAP	~1000 (includes cellular fragments)	Total	Jaenicke (2005)[1]
Sea Spray	3340	Total	Penner et al (2001)
Mineral (Soil) Dust	2150	Total	Penner et al (2001)
Biomass Burning	54	0-2 µm	Penner et al (2001)

[1] Després et al (2012)

Rocks outside of deserts often are also covered by a varnish. Parts of biological soil crusts can also be ablated from desert surfaces and all these particles may contribute to the content of biological material in dust transported over long distances during storms (Despres et al 2012). In addition recent studies in Japan suggest that numerous culturable bacteria are transported with Asian dust over the East China Sea from the arid and semi-arid regions of Asia.

In the last years much research effort had been directed to the role of biological particles as ice nuclei and in forming clouds and rain. It is well known, that biological material acts much earlier (in term of freezing) then mineral (inorganic) material. So the cryosphere (deposited precipitation) is full of biological material. Resuspension of ice crystals then might add to the primary biological atmospheric aerosols.

Atmospheric biological particles have also an impact on hygiene and could cause adverse respiratory effects on humans.

The Table gives an impression about the source strength estimates published so far on global sources of primary biological particles. The other sources Sea Spray, Mineral Dust, Biomass Burning are given for comparison. That Table shows clearly, what an important fraction of the Atmospheric Aerosol the Primary Biological Particles are.

Recommendations for the interpretation of "black carbon" measurements

Andreas Petzold[1], John A. Ogren[2], and the members of GAW SAG Aerosol

[1] Forschungszentrum Jülich GmbH, Institut für Energie- und Klimaforschung IEK-8, 52425 Jülich, Germany
[2] NOAA/ESRL Global Monitoring Division, Boulder, CO 80305, USA

Keywords: Black carbon, elemental carbon, air quality, monitoring.
Presenting author email: a.petzold@fz-juelich.de

Although black carbon (BC) is one of the key atmospheric particulate components driving climate change and air quality, there is no agreement on the terminology that considers all aspects of specific properties, definitions, measurement methods, and related uncertainties. Following Bond et al. (2013), who deserve credit for synthesizing BC definitions for the first time, BC is characterized by the following distinct properties: (1) it strongly absorbs visible light; (2) it is refractory with a volatilization temperature near 4000K; (3) it is insoluble in water and in the other components of the atmospheric aerosol; and (4) it consists of aggregates of small carbon spherules of < 10 to approx. 50 nm in diameter. In order to include distinct microstructure features, the authors add a fifth property saying that (5) it contains a high fraction of graphite-like sp2–bonded C atoms; see Table 1 for details.

There is much ambiguity in the scientific literature of measurements and numerical models that refer to BC with different names and based on different properties of the particles, with no clear definition of the terms. In consideration of the inadequate definitions available in the literature, and in order to overcome this unsatisfying situation, the authors propose a consistent terminology which is built along material properties.

The term “black carbon” (BC) is considered a useful qualitative description when referring to light-absorbing carbonaceous substances in atmospheric aerosol. In the absence of a method for uniquely determining the mass of BC, the term "BC" should be used as a qualitative and descriptive term when referring generally to material that shares some of the characteristics of BC in particular its carbonaceous composition combined with its light-absorbing properties. For quantitative applications the term requires clarification of the underlying determination:

- Equivalent black carbon (EBC) should be used instead of BC for data derived from optical absorption methods. It is recommended to report the optical measurements primarily as light absorption coefficient, and secondarily as EBC, together with a suitable mass absorption coefficient (MAC) for the conversion of light absorption coefficient into mass concentration.
- Refractory black carbon (rBC) should be used instead of BC for measurements derived from laser incandescence methods.
- Elemental carbon (EC) should be used instead of BC for data derived from methods that are specific to the carbon content of carbonaceous matter (evolved carbon, aerosol mass spectrometry, Raman spectroscopy).
- Soot is a useful qualitative description when referring to particles formed from incomplete combustion. This term is appropriate to and widely used in the research field on the formation of carbonaceous particles in combustion processes and on the emission of particulate matter from combustion sources.

Table 1. Properties defining Black Carbon

Property	Characteristics
Microstructure	graphitic-like structure containing a high fraction of sp^2-bonded carbon atoms
Morphology	aggregates consisting of small carbon spherules of < 10 to approx. 50 nm in diameter
Thermal stability	refractory material with a volatilization temperature near 4000K, gasification is possible only by oxidation which starts at temperatures above 340°C
Solubility	insoluble in organic solvents, in water, and in the other components of the atmospheric aerosol
Light absorption	uniformly absorbing in the spectral range of visible light with MAC(550 nm) > 5 m^2g^{-1} for freshly produced particles; characterized by a significant, non-zero and wavelength-independent imaginary part of the refractive index over the visible and near-visible spectral regions

The coherent terminology proposed here reflects the widespread origin of BC data and permits a consistent reporting of data in the scientific literature that were generated by similar methods. In order to support this effort authors of research papers are requested to clearly state means of calibration and conversion as metadata with any published values.

Keywords: carbonaceous aerosols, atmospheric aerosols, measurement techniques
Presenting author email: regina.hitzenberger@univie.ac.at

Black (BC) and elemental carbon (EC) originate from incomplete combustion of carbonaceous fuels and are important constituents of atmospheric aerosols because of their optical and climatic effects (Jacobson 2005) and their possible health effects (Kim *et al.* 2003). Despite intensive efforts over the last decades, no standard measurement technique has been identified. In this presentation, we use the term BC for data obtained by optical methods, and EC for those obtained by thermal methods.

The study is focussed on an intercomparison of various measurement methods for BC and EC in two Central European cities (Prague, Czech Republic, and Vienna, Austria) which are rather similar in geographical features (total area covered, hilly surroundings, river, building density and characteristics) and have similarities and differences with regard to aerosol sources (in particular sources of black / elemental carbon). In earlier studies in Vienna under summer (Hitzenberger *et al.* 2006) and winter conditions (Reisinger *et al.* 2008) we found different conversion factors for BC and EC measured with different methods for the seasons.

The goal of the current study is to investigate whether similar conversion factors are applicable at the sites and whether the conversion factors obtained earlier (i.e. ca. 10 years ago) for Vienna are still valid or whether changing source conditions have resulted in shifts of the carbonaceous fractions of the aerosol that would require a new set of conversion factors.

For this goal, we performed two back-to-back campaigns in the two cities. The summer campaign was performed first in Prague (June 25 - July 9, 2012) and then in Vienna (July 16 – 30, 2012). The winter campaign was performed in Vienna (Jan. 14 – 30, 2013) and subsequently in Prague (Feb. 4 – 16, 2013).

In both campaigns, BC concentrations were measured on-line with a Multi Angle Absorption Photometer (MAAP) and a Micro-Aethalometer. For Prague, also data from a semi-continuous Sunset Analyzer (NIOSH and EUSAAR II protocols) are available. Off-line measurements of BC and brown carbon (BrC) were also performed using the modified integrating sphere technique capable to separate BC and BrC (Wonaschuetz *et* al 2009). EC concentrations were measured off-line using a Sunset analyzer. In addition to the EC / BC measurements, number size distributions and mass size distributions of the total aerosol were obtained and later analyzed for major ions as well as for black carbon (usually attributable to Diesel traffic) and brown carbon (usually attributable to wood combustion).

First results from the summer study on the intercomparability of the different methods of EC and BC determination show that as expected, the methods are rather well comparable under summer conditions, which agrees well with the earlier study in Vienna. The campaign averages seem to be rather different (e.g. in Vienna, the highest average EC concentration - 1.5 µg/m³ - was measured with the Aethalometer and the lowest - 0.5 µg/m³ - with the Sunset analyzer, transmission correction), but if the data variation is considered, these differences are not significant. Similar results were found for the Prague campaign. The influence of biomass smoke in summer in Prague is sometimes visible also in the BrC data, and is mostly absent in the Vienna summer data (BrC concentrations seldom were found to be above the detection limit). The full results of the intercomparison study will be the focus of this presentation.

Seasonal variations of black carbon physical properties influenced by different sources in London urban environment

Dantong Liu[1], James Allan[1,2], Michael Flynn[1], Dominique Young[1], Hugh Coe[1] and Martin Gallagher[1]

[1]Centre for Atmospheric Science, University of Manchester, Manchester, UK, M13 9PL
[2]National Centre for Atmospheric Science, University of Manchester, Manchester, UK
Key Words: Black carbon, Sources, Physical properties, Coating
Presenting author email: Dantong.liu@manchester.ac.uk

A recent comprehensive assessment of the contribution by black carbon aerosol (BC) to total climate determined it to be +1.1 W m^{-2}, and is deemed to be the second most important human emission in terms of its climate-forcing in the present-day atmosphere [Bond et al., 2013]. One of the most important and fundamental constraints on modelling BC climate forcing is determining its source strength. BC can be emitted from different combustion related sectors, i.e. they are often classified as fossil fuels for transportation; biofuels for industrial and residential uses including solid unprocessed biofuel, and open burning of biomass. The motivation to treat the source-attributed BC separately is due to its complex physical properties being largely source dependent, such as the BC size, mixing state, optical and hygroscopic properties. The variety of BC physical properties from sources can lead to considerable variations and uncertainties when modelling the BC direct forcing effect on climate and also the indirect forcing due to their different behaviours when interacting with clouds.

In urban environments, the BC from diesel fuel such as vehicle emission has been widely reported and been incorporated in most of the regional models. Although a few studies have emphasized the importance of emissions from residential solid fuel burning (i.e. from wood burning and cooking) in UK winter time [Allan et al., 2010; Liu et al., 2011], the properties of BC associated with these sources and their differences compared to that from vehicle emissions have not been well characterized.

This study reports results of continuous BC measurements from the Clean Air for London (ClearfLo) campaign for two major intensive observation periods (IOPs) during 2012. Both IOPs lasted for four weeks and were conducted in winter (11st Jan.- 08th Feb.) and 2012 summer (18th Jul.-22nd Aug.) respectively, the latter being during the period of the London Olympic Games. The experimental site was located in the grounds of a school in North Kensington, which is representative of a typical London urban background environment. A long term source attribution study in London based on the positive matrix factorization (PMF) analysis of AMS data shows that London urban environment in winter is significantly influenced by the source of solid fuel burning, such as wood burning for residential heating. In contrast vehicle emissions almost form the only BC source in summer. In the present study physical properties of BC were characterized using a single particle soot photometer. By assuming a core-shell model of coated BC, the relative coating thickness of the aprticles, which is the entire BC particle size (D_p) divided by refractory BC core size (D_c) - D_p/D_c, was also determined using Mie theory.

The physical properties of BC exhibited seasonal differences, summarized in Figure 1. The winter experimental period in London was generally more polluted than summer, with almost twice the BC mass loading on average. Both summer and winter showed a morning rush hour peak of BC mass, whereas an additional evening peak showed in winter. The BC particles in winter, influenced by solid fuel burning, showed larger core size (geometric mean mass diameter D_{geo}170-205nm) than in summer (D_{geo}155-180nm). The summer BC, dominated by vehicle emissions, showed consistent core size distribution throughout the experiment without any diurnal variation, however an apparent diurnal trend of BC core size was observed when influenced by solid fuel burning. The winter-time BC showed significantly thicker coatings than in summer (as reflected by D_p/D_c). The thickest BC coatings in summer were observed between 14:00-15:00 corresponding with the maximum photochemical reactions; however the strongest mixing occurred at midnight in winter. The work we will also present a methodology using Mie calculations to estimate the mass absorption cross section (MAC) and the absorption enhancement due to the coating for different sources of BC and relate these to different photochemical ages.

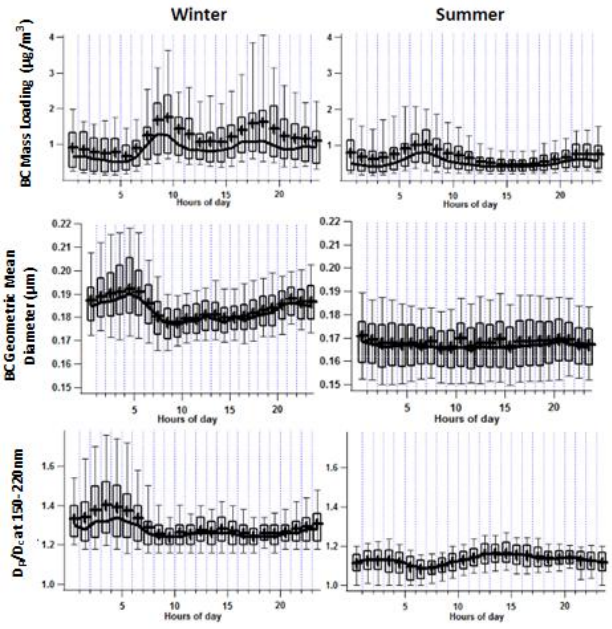

Figure 1. The diurnal trends of BC physical properties in winter and summer, from top panel to the bottom: BC mass loading, BC geometric mean diameter and D_p/D_c at 150-220nm

Influence of vertical transport on the mixing state of black carbon at the high-alpine Jungfraujoch site

M. Gysel, M. Laborde, N. Bukowiecki, E. Hammer, P. Zieger, U. Baltensperger and E. Weingartner

Laboratory of Atmospheric Chemistry, Paul Scherrer Institute, 5232 Villigen PSI, Switzerland
Keywords: Black Carbon, Mixing State, Jungfraujoch, SP2
Presenting author email: martin.gysel@psi.ch

Atmospheric black carbon (BC) aerosol particles are mostly emitted by anthropogenic combustion processes. They are a concern due to their adverse effects on human health and their contribution to climate warming (Shindell *et al.*, 2012). Climate-relevant BC properties such as the mass absorption cross-section, cloud condensation nuclei activity and ice nuclei activity depend on the mixing state of BC. BC particles are often emitted with almost no coating and atmospheric aging processes such as condensation and coagulation result in acquisition of coatings with other aerosol components.

In this study we investigated the mixing state of BC particles observed at the high-alpine research station Jungfraujoch (3580 m asl) in the Swiss Alps. A single particle soot photometer (SP2; Schwarz *et al.*, 2006) was applied for quantitative detection of BC mass in individual particles using laser-induced incandescence. The coating thickness of BC particles is determined by comparison of the optical particle diameter (derived from the light scattering signal) with the BC core diameter (derived from the incandescence signal).

An example of the BC properties observed at the Jungfraujoch is shown in Fig. 1 for two days in summer 2010. The green shading indicates times when the Jungfraujoch was exposed to free tropospheric (FT) air, the pink shading indicates times with distinct influence from injections of the planetary boundary layer (PBL), and the grey shadings indicate local pollution from a snowcat. The arrival of PBL influence results in an increase of both BC particle number concentration (Fig. 1A) and BC mass concentration (Fig. 1B) by about one order of magnitude, while the number fraction of BC-containing particles (mass equiv. BC core diameter D_{MEV} > 70 nm) to purely scattering particles (optical diameter > 125 nm) remains unchanged (Fig. 1A). Fresh snowcat exhaust can be identified by a massive increase of BC-containing particles, while the concentration of purely scattering particles remains almost unaffected. Fig. 1C shows the median coating thickness ($\Delta_{coating}$) of BC cores with $D_{MEV} \approx 200$ nm. BC from the snowcat exhaust is uncoated within experimental uncertainty. A substantial coating thickness of $\Delta_{coating} \approx 60$ nm is observed for FT air and PBL influence results in a slight decrease of the coating thickness to $\Delta_{coating} \approx 40$ nm. The latter value is substantially larger than that of fresh pollutions in urban areas (e.g. Laborde *et al.*, 2012), thus indicating that the time scale for the acquisition of a substantial coating is shorter than the typical transport time from the BC source to the Jungfraujoch.

The whole data set covering 1.5 months will be used to investigate whether the coating thickness difference between FT air and PBL influenced air reported in Fig. 1 is generally representative. The influence of coating thickness variations on the mass absorption cross-section of the BC particles will also be addressed.

Fossil and non-fossil sources of OC and EC in Switzerland for winter-smog episodes

S. Szidat[1,2], P. Zotter[3], Y.L. Zhang[1,2,3], V.G. Ciobanu[3], L. Wacker[4], Baltensperger[3], and A.S.H. Prévôt[3]

Presenting author email: szidat@iac.unibe.ch

Persistent inversion conditions may occur in Switzerland in the plateau and in Alpine valleys during winter. Such winter-smog episodes may lead to high concentrations of particulate matter with an aerodynamic diameter <10 µm (PM_{10}) exceeding the legal daily limits of 50 µg/m^3 over several days to weeks. As such conditions may cause acute health effects, the emission sources of PM in general and of carbonaceous aerosols in particular are of special interest for these episodes. A substantial contribution of biomass burning was indicated in previous campaigns in Switzerland (Szidat 2009).

From winter 2007/2008 to winter 2011/2012, several stations of the Swiss federal and cantonal air monitoring programs provided quartz fibre filters for 5 days per winter (simultaneous collection for all stations) with high PM_{10} concentrations (Figure 1). Samples were analysed for major anions and cations as well as organic carbon (OC) and elemental carbon (EC) concentrations.

Figure 1. Map of the study. Stations marked in red participated only during one or two winters.

Fossil and non-fossil sources were apportioned for all filters by measurement of the long-lived radioisotope ^{14}C (radiocarbon) based on the fact that fossil materials are extinct in ^{14}C due to its age, where as fresh plants contain radiocarbon on the contemporary level (Szidat *et al.* 2006). ^{14}C analysis was performed on OC and EC separately, because both fractions typically originate from diverse sources with different fossil/non-fossil shares EC originates only from combustion of fossil-fuels and biomass burning. OC can be emitted as primary organic aerosol from biogenic sources, wood burning and fossil fuel combustion or can be formed in the atmosphere as secondary organic aerosol. In total, >500 individual ^{14}C determinations were conducted.

Special emphasis was laid upon an optimized isolation procedure for EC, as the ^{14}C value of this fraction directly reflects the biomass-burning contribution of the emissions. EC isolation was performed with the new protocol Swiss_4S, which combines steps of water extraction, combustion in oxygen and evaporation in helium for complete OC separation with online monitoring of the optical transmission (Zhang *et al.* 2012).

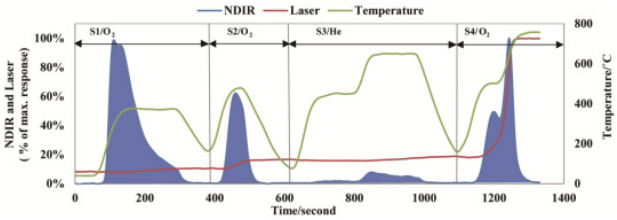

Figure 2. Thermogram based on the Swiss_4S protocol for isolation of EC for ^{14}C analysis (Zhang *et al.* 2012).

On the average, the non-fossil fractions of OC were larger than 75% for each station, which indicates that primary or secondary traffic emissions contributed only to a minor extent during the winter-smog episodes. This was even valid for the motorway (Reiden, Moleno) and kerbside stations (Bern), which demonstrates the importance of regionally mixed over local emissions. ^{14}C analysis of EC revealed that biomass burning contributed on the average by one to two thirds to the total burden of this carbonaceous aerosol fraction depending on the station characteristics: whereas traffic-related sites showed smaller proportions, dominating biomass-burning emissions were observed in Alpine valleys, where residential wood heating is common. In this work, we will present final results and discuss in detail the contribution of biomass burning for winter-smog episodes in Switzerland and its trend over the five years of the study.

Atmospheric aerosol particles have direct impact on the climate of the earth through scattering and absorption of radiation. The carbonaceous fraction of particulate matter, which consists of elemental carbon (or black carbon) and a variety of organic compounds (organic carbon), plays a significant role on this climatic change and on public health, as well. Organic carbon is considered one of the main elements of aerosols that scatter radiation thus; the main component of particulate matter that absorbs light is elemental carbon.

Long-term (5-year) measurements of Elemental Carbon (EC) and Organic Carbon (OC) in atmospheric aerosols are presented here for the first time in the area of Athens, Greece. Furthermore, the seasonal variability of carbonaceous content has been studied, reflecting the effects of the on-going recession on the quality of the air.

To calculate the concentration of OC and EC, a total of 1500 samples have been collected using Dichotomous Partisol and Partisol FRM samplers on a 24hour basis, at Penteli's premises (National Observatory of Athens station: 38°3'N, 23°5'E, 527 m a.s.l) covering a 5 year period. All chemical analyses presented in this research, were conducted on the $PM_{2.5}$ fraction, since fine fraction of aerosols constitutes the major carrier of the studied air pollutants. The applied method for OC and EC measurements was described in detail by Theodosi *et al* 2010.

The daily concentrations and the seasonal cycle of organic and elemental carbon for the studied period, is presented in Fig.1a, and 1b, respectively. The levels of OC and EC concentrations appear to decrease from 2008 to 2010 while, since 2010 an increase is observed during the colder periods of the year. This could probably be attributed to the reduction of sources of air pollutants from 2008 to 2010 due to the beginning of the crisis in the economy while, since 2010 biomass burning seems to dominate in domestic heating, resulting in augmented carbonaceous aerosol production.

It can be observed that OC and EC present similar covariance during the studied period and their maximum values appear mostly on fall to winter season, as it was expected, since during this period of the year there is fuel combustion and domestic heating that mainly leads to production of elemental and organic carbon.

The whole period average estimated concentration for OC was 2.32 ± 1.29μg/m^3 and for EC was 0.54 ± 0.39μg/m^3. The average OC/EC ratio of the aforementioned in situ measurements was 6.17 while, the concentrations of OC and EC appeared to be well correlated (R^2=0.48).

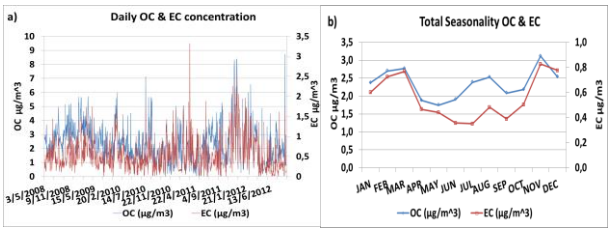

Figure 1 a. Daily OC and EC concentrations and b. Seasonal cycle of OC and EC concentrations at Penteli during the sampling period from 2008 until 2012.

The organic to elemental carbon ratio indicates that the organic carbon is mostly secondary. During colder period of the year additional sources like household heating contribute to the total carbon loadings. More importantly the type of domestic heating is considered a key parameter. As a consequence, it could be assumed that the deterioration of the air quality constitutes an additional side-effect of the years of recession in Greece.

Future studies will be focused on the correlation of OC and EC concentrations to ion concentration and optical properties of aerosols.

Results from a intensive campaign carried in La Paz (16°30'13.83"S; 68° 7'45.56"W; 3580 m a.s.l.) Bolivia are presented on this work. Particle size distribution was measured using a Mobility Particle Size Spectrometer (following Wiedensohler et al.; 2012), whereas the particle mass concentration of black carbon (BC) was measured using a Multi Angle Absorption Photometer (MAAP). In addition meteorological parameters as well as CO concentration were collected. The instruments were set up at the Planetarium of University Mayor de San Andres, La Paz, Bolivia. The building is located beside a road with heavy traffic. Since La Paz is located in a valley reaching from approximately 3200 to 4000 m a.s.l., cars and trucks are operated on a high load when driving uphill.

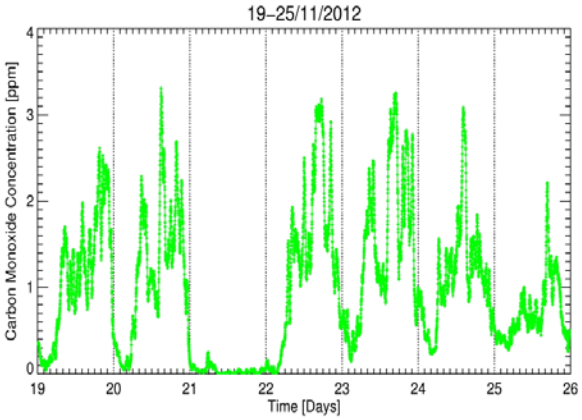

Figure 1: Carbon monoxide gas concentration for the week November 19 to 25, 2012.

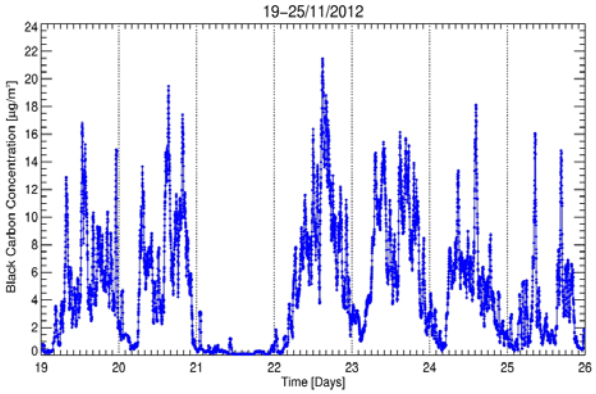

Figure 2: Black carbon particle mass concentration for the week November 19 to 25, 2012.

La Paz and El Alto (located at approximately 4000 m a.s.l.) are two of the major cities in the region. There are no other larger settlements in the surrounding. During November 21, 2012, the whole traffic was banned because of a national census in both cities, giving us the opportunity to study the influence of the traffic on the black carbon particle mass concentration, the particle number size distribution as well as the carbon monoxide gas concentration.

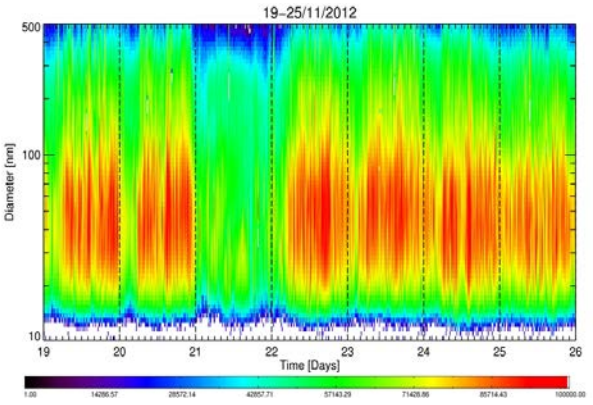

Figure 3: Particle number size distribution for the week November 19 to 25, 2012.

As seen from Figure 1, on November 21, 2012, the carbon monoxide gas concentration dropped to a value near Zero ppm from around 2ppm, during workdays November 19 -20 and 22-23, 2012. This indicated that due to the traffic ban, almost all sources of incomplete combustion have been switched-off. Figure 2 illustrates the same behavior for the BC particle mass concentration, meaning that BC was almost exclusively produced by the traffic. During regular working days, peaks of BC particle mass concentration were around 15 µg/m^3, whereas on November 21, 2012, the values were clearly below 1 µg/m^3. In Figure 3, a contour plot of the particle number size distribution of the week November 19 to 25, 2012 is shown. The red color illustrates high, whereas green and blues describe low particle number concentrations. Again, on November 21, the concentrations drop drastically, demonstration that the major fraction of the aerosol in the city of La Paz is produced by traffic.

Presenting author email: mariarosaria.calvello@imaa.cnr.it

A two-year dataset of almost continuous Black Carbon (BC) content measurements by a Magee AE31 7-wavelenghts aethalometer (370 to 950 nm) near a crude oil pre-treatment plant in South Italy (Agri Valley, 40.33°N, 15.92° E, 582 m a.s.l) has been analyzed. Since 1996 an intense crude-oil extraction together with a pre-treatment activity has been carried out at the site with continuous and controlled combustion processes and smoke emissions.

A suitably implemented algorithm has been applied to the aethalometer data in order to analyse absorption coefficient spectral dependence and to reduce the error in UVPM detection (Esposito *et al.*, 2012). BC and UVPM data have been compared to some organic compounds concentrations (Benzene, Toluene, Methane, Non-Methane Hydrocarbons) routinely measured at the same site and for the same period by ARPAB (Basilicata region environmental protection agency).

Recurrent trends have been searched for on a wide temporal scale (two-years diurnal cycles/ seasonal pattern, summer and winter) by applying the statistical Lomb-Scargle periodogram technique to the entire data-set. This is a powerful technique to be applied for frequency analysis of not equally-spaced data to obtain reconstructed spectra on both seasonal and annual basis (Hocke *et al*., 2009). These spectra can be considered as representative of background emissions to be compared with much intense emissions taking place in shorter periods (few days to few weeks) during the year (Pavese *et al*., 2012).

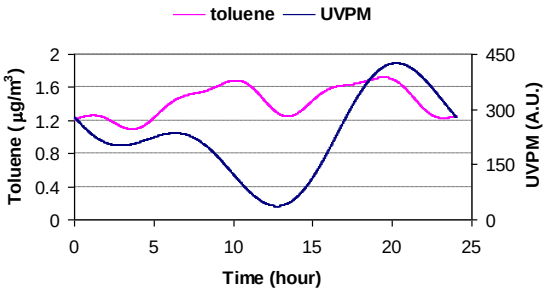

Figure 1: Reconstructed spectra of toluene and UVPM "typical day" as obtained by Lomb-Scargle periodogram for the two-year database.

As an example, reconstructed spectra of toluene and UVPM "typical day" from two-years concentrations data are shown in Figure 1. The differences observed can suggest different dynamics in aerosol formation and/or in adsorption processes onto atmospheric particles.

On the contrary, considering an episode of intense emissions (March, 8th- 19th 2011), UVPM and toluene time behaviours show similar patterns, as reported in Figure 2, highlighting the necessity to study emissions on different time-scales.

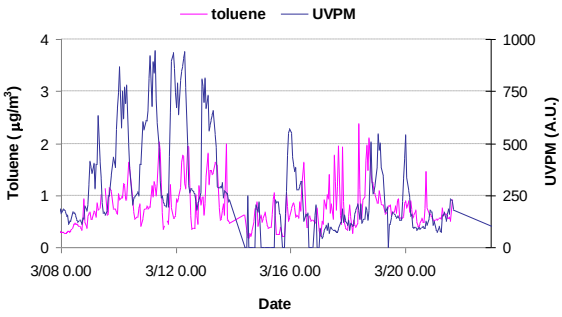

Figure 2: Temporal variation of toluene concentrations and UVPM hourly mean values for the period march 8th - 19th 2011.

To complete this study, an analysis of meteo-climatic parameters such as solar radiation, wind intensity and prevalent direction, has been carried out to verify if and when these parameters contribute to a major/minor agreement among combustion products time patterns.

This work was supported by "Osservatorio Ambientale della Val d'Agri" in the framework of the project "Integrated model for environmental matrix" and by ARPAB.

The Arctic and northern boreal regions of Eurasia are experiencing rapid environmental changes due to pressures by human activities. The Arctic environment is highly sensitive to changes in aerosol concentrations or composition, largely due to the high surface reflectance for the most part of the year. Secondary particle formation from atmospheric vapours is a mechanism, potentially affecting the aerosol particles, and the climate effects which follow, in these remote regions (e.g. Asmi et al., 2011). Direct measurements, especially in the Russian side of the Arctic, are though still lacking.

Tiksi meteorological observatory in northern Siberia (71°36´N; 128°53´E) on the shore of the Laptev Sea has been operating since 1930s. Recently, it was upgraded and joint in the network of the International Arctic Systems for Observing the Atmosphere (IASOA, www.IASOA.org), in the framework of the International Polar Year (IPY) Activity (#196) project. The project is run in collaboration between NOAA with the support of the NSF, Roshydromet (AARI and MGO units), government of the Republic of Sakha (Yakutia) and the FMI. FMI activities in Tiksi were initiated in summer 2010 and include aerosol size distribution measurements starting at 7 nm size. These are measured with a twin-DMPS system and here the data are used to pinpoint secondary particle formation events, as well as to tie them with meteorological and air mass properties.

In Figure 1, average concentration of nucleation mode (here: 7-25 nm) particles in each month is presented. It appears that the rise of sunlight in the month of March strongly assist secondary particle formation. With a snow covered ground in early spring, it is likely that the nucleating and condensing vapours are transported from longer distances. Another smaller peak in particle formation occurs in summer when local vegetation contributes as a source of vapours.

Analysis of air mass origin during the observed events supports the conclusions. During early spring, nucleation mode particles are increasingly seen in high Arctic air masses, while during summer, the small particles appear also in continental Siberian airflows.

A climate impact of the secondary particles is also studied. The preliminary results show that the particle growth rates are much higher in summer in comparison to other seasons, thereby allowing them to affect the climate more often. This is connected with vegetation sources of biogenic organic vapours, as seen with clear correlations with air mass origin and temperature (Fig. 2).

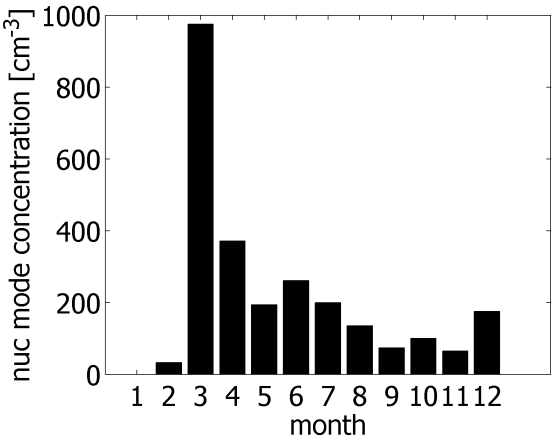

Figure 1. Average concentration of nucleation mode (7-25 nm) particles per each month.

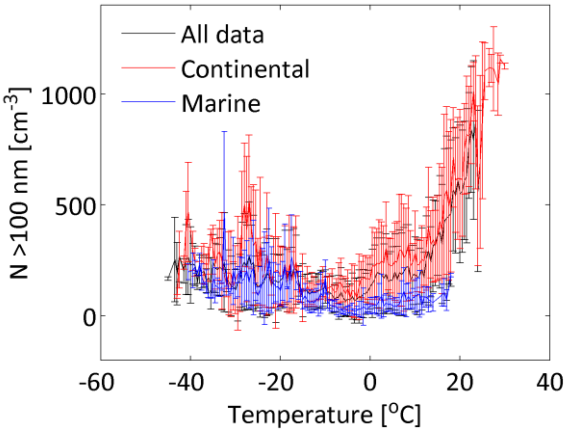

Figure 2. Accumulation mode (>100 nm) concentration as a function of temperature (black), and in continental (red) and marine (blue) air masses separately.

Events of new particle formation (NPF) in tropical boundary layer followed by consecutive growth towards Aitken mode size range are sparse compared to mid- latitudes Kulmala et al. (2004). This is also the case for rainforest environment. More often short episodes of elevated ultra-fine and Aitken mode aerosol particle concentrations are observed their origin and the processes governing these episodes do however remain unclear. Based on observations performed in the Amazonian rainforest environment combined with statistical analysis we present a mechanism explaining the erratic appearance of ultra-fine aerosol in tropical boundary layer of the rainforest.

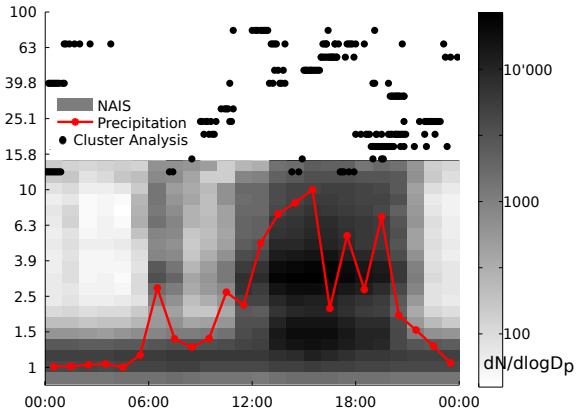

Figure 1: NAIS negative ion concentration 95th percentile diurnal pattern combined with cluster analysis method results (black dots). Mean values for precipitation are given in arbitrary units.

Abstract review

To observe any underlying ultra-fine particle processes we chose to look at the SMPS data and applied a statistical method based on kmeans cluster analysis technique. MacQueen (1967) has described kmeans cluster analysis in detail. Prior to our study cluster analysis has been implement in aerosol science for other purposes, such as principle meteorological component analysis in particle nucleation day classification (Hyvönen et al., 2005) and investigation of processes controlling the evolution of aerosol particle size distribution properties (Tunved et al., 2004). In this study we expand application of cluster analysis to a method that requires preliminary filtering and normalization of data. The introduced method allows for mining ultra fine particle statistics by analysing particle size distributions selectively.

Each scan was normalized to its maximum number concentration; thus, we are focusing on different shapes of particle size distributions instead of absolute number concentrations. Only size distributions having a local a maximum between 10 to 80 nm were considered further analysis. This was achieved by discarding size distributions whose second order derivative of number size distribution curve was greater than 0.

Diurnal occurrence cycle for the clusters reveals a pattern that we eventually compare to ion production by precipitation diurnal pattern. After ion production is stopped, 20 nm particle formation by self–coagulation estimates to 800 cm^{-3}.

Introduction

It is well known that atmospheric aerosols influence the Earth's climate directly by light scattering and indirectly by changing cloud properties. Atmospheric aerosols are either emitted directly to the atmosphere (primary sources such as sea spray, windblown dust, soot) or formed by gas-to-particle conversion (secondary sources such as nucleation). A recent study by Merikanto et al. (2009) indicates that up to 45% of **c**loud **c**ondensation **n**uclei (CCN) are formed by nucleation. Many nucleation events have been observed in the planetary boundary layer (e.g. Riipinen et al., 2007). However, only a few measurements have been carried out in the free troposphere (FT) (e.g. Weingartner et al., 1999; Boulon et al., 2010); hence our knowledge of aerosol nucleation in the FT is limited.

In January and February 2013 the **Nu**cleation, **Cl**oud and **A**erosol **C**haracterization **E**xperiment (NUCLACE) was conducted at the high alpine research station Jungfraujoch (JFJ) located in the lower FT at 3580 m asl. in the Swiss Alps. The goal was to characterize the properties of newly nucleated aerosol particles (i.e. their size, charge, nucleation and growth rates) and to understand their detailed formation mechanisms by measuring the prevailing precursor gas concentrations with state-of-the-art instrumentation.

Methods

For this purpose a nano scanning mobility particle sizer (nanoSMPS) and a condensation particle counter (CPC) were installed in the cupola of the Sphinx building on the JFJ. The nanoSMPS measured the number size distributions of particles with diameters D between 5 and 90 nm. The sampling was performed through the wall with a specific inlet (length = 40 cm, aerosol sampling flow 1 l/min, sampling line make up flow 8 l/min). The size spectra were corrected for CPC efficiency and diffusion losses in the sampling line. To avoid freezing of the inlet by supercooled cloud droplets a heating system was employed. An electrostatic precipitator was added to the sampling line to periodically remove all charged aerosols up to 120 nm. With this setup the total and neutral particle size distributions were measured with a time resolution of 200 s and the size dependent charged fraction was calculated.

In addition, two chemical ionization atmospheric pressure interface time of flight mass spectrometer (CI-APi-TOF, Jokinen et al 2012) were employed to measure neutral clusters in the gas phase, and two atmospheric pressure interface time of flight mass spectrometers (APi-TOF, Junninen 2010) measured the composition of charged clusters (positive and negative).

First Results

A number of nucleation events were observed. Nucleation mostly occurred at very low ambient temperatures (around -30°C) and was often related to the disappearance of clouds that were present at the station. Figure 1 shows such a typical nucleation event, where the particles grew to D = ~20 nm. This event shortly occurred after the clouds vanished around 12:00. Future data analysis will also include the measured precursor gas concentrations.

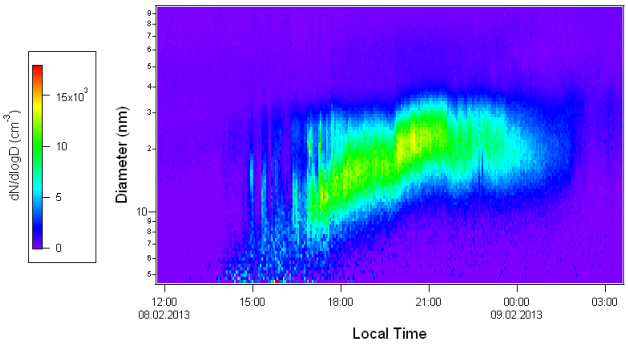

Figure 1. Evolution of particle number size distributions during a nucleation event in the free troposphere.

Enhancement in CCN concentrations during new particle formation events

Z.J. Wu[1], W. Birmili[1], L. Poulain[1], Z.B. Wang[1], A. Hamed[1,2], S. Henning[1], F. Stratmann[1], H. Herrmann[1], A. Wiedensohler[1]

Presenting author email: wuzhijun@tropos.de

New particle formation (NPF) events are an important source of cloud condensation nuclei (CCN). However, the contribution of atmospheric NPF events to the global CCN budget remains the single largest uncertainty (Kerminen, et al., 2012). Therefore, information on mechanisms and the vapors responsible for NPF and growth would be needed for accurate prediction of CCN in order to realistically capture aerosol radiative effects. In our study, we investigate the effects of particle formation and growth and chemical ageing of pre-existing particles on CCN number concentration during the NPF events based on the observations made at a central Europe research station, Melpitz, Germany.

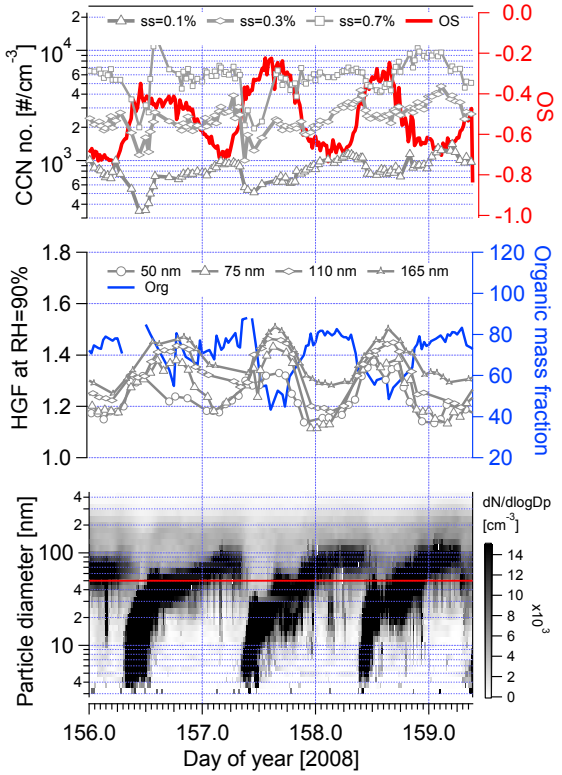

Fig. 1: Time series of different parameters during NPF events. The detail description is given in the text.

Investigations of the contribution of NPF on CCN concentrations are based on the size-resolved chemical composition (AMS), particle hygroscopic growth factor (HGF), particle number size distributions, sulfuric acid [H_2SO_4] and OH radical concentrations at Melpitz in 2008. The NPF bursts and continuous growth were continuously observed (Fig.1.). As a first step, the critical diameter (D_{crit}) at which 50% of the particles were activated was calculated from κ:

$$D_{crit} = \left(\frac{4A^3}{27\kappa \ln^2 S_C}\right)^{1/3}$$ (Petters and Kreidenweis, 2007)

Here, κ is calculated from size-resolved AMS data using the ZSR mixing rule.Secondly, the number concentration of potential CCN is derived by integrating the number size distribution of particles larger than D_{crit}. The oxidation state (OS) was calculated from AMS data according to Kroll et al, (2011) for the whole size range (PM1). The organic mass fraction was taken in the size range 50-200 nm (mobility diameter).

Comparing the increase of CCN number concentrations at the start time of the NPF bursts (B in table 1) and at the end time of NPF bursts (E in the table 1) shows that on average, the CCN number concentrations are enhanced by the factors of two between the beginnings and the end of NPF events. However, the increments are varied with varied super saturation values (SS). (See Table 1)

Table 1: Comparisons in CCN number concentrations (unit: /cm^3) before and after NPF events.

SS	0.1%		0.3%		0.7%	
DOY	B	E	B	E	B	E
157	419	913	1510	2696	2923	5982
158	542	1054	1313	3798	2298	6508
159	800	1277	2592	3651	4941	6794

As shown in Fig. 1, the HGF of 50-165 nm particles increased from 1.2 to 1.5 during NPF event. This is most likely due to that pre-existing particle gets aged quickly in a photochemically active environment associating with NPF. Both condensation of H_2SO_4 and aging of organic fraction (as indicating by increase in OS) could lead to increase in particle hygroscopicity. Correspondingly, their ability to act as CCN enhanced even though the NPF did not grow to CCN size during this timeframe. During nighttime, particles grew quickly due to condensation of organic vapors. At the same, the particle HGF declined significantly. As consequence, the ability of particles acting as CCN activity decreased significantly. Typically H_2SO_4 concentration is close zero during nighttime. Thus, the semi-volatile organic condensation plays a key role in particle growth. More organics condensed onto newly formed CCN-sized particles and higher supersaturations are needed to activate particles with the same size. This process weakened the contribution of NPF to CCN. But, the net effect leads to increase in CCN concentration, as listed in Table 1. More analysis for a longer-data set at Melpitz site, are ongoing and will be discussed in our presentation. *Petters, M.D. and Kreidenweis, S.M. (2007). Atmos.Chem. Over the continents, we are familiar with frequent formation of new nanometer-sized particles in the atmosphere, called "new particle formation" (NPF) (Kulmala et al., 2004). After subsequent condensation growth, the nanoparticles become large enough to be optically active and to impact on cloud formation, and thereby climate. In the marine boundary layer of pristine oceans, NPF events are not frequent (Pirjola et al., 2000). In the NanoShip project we investigate for the first time whether NPF events take place in a polluted marine boundary layer, like the North Sea considering ship traffic being the source for relevant precursors involved in the NPF.

During the NanoShip project, particle number size distribution measurements were carried out at a marine site (Høvsøre) at the Danish peninsula Jutland during 2012 to investigate the link between formation events and winds from the North Sea. Also archived data from the Norwegian and Dutch EUSAAR sites Birkenes and Cabauw were used to infer the appearance and frequency of formation events during conditions with winds from south-east and north-west, respectively.

We can infer where the formation of 1.5 nm diameter particles takes place by using the particle number size distribution data from Høvsøre and meteorological back trajectories according to the NanoMap method described by Johansson et al. (2012).

The NanoMap method can basically be described as follows (example): We hypothetically see that formation of 1.5 nm diameter particles is taking place between 10:00 and 12:00 am at Høvsøre, and that these particles grow to 30 nm in diameter after 7 to 9 hours. Hence, the 30 nm particles that we observe at Høvsøre in the evening have been formed 7 to 9 hours ago upwind of the site. With the back trajectories we trace the air back to when the particles were formed as 1.5 nm diameter particles somewhere over the North Sea.

In total, 82 days were classified according to the Dal Maso et al. (2005) classification, and during 41 % of these days there was a NPF event, and 17% of the days were a type 1 event. Only type 1 events were used in the NanoMap analysis. Figure 1 shows the location of particles with predicted diameters of 1.5 nm (preliminary results) from the NanoMap analysis for the 14 days with type 1 NPF events at Høvsøre.

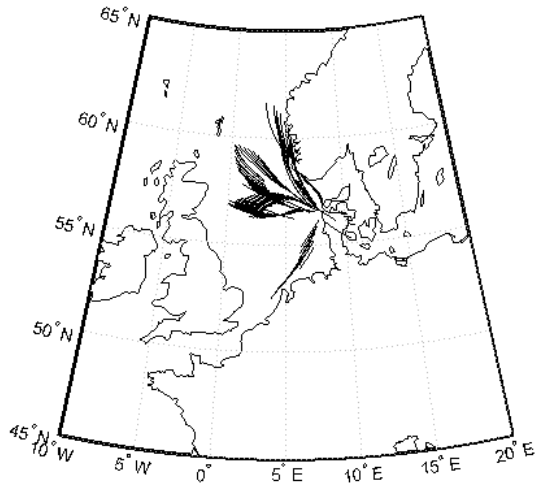

Figure 1. The location of new particle formation of 1.5 nm diameter particles (black lines) according to the NanoMap method and particle number size distribution data recorded at Høvsøre (56°27' E, 8°09' N, 2 m a.s.l).

We can conclude that NPF events are taking place frequently over the North Sea. The favourable conditions are preferably when we have cyclonic, low pressure air masses reaching the Danish marine site.

At the EAC conference, we intend to present in addition, an analysis of EMEP emission maps, aerosol condensation sinks, and if certain meteorological conditions or aerosol sources, like shipping are favouring the NPF over the North Sea.

The planetary boundary layer (PBL) is chemically and physically the most dynamic part of the atmosphere as it has high loading of aerosol particles and their gaseous precursors. Secondary formation of atmospheric aerosol particles, so-called new particle formation (NPF), is believed to be the dominant source of aerosol particles in the atmosphere. Nucleation is a process of gas-to-particle conversion, beginning with a few gas molecules colliding to form a cluster of 1-2 nm in diameter (Kulmala et al. 2013). This first step of NPF is followed by the growth of the newly formed particles.

At this moment, the mechanisms of particle formation and the vapors participating in this process are not truly understood. Especially, in which part of the atmosphere the NPF takes place, is still an open question. To detect directly the very first steps of NPF in the atmosphere, we measured these chemical and physical processes within the PBL (altitudes up to 1 km). We used airborne Zeppelin measurements and ground based in-situ measurements. Using Zeppelin, we focused on the time of the development of the PBL from sunrise until noon to measure vertical profiles of aerosol particles and chemical compounds.

We have measured the vertical and the horizontal extension for NPF events using an instrumented airship, Zeppelin. The vertical profile measurements represent the particle and gas concentrations in the lower parts of the atmoshere: the residual layer, the nocturnal boundary layer, and the PBL. At the same time, the ground based measurements records present conditions in the surface layer. Horizontal, almost Lagrangian, experiments are possible as the airship drifts with the air mass.

The key instruments to measure the onset of NPF were Atmospheric Pressure interface Time-Of-Flight mass spectrometer (APi-TOF, Junninen et al. 2010), a Particle Size Magnifier (PSM, Vanhanen et al. 2011), and a Neutral cluster and Air Ion Spectrometer (NAIS, Mirme and Mirme, 2011). These instruments are able to measure particles at the size range ~1-2 nm where atmospheric nucleation and cluster activation takes place (Kulmala et al. 2013). The high time resolution of the instruments allowed us to observe the starting time of the NPF events. In addition, particle number size distributions from 1 nm to 1 µm, and concentration of NO, NO_x, O_3, CO, OH, HO_2, and lifetime of OH were measured, as well as meteorological parameters.

On June 2012, Zeppelin was measuring nucleation occuring in the Po Valley area, Nothern Italy, especially over the San Pietro Capofiume (SPC) field site. The newly formed particles were observed some hours after sunrise at ground level in SPC. The onset of NPF was usually observed onboard Zeppelin when it was measuring inside the rising mixed layer which is connected to the surface layer by effective vertical mixing. This observation suggests that the onset of NPF starts in the surface layer, and not in nocturnal boundary layer nor inside the residual layer. The newly formed, subsequently growing, particles were observed to be homogeneously distributed inside the mixed layer.

These measurements are part of the PEGASOS project which aims to quantify the magnitude of regional to global feedbacks between the atmospheric chemistry and physics, and thus quantify the changing climate. The Zeppelin flights are observing radicals, trace gases, and aerosols inside the lower troposphere over Europe. The main nucleation campaigns were performed in Po Valley (summer 2012), and Hyytiälä, Southern Finland (spring 2013). The results will support the numerical air-quality and climate modelling.

This research is supported by European Commission under the Framework Programme 7 (FP7-ENV-2010-265148), the Academy of Finland Centre of Excellence program (project no. 1118615) and the Finnish Cultural Foundation. The Zeppelin is accompanied by an international team of scientists and technicians who are all acknowledged.

Events of increased particle number concentrations around trade wind cumuli near Barbados

B. Wehner[1], F. Ditas[1], A. Wiedensohler[1] and H. Siebert[1]

[1]Leibniz Institute for Tropospheric Research (TROPOS), 04318 Leipzig, Germany
Keywords: new particle formation, clouds, ultrafine particles.
Presenting author email: birgit@tropos.de

Beside numerous measurements at ground-based stations, new particle formation has been occasionally observed in higher altitudes of the troposphere. However, such measurements are rare and thus the relevant processes and meteorological conditions under which particle formation and growth occur are still not completely understood.

In November 2010 and April 2011 the CARRIBA (**C**loud, **A**erosol, **R**adiation, and Tu**R**bulence in the trade w**I**nd regime over **BA**rbados) campaign (Siebert et al., 2012) has been performed to observe the role of aerosol particles within the life cycle of trade wind cumuli. During these campaigns more than 30 research flights using the helicopter-borne platform ACTOS (Airborne Cloud and Turbulence Observation System) have been done. For measuring aerosol particles a new FastCPC (Wehner et al., 2011) has been implemented on ACTOS to measure the total particle number concentration *N* with a time resolution of 10 Hz. The aerosol particle number size distribution from 6 nm to 2.5 µm was measured using an SMPS (designed by TROPOS) and an OPC (Model 1.129, Grimm Aerosol Technik, Ainring, Germany). Furthermore, ACTOS contains various instruments to measure cloud properties and thermodynamic parameters, such as temperature, humidity and wind vector.

Results & Discussion

The flight pattern of the individual flights started usually with a vertical profile over the sea east of the island of Barbados. After that ACTOS was usually carried to a field of shallow cumuli with typical cloud cover of 10 to 30%.

During individual flights, *N* was nearly constant around clouds about a few hundred cm^{-3}. During approximately 70 % of all flights one or more events with significantly increased (more than a factor of 5) values of *N* have been observed. These events were often connected to clouds, i.e. the number concentration increased close to cloud edges. However, in a few cases there was no cloud influence visible.

Figure 1 shows an example for increased particle number concentrations near cumulus clouds. The liquid water content (LWC) is used as cloud indicator. Here, the background value of *N* is around 300 cm^{-3}, while some peaks reach values above 4000 cm^{-3} near a cloud. Anthropogenic pollution as particle source can be excluded because the concentration of CO_2 did not show any increase in these regions.

Figure 1 shows no obvious correlation between specific humidity *r* or vertical wind speed *w* and observed increased particle number concentration. This is similar to most other cases and a more detailed analysis needs to be done.

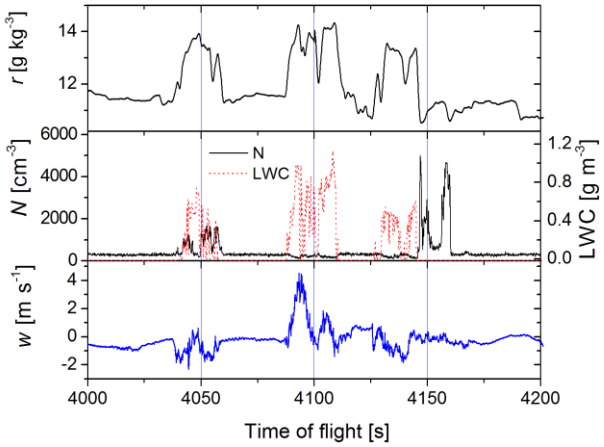

Figure 1. Time series of specific humidity *r*, total particle number concentration *N*, liquid water content LWC, and vertical wind speed *w*.

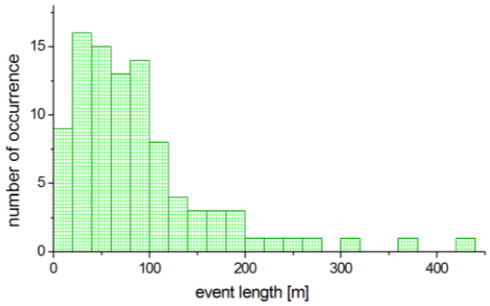

Figure 2. Length of events of increased *N*.

After a quality check, 95 events of increased particle number concentrations have been detected. Most of them occur close to cloud edges (~95%) others without any cloud nearby. More than 50% of them lasted between 1 and 5 s corresponding to a horizontal extension between 20 and 100 m. The detection of such small regions was possible due to the combination of the low true airspeed of 20 m/s and the fast measuring instrumentation. The implication of such particle bursts for further cloud development is not yet fully understood. In conclusion, the cloud system does not only act as a particle sink for CCN but also as a particle source. The relevance of new particle formation for the particle balance in general will be part of an on-going discussion.

Fine aerosol particles have been studied in the last years due to their important role in several atmospheric processes and effects on climate and human health. New particle formation events are observed all over the world both in polluted and clean, background air. Similarly, in Hungary NPF events can be detected in polluted cities like Budapest (Salma *et al* (2011), Borsós *et al* (2012)) as well as in rural air at K-puszta (Yli-Juuti *et al* (2009)). Our former results showed that at K-puszta new particle formation (NPF) can be frequently observed, the number of NPF events peaked in spring and autumn (September) per each year.

In this work we summarize our results on the particle formation at K-puszta station between Nov. 2008 and Dec. 2012. The size distribution of the particles between 3-800 nm is evaluated. On the basis of DMPS spectra the classification of particle formation events is carried out according to the recommendations of Yli-Juuti *et al* (2009). The event classification is studied with respect to the seasonal variation and the frequency of the particle formation event types (event, non-event and unclassified) is also discussed.

Figure 1. Event classification statistics (2012), K-puszta.

Generally, our four year statistics on new particle formation (NPF) shows that winter is the most inactive period. In contrast the number of NPF events was found to be the highest in spring and in autumn as presented for 2012 (Figure 1). As a consequence of the above-mentioned seasonal variation of the NPF events, the frequency of the nucleation mode (3-25 nm) was the highest during spring and autumn (Figure 2). On the other hand, in winter the accumulation mode (100-800 nm) showed the highest, while in spring and summer the lowest frequency. This seasonality is also shown by the "typical" seasonal number size distributions. This means that in spring the freshly formed particles, while in winter the aged particles characterize the aerosol size distribution.

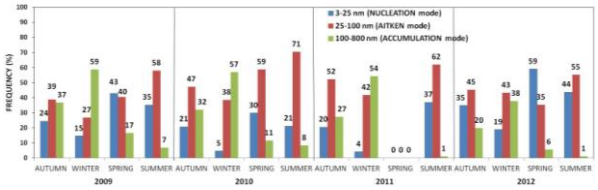

Figure 2. The seasonal frequency of the maximum concentrations in different particle modes (2009-2012).

The growth rate (GR) of the freshly formed particles is also calculated (Hirsikko *et al* (2005), Yli-Juuti *et al* (2009)). Our results on four-year data showed the high variability of particle GR with no significant seasonal variation at K-puszta. The rates were estimated between a few and 14 $nmhr^{-1}$ except some days with higher GR (between 16.5-18.41 $nmhr^{-1}$). The average GR was 5.85 $nmhr^{-1}$. On the other hand, the formation intensity of new nucleation mode particles (smaller than 25 nm) is also estimated. The calculation is based on the method considering the change of the particle number concentration in each size modes per unit time. The average formation rate for 10 nm particle size range was found between 0.33-46.31 particles $cm^{-3}sec^{-1}$.

The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement n° [262254], [ACTRIS]; and TÁMOP-4.2.2.A-11/1/KONV-2012-0064 (The project is realized with the support of the European Union, with the co-funding of the European Social Fund).

Keywords: wood burning, organic aerosol, black carbon, smog chamber.
Presenting author email: emily.bruns@psi.ch

Complete aerosol characterization is critical to understand aerosol influences on climate, air quality and health. Domestic wood burning is a significant source of atmospheric aerosols (Lanz et al., 2010), particularly in the winter, as it is a common heating method. Nevertheless, uncertainties remain in the magnitude and characteristics of wood burning emissions, including their chemical composition and optical properties.

In addition to directly emitted primary emissions, previous laboratory experiments have shown that oxidation of gas phase biomass emissions produces compounds with sufficiently low volatility to readily partition to the particles to form secondary organic aerosol (SOA). However, the total organic aerosol mass (OM) formed relative to black carbon (BC) tends to be lower than that observed in the atmosphere from biomass burning (Grieshop et al., 2009a,b; Heringa et al., 2011). This may be because previous laboratory studies were conducted at higher-than-ambient winter temperatures. This may affect both burner operation and gas/particle partitioning of semi-volatile organic aerosol, both of which may affect aerosol composition and loading.

We report results from experiments characterizing primary and secondary wood burning emissions performed at representative winter temperatures for the first time using a newly designed smog chamber capable of conducting photochemical experiments at low temperatures. Primary wood burning emissions were diluted to atmospherically-relevant concentrations (~5-120 μg/m^3) and injected into the chamber (7 m^3) using a heated inlet system. Formation and aging of secondary products was initiated by OH photochemistry. The effects of temperature and humidity were studied by performing experiments at 263 K and 288 K and at 50% and 90% relative humidity. The effect of wood loading in the stove was also studied.

Chemical composition and quantification of the non-refractory aerosol fraction was determined by high resolution aerosol mass spectrometry. Aethalometers were utilized with and without a thermal desorber to quantify BC and to examine the effects of organic coatings on BC optical properties. Measurements of gas phase species were made with a suite of instruments, including a proton transfer reaction mass spectrometer, to gain insight into the partitioning of compounds between the gas phase and particles with aging.

Conducting experiments at 263 K resulted in higher OM/BC ratios for the primary emissions (1.5-14) compared to experiments at 288 K (0.3-0.8) and better agreement with ambient measurements (OM/BC~7-19). (Szidat et al., 2006 and references within; Gianini et al., 2012). Also, lower temperatures enhanced the SOA/BC ratios. (Figure 1)

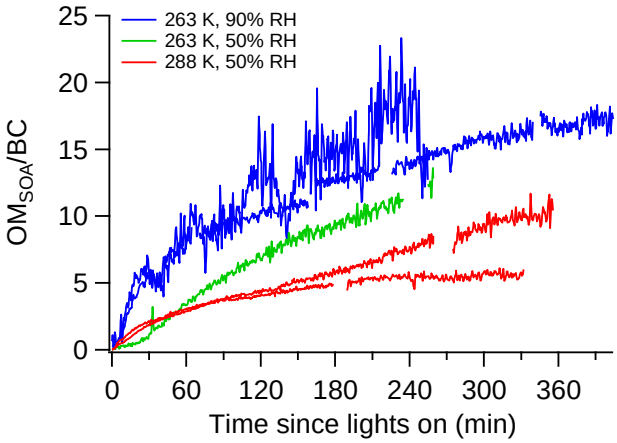

Figure 1. The ratio of SOA to BC during aging as a function of temperature and relative humidity.

These results are important in reconciling discrepancies between field and laboratory measurements. Total hydrocarbon and OH exposure will allow for consistent comparisons between experiments.

High fuel loading was found to generate significantly more polycyclic aromatic hydrocarbon (PAH) compared to average loadings and to produce considerable amounts of SOA after oxidative aging. As PAHs and their oxidation products are known to have deleterious effects on health, this is a significant finding to aid in the mitigation of negative wood burning impacts by improving burner operation protocols.

This work was supported by the PSI-FELLOW/COFUND program, the Competence Center Environment and Sustainability of the ETH Domain and the Swiss National Science Foundation.

Keywords: methoxyphenols, OH reaction, rate coefficient, SOA.
Presenting author email: amelie.lauraguais@univ-littoral.fr

Methoxyphenols are low molecular weight semi-volatile polar aromatic compounds produced from the pyrolysis of wood lignin.

The atmospheric reactivity of methoxyphenols (2-methoxyphenol or guaiacol, 3-methoxyphenol, 4-methoxyphenol, 2-methoxy-4-methylphenol and 2,6-dimethoxyphenol or syringol) with hydroxyl radical has been studied in a simulation chamber (8 m^3) at 294 ± 2 K, atmospheric pressure and dry conditions (RH < 1%).

Their OH rate coefficients, determined using the relative kinetic method, are summarized in table 1 together with their atmospheric lifetime. The atmospheric lifetime of methoxyphenols is around 2 hours, indicating that they are too reactive to be considered as stable tracers for wood smoke emissions.

In the discussion, the reactivity of methoxyphenols will be compared with other substituted aromatics and interpreted in relation to the type, number, and positions of the different substituents on the aromatic ring.

Table 1. Rate coefficients for methoxyphenol reaction with OH radicals (at 294 ± 2 K) and associated atmospheric lifetimes.

Compound	k_{OH} [a]	τ_{OH} [b]	Reference
2-methoxyphenol (guaiacol)	7.53 ± 0.41	2.3	Coeur *et al.* (2010)
3-methoxyphenol	9.80 ± 0.46	1.8	Coeur *et al.* (2010)
4-methoxyphenol	9.50 ± 0.55	1.8	Coeur *et al.* (2010)
2-methoxy-4-methylphenol	9.45 ± 0.59	1.8	Coeur *et al.* (2010)
2,6-dimethoxyphenol (syringol)	9.66 ± 1.11	1.8	Lauraguais *et al.* (2012)

[a] Units of 10^{-11} cm^3 $molecule^{-1}$ s^{-1}.
[b] Units of hour. $\tau_{OH} = 1/k_{OH}[OH]$, where 12 hour daily average [OH] = 1.6×10^6 molecule cm^{-3}.

Secondary organic aerosol formation from the OH reaction with guaiacol and syringol was also investigated under high NO_x conditions. The aerosol production was monitored using a SMPS (Scanning Mobility Particle Sizer). The SOA yields (Y) were determined as the ratio of the suspended aerosol mass corrected for wall losses (M_0) to the total reacted methoxyphenol concentration assuming a particle density of 1.4 g cm^{-3}. For guaiacol and syringol, particle formation was observed in the first few minutes of the reaction, with a very fast increase in the particle number concentration followed by a gradual decrease over the course of the experiment (Fig. 1).

The SOA yields were in the range 0.10-0.36 and 0.003-0.87 for syringol and guaiacol, respectively. Syringol SOA yields were lower than those of guaiacol, likely due to novel methoxy group chemistry that leads to early fragmentation in the gas-phase photooxidation (Yee *et al.*, 2013).

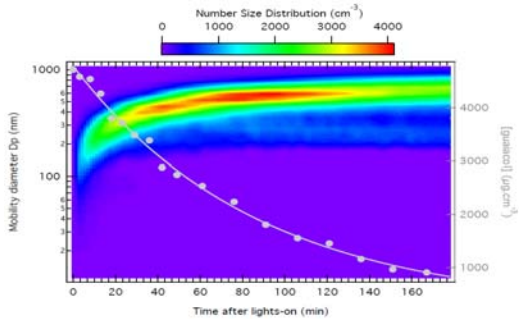

Figure 1. Typical concentration-time profiles for guaiacol and SOA (number-weighted size distribution) from a guaiacol/OH experiment.

SOA formed from the OH reaction with guaiacol have been characterized: 4-nitroguaiacol and 5-nitroguaiacol were clearly identified by GC/MS (Gas Chromatography/Mass Spectrometry), indicating that these compounds may be used as biomass burning aerosol tracers. Complementary analyses were also performed by Transmission (TEM) and Scanning (SEM) Electronic Microscopy: the corresponding pictures show that SOA are in an amorphous state which suggests the formation of oligomers.

Particle-bound Methoxyphenols and their atmospheric nitration products as wood combustion tracers

J. Orasche[1, 2, 3], J. Schnelle-Kreis[1], G. Abbaszade[1, 3], M. Elsasser[1, 2], R. Zimmermann[1, 2, 3]

Keywords: Methoxyphenols, NO_3-radicals, wood smoke, particulate matter
Presenting author email: juergen.orasche@helmholtz-muenchen.de

In many countries all over the world generation of heating energy wood is still the major source for heating and cooking or has even started a renaissance, respectively. The application of wood is quite cheap but enforces environmental problems and health risks. This indicates, that the question of the linkage between Environment and Health, due to economical reasons, more and more becomes a question of the linkage between Energy and Health.

For elucidation and validation of air polluters, responsible sources must be well indicated by suitable source tracer compounds. Since most of the emitted compounds from wood combustion are highly degradable within the atmosphere, it is worth to examine their atmospheric reaction products, too. Therefore we investigated on methoxyphenols and their reaction products with NO_3-radicals. In a winter sampling campaign in the city of Augsburg, Germany, methoxyphenols and their related products were monitored by high resolution PM_1 filter sampling. By hourly filter changing 24 samples were collected a day. Filters were analyzed with a highly sensitive insitu-derivatization-thermal-desorption gas-chromatography time-of-flight-mass-spectrometry method (IDTD-GC-TOFMS) (Orasche et al. 2011). One step before methoxyphenols were well identified by emission measurements at different combustion conditions within a dilution sampling set-up (e. g. Orasche et al. 2013).

As described by Liu et al. (2012) for reaction chamber experiments a clear dependency of nitration products to NO_3-radicals can be observed. The NO_3 concentrations were related to the increasing NO_x-concentrations during the night time due to missing photo-oxidation-reactions. Figure 1 visualize this relationship between NO_2 and Hydroxynitrobenzene. The rise of concentrations takes place one to two hours later than increase of those of the precursors. Figure 2 shows the correlation between syringaldehyde and 2,6-Dimethoxynitrophenol. It indicates that an additional reaction pathway of syringaldehyde has to be discussed.

The results are indicating that in future source apportionment studies stable secondary organic aerosols (SOA) should be involved to avoid underestimation of specific sources. Moreover the health effects of compounds like the nitrated methoxyphenols have to be investigated carefully.

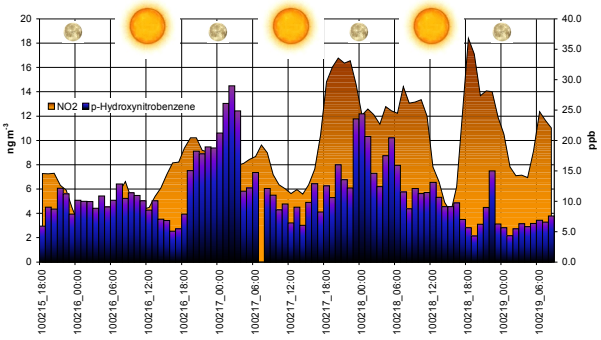

Figure 1. The relationship of p-Hydroxynitrobenzene and NO_2 during day- and night-time.

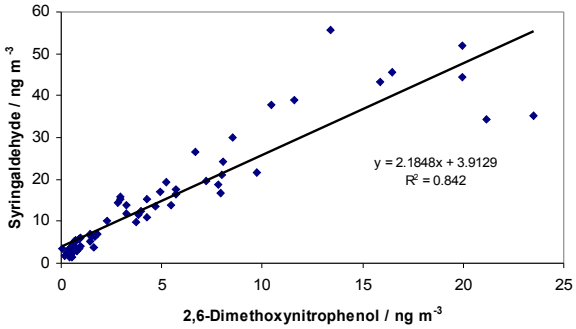

Figure 2. Correlation between Syringaldehyde and 2,6-Dimethoxynitrophenol.

[#]Presenting author email: lakeli@ust.hk; [*]Corresponding author email: keckchan@ust.hk

Aqueous-phase reactions of organic compounds are an important source of secondary organic aerosol (SOA) (Ervens 2011). Previous laboratory studies focused mostly on small aldehydes such as glyoxal (De Haan 2009; Tan 2009) as precursors, and recently on pinene oxidation products (Lee 2011).

Here we showed experimental results of aqueous-phase reactions of a semi-volatile and slightly water soluble methoxy-phenol from biomass burning, vanillin ($C_8H_8O_3$). Reactions were performed in a vessel (Lee 2011) with UV (254 nm) irradiation under two conditions: (1) photochemical oxidation with H_2O_2 as an OH radical source; and (2) direct photolysis without H_2O_2 added. Solution of the resulted products, as well as the ammonium sulfate added (Lee 2011), was atomized continuously and dried before on-line analyses. An Aerodyne High-resolution Time-of-Flight Aerosol Mass Spectrometer (HR-ToF-AMS) was used to measure the dried particle compositions, and a Hygroscopic Tandem Differential Mobility Analyzer (HTDMA) and a Cloud Condensation Nuclei counter (CCNc) were used to determine the particle growth factor and CCN activity respectively.

Prior to UV irradiation, most of vanillin evaporated to the gas phase during drying and gave negligible organic mass in particles (Figure 1, before time < 0 min). A large amount of SOA was formed and retained after reactions under both conditions, although products might be different under these two conditions according to HR-ToF-AMS characterization (Figure 1). Off-line analyses by liquid chromatography-mass spectrometry (LC-MS) and derivatization prior to gas chromatography-mass spectrometry (GC-MS) also confirmed that the product identities from these two conditions are different. Organic mass first increased rapidly and then decreased under condition (1), but kept increasing slowly under condition (2), as shown in Figure 1A and 1C, respectively. It was found that the degree of oxygenation of products from condition (1) first increased and then decreased, suggesting a competition between functionalization and fragmentation (Kroll 2009; Lee 2011), while it kept decreasing under condition (2). Hygroscopic behavior and CCN activity of ammonium sulfate decreased substantially with the organic products retained in the particles. The resolved growth factor of organics correlated with the increase of degree of oxygenation (O:C ratio) of organics formed.

Our results suggest that aqueous-phase reactions of methoxy-phenolic compounds from biomass burning can retain this portion of carbon mass in the particle phase even after extensive drying/dilution processes. This portion of carbon mass, once retained, significantly alters the particle hygroscopicity and CCN activity, which is not being considered in current climatic and visibility models.

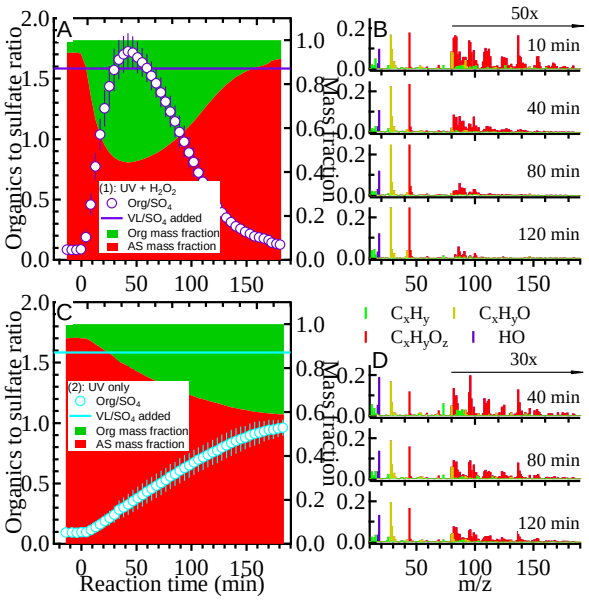

Figure 1. Changes of organic to sulfate ratio, organic mass fraction, and mass spectral feature during reactions under conditions (1) (A and B) and (2) (C and D).

Keywords: aqueous phase atmospheric chemistry, biomass burning aerosol, guaiacol, secondary organic aerosol
Presenting author email: irena.grgic@ki.si

Secondary organic aerosol (SOA) formed through the gas-phase oxidation of volatile organic compounds (VOCs) and further gas-to-particle partitioning cannot explain the gap between atmospheric observations and model predictions of organic aerosols (Heald *et al*., 2005). However, there is growing evidence that reactions in atmospheric waters may represent an additional and important source of SOA (Lim *et al*., 2010). Formation of low-volatility products in the aqueous phase has been observed during reactions of carbonyl and monoaromatic compounds found in the atmosphere (Ervens *et al*., 2011; Sun *et al*., 2010).

Monoaromatic compounds can be considered as a proxy for anthropogenic and biomass burning emissions. Methyl-nitrocatechols have been identified as an important class of SOA compounds from biomass burning and proposed as suitable tracers (Iinuma *et al.*, 2010; Kitanovski *et al*., 2012). In addition to nitro-catechols, other nitro-aromatics were determined in urban winter aerosols (Fig. 1), and constitute nearly 1% of the organic carbon (Kitanovski *et al*., 2012). A noticeable unknown peak consistent with a nitroguaiacol isomer was also detected in the latter study.

In the present study, the formation of SOA through aqueous-phase photooxidation (and nitration) of guaiacol (2-methoxyphenol), known to be emitted upon biomass burning, was studied. The main objectives were to chemical characterize the low-volatility products and examine their possible presence in ambient aerosols.

The aqueous phase reactions were performed in a thermostated reactor under well-defined experimental conditions. A solution of guaiacol was exposed to simulated sunlight (Xenon lamp, 300 W) in the presence of H_2O_2 (source of OH radicals) and NO_2^-. After isolation of the main reaction products by solid-phase extraction (SPE), their chemical structures were elucidated. To this aim, the SPE extract was first subjected to semi-preparative liquid chromatography, after which the main products were fractionated and isolated. Nuclear magnetic resonance spectroscopy (NMR) and liquid chromatography/negative ion electro-spray ionization tandem mass spectrometry (LC/(−)ESI-MS/MS) were used for structural elucidation.

The main products of guaiacol photooxidation and nitration are two nitroguaiacols (4-nitroguaiacol, 4NG; and 6-nitroguaiacol, 6NG) and one dinitroguaiacol (4,6-dinitroguaiacol, 4,6DNG). In addition, several minor phenolic oxidation products and oligomers of guaiacol and nitroguaiacol were formed. Using the isolated compounds as standards, several guaiacol products were identified in ambient PM10 from the city of Ljubljana (Slovenia) by means of LC/(−)ESI-MS/MS.

Photosensitized reactions at the air-sea interface: a potential source of aerosol

R. Ciuraru, F. Bernard, S. Rossignol, L. Fine, C. George

Université de Lyon, Université Lyon 1, CNRS, UMR5256, IRCELYON, Institut de recherches sur la catalyse et l'environnement de Lyon, Villeurbanne, F-69626, France
FranceKeywords: multiphase chemistry, sea-surface microlayer, volatile organic compounds
Presenting author email: raluca.ciuraru@ircelyon.univ-lyon1.fr

The sea surface microlayer is the organic-enriched layer present at the air-sea interface which has different physical and chemical properties compared to subsurface waters. The chemical analysis of this microlayer is of great interest for many reasons including its major influence to reduce air–sea gas exchange by impeding molecular diffusion across the interface and by influencing the characteristics of water motion at the interface. Surface seawater contains a variety of substances which act as photosensitizers. They include components of the dissolved organic matter known also as humic acids. The sea surface microlayer is the primary recipient of the solar energy. Since the microlayer is enriched in chemicals and biota, a number of processes are likely to be more effective here than in the rest of the water column. These include changes in the chemical composition of the living cells of phytoplankton and the photodegradation of organic matter.

The focus of this study is to determine if the organic film acts as a hydrophobic barrier for the air-sea gas exchange and to identify and characterize the gaseous emissions and aerosol formation from the surface due to the photochemical processing of the sea surface microlayer. For this purpose, synthetic aqueous mixtures of NaCl, NaBr, NaI, photosensitizers (humic acids) containing an organic surfactant (hexanol, octanol, nonanoic acid) have been irradiated by means of a Xe lamp in a small Quartz cell. Potential gaseous products arising from this interfacial chemistry have been identified using a High Resolution Proton Transfer Reaction – Time of Flight Mass Spectrometer.

It has been observed that the presence of a thick organic film on the salt solutions reduces the transfer from the aqueous solution to the gas phase.

Experiments with an organic monolayer coverage at the air / interface led to the formation of a variety of gaseous aldehydes (heptanal, octanal, nonanal, nonenal), alkenes and –dienes (butene, 5-methyl-1, 4-hexadiene) . All these compounds were confirmed by GC/MS analysis. A formation of methylglyoxal and acetylacetone has also been detected. Surprisingly, isoprene formation was also observed under irradiation. Isoprene is being made possible by a specific chemistry occurring solely at the air/water interface and the corresponding mechanism will be presented.

Experiments were also performed with benzophenone, imidazole and 2-imidazolecarboxyaldehyde as photosensitizers and the results will be discussed.

Furthermore, experimental studies in a $2m^3$ multiphase atmospheric simulation chamber will be presented. In this experimental approach, natural or artificial sea water containing a surfactant and a photosensitizer can be irradiated by UV/VIS lamps. But this tool is especially designed to follow the aerosol formation potential of the above mentioned photosensitized reactions at the air/water interface.

Indeed, the photochemical processing of the microlayer will lead to the emission of a series of functionalized VOC which will be measured using a PTR-ToF MS and a GC/MS. The chemical processing of a large subset of these VOCs will lead to the formation of Secondary Organic Aerosols. The physical and chemical properties of these particles will be monitored and characterized by means of a SMPS and an Orbitrap LC/MS measurements.

These results highlight the presence of an undocumented chemistry at the air/water interface having a real potential of affecting the budget of VOCs and SOA loading in the marine boundary layer.

Black Carbon Containing Particles at a Rural Site Southeast of London: ClearfLo Winter IOP Detling Site

Clean Air for London (ClearfLo) is a large, multidisciplinary study of the London urban atmosphere aimed at understanding the relationships between surface meteorology, gas-phase composition and particulate matter at a city street site, a city background site (away from local traffic sources) and at rural locations that sample the outflow from the London urban area. During the winter intensive (January to February, 2012) we deployed a suite of instruments at a rural site southeast of London in Detling, UK.

Data were collected through several co-located inlets mounted on a 9 m tower. Real-time particle instruments included an Aerodyne high-resolution time-of-flight mass spectrometer (HR-AMS), an Aerodyne soot particle mass spectrometer (SP-AMS), a multi-angle absorption photometer (MAAP), photo-acoustic soot spectrometers (PASS), a scanning mobility particle sizer (SMPS), cavity enhanced phase-shift particle extinction monitors (CAPS PMex), and a single particle soot photometer (SP2). Particle properties were measured with and without a thermal denuder (TD) in order to understand the effect of coatings on optical properties. Bulk particle chemistry was measured with filter samplers and a rotating drum impactor.

Gas phase measurements included air mass tracers (CO, CO_2, O_3, NO_x) and volatile organic compounds using a proton-transfer reaction mass spectrometer (PTR-MS). The micro-orifice volatilization impactor chemical ionization time-of-flight mass spectrometer (MOVI-CI-TOFMS), a recently developed chemical ionization instrument that measures organic acids in both the gas-phase and the particle-phase, was also deployed.

Over the course of the campaign, sampled air masses were of local (A249 motorway 200 m south of the site), regional (London to the northwest, industrial areas north of the site, or Maidstone city southwest of the site) or continental (mainland Europe) origin. Air mass origins were determined from back trajectories calculated by University of Leicester with the UK Met Office NAME dispersion model and from local wind speed and direction.

This talk will focus on black carbon containing particles measured at Detling. The SP-AMS instrument made in situ measurements of the chemical composition and size distributions of black carbon containing particles, both the black carbon component and any coatings. The mass spectra were analyzed with positive matrix factorization (PMF) yielding three factors. The first factor has dominant peaks at m/z 60 and 72, indicative of solid fuel burning. The second factor has a mass spectrum suggesting hydrocarbons, while the third factor has a mass spectrum associated with oxygenated organics and more aged aerosol particles. Figure 1 shows the time trends for the three factors. Time periods that are dominated by one factor are circled in blue and will be discussed in more detail. Connections between the chemical, microphysical, and optical properties of the aerosol particles in the different air masses will be presented.

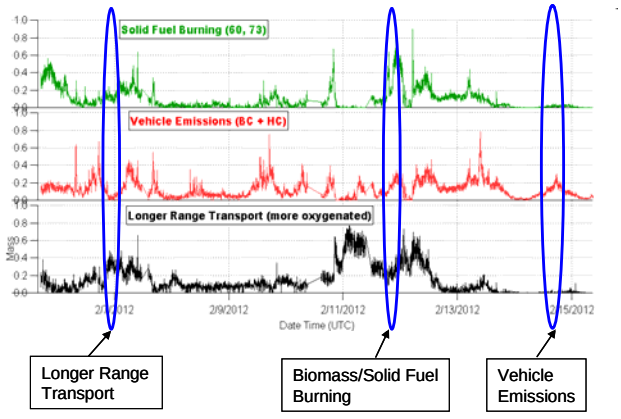

Figure 1. Time trends for PMF factors whose mass spectra suggest solid fuel burning, vehicle emissions and longer range transport sources.

Contribution of Inorganic aerosols and trace gases due to biomass burning during cooking hours at a rural site in India

Sudha Singh*, Gyan Prakash Gupta, Bablu Kumar and U C Kulshrestha
School of Environmental Sciences, Jawaharlal Nehru University
New Delhi, INDIA
Keyword: aerosols, biomass burning, cooking
(*Email: sudha29jan@gmail.com)

Biomass burning is a major source of air pollution which emits a complex mixture of air pollutants in the form of gases and aerosols (Andreae and Merlet, 2001). These have significant impact on atmospheric chemistry, climate change, and human health. But due to lack of measurements across the globe especially from developing countries, aerosol budgets have large uncertainties. There are reports on their emissions from coal combustion and wood burning from USA and Europe but measurements are very limited from developing countries. In India, traditional cooking is still common which contributes large amount of such air pollutants. This study has been carried out as part of UNEP project `Surya' to report chemical characteristics of fine atmospheric aerosols collected during cooking hours in an indoor environment in a village.

Measurements were conducted to determine indoor air pollution due to burning of wood, dung cakes and agriculture residue in rural households in Khairatpur village which is located in district Sultanpur of Uttar Pradesh state of India. Aerosol samples along with gaseous species (NO_2, SO_2, and NH_3) were collected during December 2010-January 2011 by using handy sampler (Envirotech model APM 821) installed inside the house. The samples were collected on 8 hourly basis using Teflon filters. The water extract of these filters was analyzed for major anions (F^-, Cl^-, NO_3^-, SO_4^{2-}) and major cations (Na^+, NH_4^+, K^+, Ca^{2+} Mg^{2+}) by ion chromatography (Metrohm 883 Basic IC Plus).SO_2 was estimated by using ion chromatograph and NO_2 and NH_3 were estimated by using spectrophotometer.

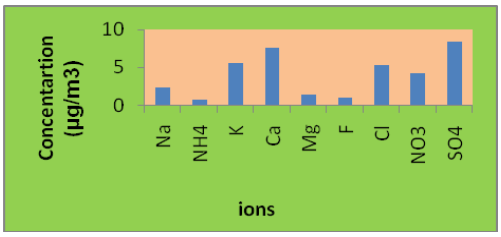

Fig.1 Concentrations (µg/m^3) of major ions during indoor cooking.

Fig.1 is the graphical representation of chemical composition of aerosol samples which indicates that SO_4^{2-} is dominant component followed by K^+, NO_3^-. SO_4^{2-} and Cl^-. Biomass burning is considered as a potential source of K^+ in air and its signature have been reported in Indian region (Kulshrestha et al., 2001). SO_4^{2-} which accounting for about 23% of the all components, is probably produced from the SO_2 emitted from biomass burning during cooking. SO_2 was recorded the highest among other gaseous species. Concentrations of gases are given in the Fig.2.

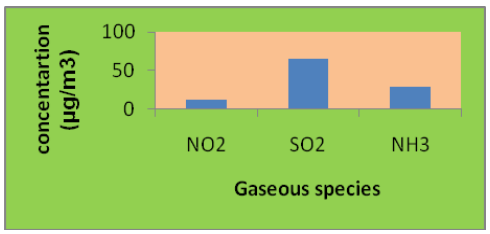

Fig.2 Concentration (µg/m^3) of trace gases during indoor cooking hours.

These findings indicated that a significant amount of aerosols as well as gases are contributed by biomass burning during traditional cooking process in rural India.

Presenting author email: asbach@iuta.de

Modern dental composite materials used for tooth restoration are made from a combination of polymer resin with e.g. SiO_2 or ZrO_2 filler particles. In order to be sufficiently strong to withstand chewing and to avoid excessive shrinkage of the composite during polymerization of the resin, the filler particle contents are high, usually >50vol%. While classic dental composites contained filler particles with sizes of several hundred nanometers up to micrometers, current materials typically also contain filler particles below 50nm. When contouring composite restorations using diamond burs, dentists often do not use water-cooling, such that filler particles are released directly into the airborne phase, leading to possible uptake via inhalation by both the dentist and the patient. It was shown in a previous study that release of nanoparticles during polishing or grinding of dental composites is generally possible (Van Landuyt *et al*., 2012). We here present a more thorough study which involved both the measurement of dentists' personal exposure as well as laboratory studies under defined conditions to characterize the particles released from a dental composite during grinding.

To characterize dentists' personal exposure, the number concentration, lung deposited surface area concentration and mean particle size were measured with a miniDiSC. The instrument was sampling through a flexible tube with its inlet placed in the breathing zone of the dentist. Simultaneously, a second miniDiSC instrument was placed approximately 5 m away to monitor particle background. Measurements were performed during extensive restorative/esthetic treatments with the so-called nano-composite Filtek Supreme XTE (3M ESPE), like veneering and total crown build-up of front teeth. Final contouring and finishing of the composite restorations was standardly performed by a diamond bur (roughness of 46-107 µm). Water-cooling and high-flow suctioning using the intra-oral vacuum suctioning device was only occasionally used, according to the standard procedures in the clinic.

The results clearly show that very high concentrations of particles are released during the various mechanical treatment steps of dental composites. The particle number concentrations in the breathing zone showed distinct peaks which could reach up to $>10^6$#/cm³. The concentration spikes usually coincided with a decrease in the mean particle size, indicating that nanoparticles have been released.

In order to better quantify the released material, laboratory measurements were conducted under defined conditions. Five different dental composites were investigated, including a so-called nano-composite (contains only nano-filler) and several (nano-)hybrid composites (contain both large filler and nano-filler particles). Dental composite blocks of defined sizes (17.4mm x 5.4mm x 1.6 mm) were prepared and ground with a rough bur (grain size 100µm), spinning at 200,000 rpm for approximately 2 minutes within an enclosure with low background concentration. The number size distributions of the airborne particles were measured with a Scanning Mobility Particle Sizer (SMPS) and particles sampled for consecutive analyses with an electrostatic precipitator (TSI NAS) with upstream unipolar charger. The investigations revealed that in all cases very high concentrations ($>10^6$ #/cm³) of mostly nanoscale particles were released, which agrees well with the personal exposure measurements. The median diameters of the size distributions during grinding of the different composites ranged from approximately 38 nm to 70 nm, but quickly increased afterwards due to coagulation.

SEM/EDX analyses of the collected samples showed that in some cases single nanoparticles were liberated from the matrix material. In addition the potency of the released material to produce reactive oxygen species (ROS) was measured by electron paramagnetic resonance spectroscopy in order to get an indication on whether the released material is potentially harmful. However, the results showed no increased activity of the material.

Results of the study will be presented and discussed particularly in view of occupational exposure and health risks of dentists.

Micro and nanoparticles released from the thermal cutting of polystyrene foams and the associated isomerization of hexabromocyclododecane (HBCD) diastereomers

Y.-Y. Kuo[1,2], H. Zhang[3], A.C. Gerecke[1]* and J. Wang[1,2]*

Presenting author email: Yu-Ying.Kuo@empa.ch

Polystyrene foam is widely used as building insulation material, architectural model and packing material. Due to its tendency to depolymerize when exposed to fire temperatures, and to generate volatile products of high fuel values, flame retardant is required to meet fire safety regulation. Hexabromocyclododecane (HBCD) is currently the most important flame retardant to protect polystyrene against ignition. However, HBCD has been listed on the 2010 Environmental Protection Agency action plans due to the fulfilment of regulatory thresholds for a persistent organic pollutant (POP). Therefore, workplace exposure and environmental emission of HBCD should be avoided.

In this study, we investigated the co-release of aerosol particles and HBCD during the thermal cutting of expanded polystyrene foam (EPS) and extruded polystyrene foam (XPS). The generated particles were simultaneously measured by a fast mobility particle sizer (FMPS) and collected by a cascade impactor (NanoMoudi). Further chemical analysis was done by a LC-MS/MS after necessary concentration and purification. In the breathing zone of a cutting worker, the number concentration of aerosol particles was above 1×10^{12} particles m^{-3} in the surrounding of operating location in both of EPS and XPS tests. The air concentration of HBCD was more than 50 μg m^{-3}. Most of the released HBCD was partitioned into particles with an aerodynamic diameter at the nano-meter scale. The average concentrations of HBCD in these submicron particles generated from the thermal cutting of EPS and XPS were 13 times and 15 times higher than the concentrations in raw foams, respectively. (Zhang *et al*, 2012)

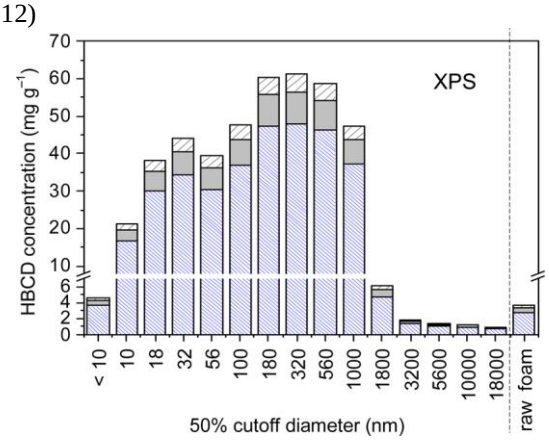

Figure 1. HBCD concentration in raw foams and in size separated particles from thermal cutting of XPS

In the meantime, HBCD underwent isomerization during this process, especially in tests of EPS form. The fraction of the more bio-accumulative α-HBCD increased remarkably, while the fraction of γ-HBCD decreased. The composition of HBCD diasteromers tended to resemble the ratio of thermal equilibrium reported by Peled *et al*. (1995) from the typical technical component. The fraction of HBCD diastereomers is independent from particle size but hugely influenced by the compartment.

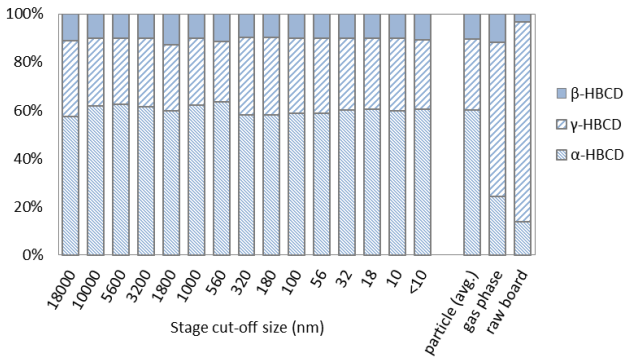

Figure 2. HBCD diastereomer fractions in different compartment and particle sizes in thermal cutting tests of EPS foam.

An occupational exposure assessment indicated that 7×10^7 particles and totally 20 μg of HBCD can deposit into the lung of the operating worker in 1 hour of working time. More than 70% of particles and 60% of HBCD of those would allocate in the alveolar region. This amount of HBCD is equivalent to the total intake of HBCD by an adult during 1−3 months in daily exposure. (Marvin *et al*, 2011)

Presenting author email: b.moroni@tiscali.it

Health risk assessment in the ceramics industry traditionally rests upon crystalline silica toxicity and exposure levels (*e.g.*, NIOSH, 2002). Notwithstanding, workers in the ceramics factories may be exposed to a number of potential toxicants, including iron (Fubini and Fenoglio, 2007). Iron, which is a major element in the pastes of clay brick and pottery productions, has been shown to modulate quartz toxicity through enhancing or inhibitory effects depending on surface concentrations (Ghiazza *et al*, 2011). In this paper the nature and properties of quartz and Fe-bearing minerals in clay brick and pottery productions and the possible mutual interactions between them, have been evaluated by means of integrated individual particle characterisation-bulk chemical analyses of both the raw materials and the airborne dust particles.

Aerosol dust samples have been collected from different working stations in different clay brick and pottery factories in Umbria (Central Italy). Individual particle characterization has been performed by means of scanning electron microscopy (SEM) coupled with image analysis and EDS microanalysis (Moroni *et al* 2013). The bulk mineralogical composition has been determined by means of X-ray diffraction (XRD), while the concentration and the solubility degree of Fe in the bulk samples at both neutral (7.2) and acid pH (4.6) have been determined by inductively coupled plasma atomic emission spectrometry (ICP-AES). Distinctive technological features of toxicological interest have been also investigated by means of experimental firing tests on the pastes performed at 950°C (clay brick) and 1050°C (pottery) peak temperature.

Quartz morphology revealed similar grain size and surface morphology in both sectors, and lower values of the shape factor in the clay brick production. Mean values of the exposure doses for quartz in the clay brick and the pottery working environments were evaluated based on the grain size, leading to 84 and 93 $\mu g\ cm^{-2}$, respectively. These values greatly exceed the minimum dose (40 $\mu g\ cm^{-2}$) able to induce significant cytotoxic and inflammogenic effects on cell cultures (Ghiazza *et al.* 2011) although the particle mass concentrations in the factories be lower than the threshold limit value (0.025 $mg\ m^{-3}$). This fact suggests the necessity of employing surface area instead of gravimetric measurements when evaluating quartz occupational exposure.

The mineralogical composition of pastes is similar before firing, with just some more variability in the clay brick, and changes after firing in the pottery for remarkably higher amounts of the amorphous phase. The clay brick pastes, on turn, show lower total iron, and higher soluble iron contents in respect to the pottery pastes. The total iron amounts are mostly related to variable amounts of Fe-bearing clay minerals (mostly chlorite) and ores in the clay brick pastes. The soluble iron contents, on turn, depend on the amounts of the amorphous phase, as the thermal decomposition of Fe-rich silicates such as chlorite produces an amorphous phase which can retain iron and prevent hematite crystallization (Nodari *et al*, 2007). These facts point to the possible role of bioavailable soluble iron in modulating quartz toxicity in the airborne dust as a function of the composition of raw materials and the mineralogical-chemical evolution in the firing process.

Mean values of the Fe/Qz ratio have been estimated based on the values of iron and quartz concentrations in the samples, leading to the following results: $Fe/Qz_{clay\ brick}<0.03$; $Fe/Qz_{pottery} \sim 0.004$ The values obtained for clay brick are in the range of possible adverse health effect (Ghiazza *et al* 2011), while the values for pottery are too low to attain reliable interaction. Results support the evidence of higher incidence of silicosis in the clay brick division (Verdel *et al* 2006), although it should be better to consider the occurrence of mixed dust fibrogenetic processes rather than simple silicosis in this case (Mossman and Churg 1998). In the light of all these points, significant reduction of the health risk may be attained only after a deep examination of the properties and the exposure conditions of the whole materials even in the same working environment. Also, generalization of the results should be kept with caution and the situation be analysed case by case.

Presenting author email: jarno.ruusunen@uef.fi

Occupational health risks related to workplace exposure to engineered nanoparticles (ENP) are still not well understood and there seems to be lack of instruments to measure of ENPs in the workplaces. On the market there are a few measurement devices for the ENP monitoring, such as the Nanoparticle surface area monitor (NSAM, model 3550, TSI, USA) (Asbach *et al*, 2009) and the Aerasense NanoMonitor (Philips, Netherlands). However, at workplaces there is still need for low-cost, easy to use and portable nanoparticle monitoring instruments. A prototype of a new engineered nanoparticle monitoring device (Dekati Low-Cost Surface Area Monitor LC-SAM, Dekati Ltd., Finland) based on escaping current technology has been built by Dekati Ltd in EU FP7 Nanodevice -project. In this study a prototype device was tested.

ENPs for the device testing were produced using Flame spray pyrolysis (FSP) (Karhunen *et al*, 2012) and Atmospheric pressure chemical vapour synthesis (APCVS) (Lähde *et al*, 2011). In addition, the aerosol generator (model 3076, TSI, USA) was used to produce ammonium sulfate ($(NH_4)_2SO_4$) and polystyrene latex (PSL) particles as reference materials, see Table 1.

The Scanning mobility particle sizer (SMPS, model 3080, TSI, USA), the NSAM, the Electrical low pressure impactor (ELPI and ELPI+, Dekati Ltd, Finland) and the Fast mobility particle sizer spectrometer (FMPS, model 3091, TSI, USA) were used to characterize the produced ENPs and the reference particles.

Material	GMD (nm)	c ($\cdot 10^4$/cm^3)
$(NH_4)_2SO_4$	40	6.9
PSL	74	1.0
Cu	98	5.7
LTO	193	5.1

Table 1. Materials used for testing, geometric mean diameter (GMD) and concentration (c) of the particles according to SMPS.

The produced ENPs were diluted with a porous tube diluter and an ejector diluter prior to sampling to achieve suitable sampling conditions. The Dekati LC-SAM was used in a small exposure chamber and the samples for the NSAM were taken from the same location.

The current I (fA) measured with the Dekati LC-SAM is relative to the active surface area of particles going through the device. For LTO ENPs the signal are presented in Figure 1a and the human lung-deposited surface area D (μm^2/cm^3) measured with the NSAM for LTO ENPs can be seen in Figure 1b. While the measuring principle of the Dekati LC-SAM and NSAM has some differences there was still a good agreement between the measured values.

As a conclusion, the Dekati LC-SAM has a good agreement between the measured values and the characteristic of the produced ENPs. Results indicated that tested device offer one alternative to measure workplace exposures for ENPs.

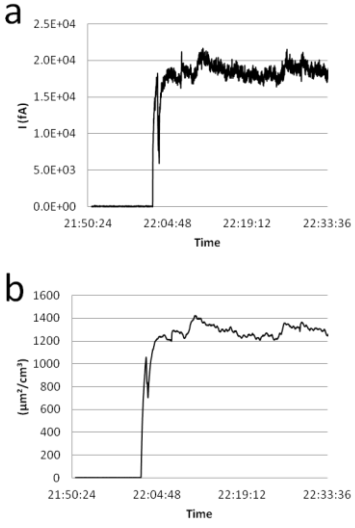

Figure 1. a) Current *I* (fA) of the Dekati LC-SAM and b) Lung deposition average *D* (μm²/cm³) of the NSAM.

The research leading to these results has received funding from the European Community's Seventh Framework Programme (FP7/2007-2013) under grant agreement n° 211464.

Keywords: occupational health, ENP, ultrafine particles
Presenting author email: anna-kaisa.viitanen@ttl.fi

Ultrafine particles have been postulated to be one of the most expanding risks for occupational health (Brun et al. 2009). In work environment the employee may expose to ultrafine particles. These originate from unintentional sources, e.g. welding fumes and combustion particles, or they may be purposely manufactured process particles, such as engineered nanoparticles (ENPs) (e.g. Maynard et al. 2005).

Work environment airborne PM originates from outdoor air and indoor sources. Indoor sources may be separated by measuring size differentiated concentrations and following work processes (Koivisto et al. 2012). Representative data is still lacking in large scale, thus measurements in work places are seen important.

Methods

We are studying the number concentration of ultrafine particles in different working environments. The measurement setup used in workplace measurements is illustrated in Fig. 1.

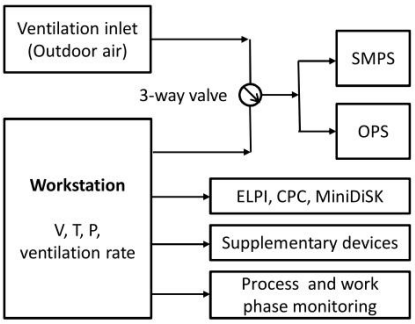

Figure 1. Measurement setup.

The exposure is defined from the work station and breathing zone. The ventilation inlet concentration defines the background. When measurements from ventilation inlet are not possible the outdoor air is measured instead where the penetration of the particles to indoors are defined with I/O measurements. For measuring number size distribution a Scanning mobility particle sizer (SMPS), Optical particle sizer (OPS), Condensation particle counter (CPC) and Electrical low pressure impactor (ELPI) are used. Personal exposure from the breathing zone is measured with MiniDiSC (Fierz et al. 2011). With this setup a particle size range of app. 3nm-10µm depending on application is achieved. Additionally other measurement devices are being used to produce supplementary information on measurements. This could be e.g. measurements of gas phase contaminants or collection of EM-samples. The work process is monitored and different processes during the working period are linked to the concentrations.

Results and Discussion

In this study the occupational exposure to fine and ultrafine particles in various working environments is measured. Fig 2. shows an example of the work place measurements. The total particle concentration and particle size distribution measured during one working day in an industrial factory handling nanodiamonds (ND) is shown. Based on the results the ND concentration during the handling process does not significantly differ from the ventilation inlet concentration (i.e. background). However, the personal exposure to large ND agglomerates may be seen. The workers inhalation exposure in this case was negligible due to proper use of respiratory protective equipment.

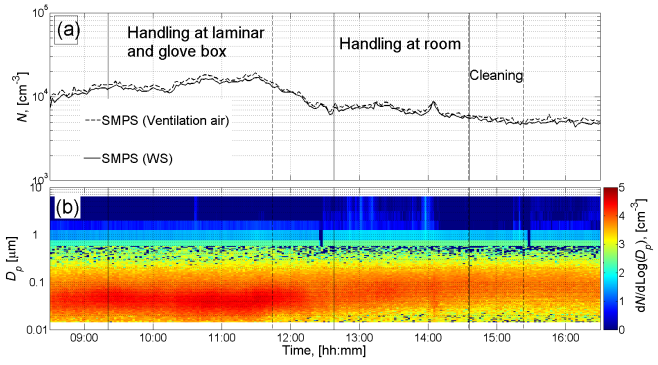

Figure 2. (a) Particle number concentration during a one day working period measured with SMPS from the work station (solid line) and ventilation inlet (dashed line). (b) Particle size distribution measured with SMPS and ELPI. Different work phases have been indicated into the figure with vertical lines.

Presenting author email: jing.wang@ifu.baug.ethz.ch

Filter sampling followed by electron microscopy has long been used for measurement of airborne particles. The method provides direct measurement of the particle geometric size and morphology, which cannot be obtained from real-time instruments. The correlation between the particle concentrations on the filter surface and those in the air deserves careful investigation. In many applications, the collection filters are assumed to be absolute filters and the collected particle concentration is directly converted to the airborne concentration. This assumption is plausible if high efficiency filters are used. On the other hand, usage of high efficiency filters requires strong pumps and power consumption. This poses difficulty for field measurement and increasingly important personal sampling. If the collection filters cannot be assumed to be absolute filters, an accurate filtration model must be established to convert the particle concentration on the filter to the airborne concentration (Cyrs et al. 2010).

In the studies of ambient and workplace airborne particulate matters, the nanoparticles play more and more important roles. They may have specific properties, high local concentrations, and thus more severe effects on the environment and human health. Personal exposure assessment is attracting increasing interests because data under the real work conditions of the workers and that of residents living in the neighborhood of the plant can be obtained. The Nuclepore filters are often used for particle sampling due to their flat surface, which facilitate the microscopic analysis for the collected particles. We investigated the feasibility of Nuclepore filter collection with subsequent electron microscopy analysis to assess the nanoparticle exposure.

The pores of the Nuclepore filter are circular in cross section and the well-known capillary tube models were used for calculating the collection of particles (Spurny et al., 1969; Manton, 1978). We also proposed a modified model based on the Spurny model. We found that the inertia parameter, I (a function of medium and particle densities, filtration face velocity, filter porosity and pore diameter), should be used to determine the applicability of the models.

To search for a proper model, we studied the overall penetrations of three different spherical and cubic nanoparticles (PSL, Ag and NaCl), and three types of fractal particles (Ag open agglomerates and partly sintered aggregates, and soot aggloemrates), covering a wide range of particle sizes (20-800 nm) and densities (1.05-10.5 g/cm3), through Nuclepore filters with two different pore diameters (1 and 3 μm) and different face velocities (2-15 cm/s). The data of the overall penetration were in very good agreement with the properly applied models (Figure 1). A good agreement of filter surface collection between the validated model and the SEM analysis of this study (Figure 2) was obtained, indicating a correct nanoparticle number distribution in the air can be converted from the Nuclepore filter surface collection and this method can be applied for nanoparticle exposure assessment.

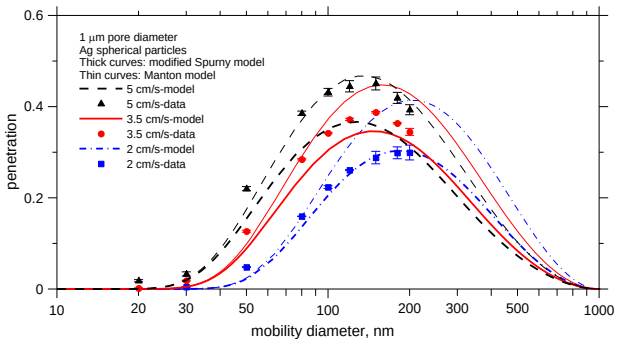

Figure 1. Comparison of Ag penetration in 1 μm filter between experiments and modified Spurny and Manton models at relatively low face velocities, 2-5 cm/s.

Keywords: Carbon nanotubes, emission measurement, SEM

The fields in which carbon nanotubes (CNTs) are found useful are rapidly growing, causing an increased demand worldwide. The industry is looking for ways to improve their production and thus increase the amount of CNTs being handled. This, together with the fear that exposure to CNT particles may cause similar health effects as asbestos (Donaldsson, 2006), create a need for accurate methods of emission assessments. We present results from field measurements performed using a range of techniques to assess emissions and exposure at a small-scale CNT producer that utilize the arc-discharge method for production of multi-walled CNTs.

Emissions and exposures when performing different work tasks in the production were examined including full-shift personal measurements. Samples of airborne particles were collected both in the emission zone and in the breathing zone of the workers. By using cyclones (BGI4L, BGI) respirable (cut-off 4µm aerodynamic diameter) dust fractions, were collected on polycarbonate (37 mm, 0.4 µm pores) filters. Particles were studied with Scanning Electron Microscopy (SEM) and online instruments were used both in the emission zone (<10cm from the source) and in the background (3 m from the closest known source). CNT containing particles were classified into 4 types displayed in figure 1. The size distribution of all measured particles in one sample is shown in figure 2.

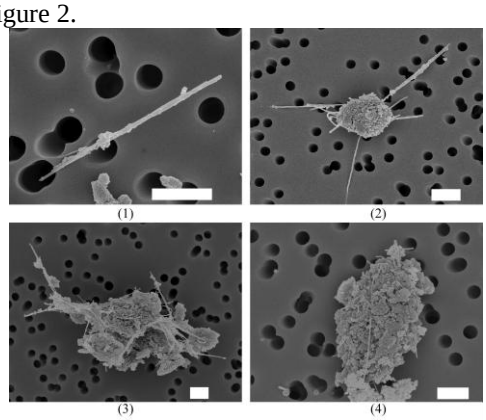

Figure 1 CNT particle types (1-4). The white scale bar equals 1 µm in each image.

Emissions of CNTs were detected in 9 out of 16 samples, with a CNT content of up to 11 CNT particles per cm^3. The CNT containing particles found in the respirable fraction did seldom exceed a length of 5 µm. Most of the CNT particles had dimensions larger than 1 µm, i. e. much larger than the mean particle diameter (0.2 µm)

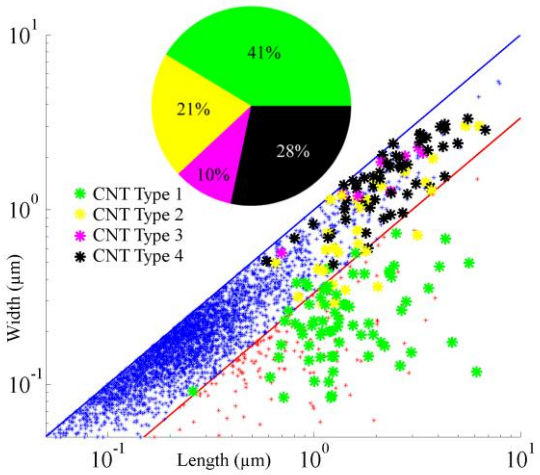

Figure 2 Distribution of measured particles in one sample, blue and red dots marks non-CNT containing particles. Particles between the blue and red line have an aspect ratio <3:1 and particles below the red line have an aspect ratio >3:1. The pie chart shows the distribution of the four different CNT types.

The combination of online instrumentation and SEM analysis contributed to clearly showed when emissions occur and what kind of particles that were emitted. The results show that several tasks in the production could cause workplace exposure.

Particle characterization during abrasive treatment of composite material containing fibres by Cryo HRTEM

K.I. Lieke[1], M. Levin[1,2], K.A. Jensen[1] and I.K. Koponen[1]

[1]National Research Center for the Working Environment, 2100 Copenhagen, Denmark
[2]Department of Nanotechnology, Technical University of Denmark, 2800 Kgs. Lyngby, Denmark
Keywords: nano fibre composite, production emission, HRTEM, cryo.
Presenting author email: KirstenLieke@gmx.de

Composite material including nano particles and fibres is today used in production and sealing of surfaces. Highly stressed surfaces such as of cars, boats and light aircrafts need to provide properties that demand the use of new materials including nano fibres, that enhance stability. Manufacturing of these surfaces involves abrasive treatment, during which material is emitted. We characterized particles from treatment of composite material including nano fibres. Nano particles can have an adverse health effect (Donaldson et al., 2002) when inhaled by humans exposed to emissions during manufacturing and surface treatment.

Particles were collected using a micro intertial impactor set similar to the one described by Kandler (2009). Sampling was performed on 2 stages (upper cut off 0.89 µm and lower cut off 0.047 µm diameter) on Ni-TEM grids with Formvar carbon foil (Plano, Wetzlar, Germany).

Transmission electron microscopy (TEM) was used for analysis of particles on 12 samples from 6 tests in total. Overview and high-resolution (HR) microscopic images were recorded using a Tecnai T20 G2 (FEI, Eindhoven, the Netherlands) at the Center for Electron Nanoscopy, Technical University of Denmark, operating at 200kV. Due to beam sensitive material a nitrogen cooled cryo transfer holder (Gatan Inc. Ca. USA) was used to keep the sample below -80 degrees Celsius during analysis. It was accounted for possible beam damage and hydro carbon deposition by using low beam current densities and short acquisition time. Energy dispersive X-ray detection (EDS) was carried out on single particles using an Oxford 80mm silicon drift detector.

Scanning electron microscopy (SEM) was performed on samples collected from deposited material (powder) with a ESEM Quanta 200 FEG (FEI, Eindhoven, the Netherlands).

Online measurements with FMPS, ELPI, CPC and GRIMM dust monitor were conducted in parallel.

Particles in the size range from 40 nm up to 500 nm (average geometric diameter) were analysed and classified based on their structure, morphology, beam stability and chemical composition.

Particles originating from the composite proofed to be partly crystalline material (Figure 1). Few nanometer thin fibres were found in agglomerates of few hundred nanometers, parts of them sticking out of the bulk. Single fibers of 100 nm in width and several 100 nanometers in length were less abundant.

Ammonium sulfate, sodium chloride and soot particles that were found in high abundances on the substrates were classified as background particles. However, composite particles, as well as fibres were sometimes found internally mixed with background particles.

Particles revealed inhomogeneous composition and irregular shape and morphology. Size, surface area and density determination will be discussed for the different materials.

SEM investigations on deposited material revealed extreme charging of particles, especially of the fibrous material. Potential issues regarding the detection by instruments using electric mobility sizing will be critically discussed.

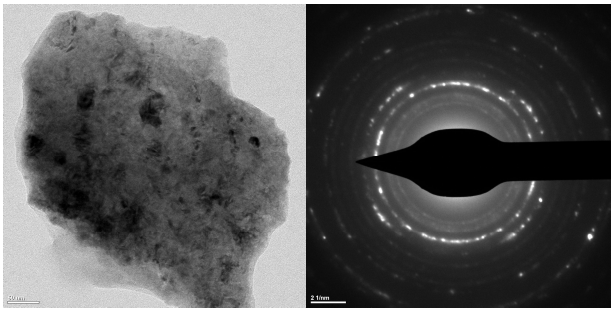

Figure 1. TEM bright field image (left) and diffraction pattern (right) of a nano particle originating from abrasive treatment of composite material.

Keywords: mobile platform, urban pollution, real time monitoring, traffic rates
Presenting author email: david.cappelletti@unipg.it

In this paper we propose an innovative approach to the study of urban pollution dynamics, with a particular emphasis to vehicular traffic and generated aerosols. In synthesis, a mobile monitoring platform has been developed exploiting the urban transport system in Perugia (Italy), called Minimetrò. It is based on a monorail train, exploiting a relatively high number of cabins (in average 20) driven by a wire rope continuously running at medium low speed (4-5 m/s) along a radial transect (~3 km, in approx. 20 minutes) over the city. The cabins travel on a monorail built 5 meters above the road level. The cabin path starts from a large suburban parking area, it crosses various heavy traffic roads and road crossings, passes through a park, climbs Perugia hill, and finally reaches the city center inside a terminal tunnel. All these features make the Minimetrò system a good mobile platform for real time investigation of the dynamics of formation and dispersion of pollutants in the urban area.

The basic idea has been to customize and integrate an Optical Particle Counter (OPC, 6 sec. resolution, 22 size classes) inside the cabin. To complement the information coming from the mobile station, two other fixed OPCs (FAI Instruments) have been installed at both ends of the Minimetrò line. Moreover the Minimetrò line passes at short distance (50 m) from the urban background and traffic monitoring stations of air quality. These provide hourly averaged O_3, NO_x, Benzene and CO concentrations, as well as 24h PM_{10} and $PM_{2.5}$ data records. In addition, the main weather parameters are recorded as well as a PBL stability monitor (FAI Instruments) has also been installed in this station. Finally, traffic rates are recorded continuously in two points along the Minimetrò line with a 5 minutes time resolution.

An example of aerosol data is shown in Figure 1, where the number concentration of coarse fraction particles (D_P>1 μm) is shown, for a particular day, as a function of the position along the path (*y* axis, in meters) and time of the day (*x* axis). The color code are number concentration of particles per volume of air. In this particular example the variable impact of a Saharan dust intrusion occurring in the late afternoon is evidenced in different areas of the city. In addition, higher particles concentrations (red areas in the graph) are observed near heavy traffic roads, which point to a role of particle resuspension.

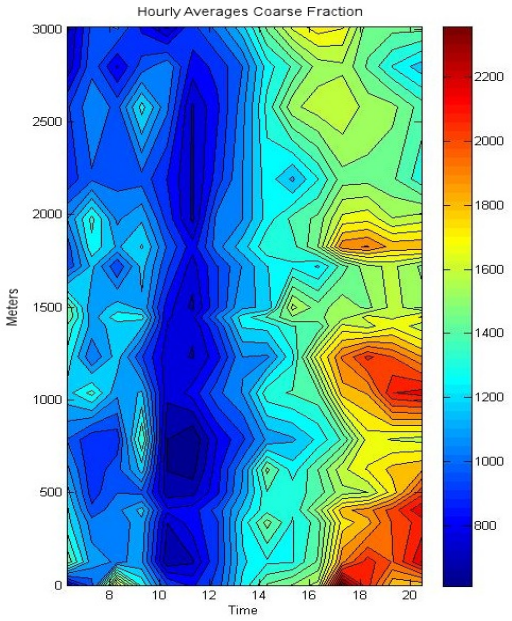

Figure 1 - Spatial – temporal distribution of coarse fraction particles recorded in date 20/10/2012.

The data acquisition started in September 2012 and will last one year. Ad-hoc statistical techniques are employed to fully exploit this large amount of information: functional data analysis can handle high frequency time series, while additive models can produce maps as those in Figure 1 and explain the contribution of covariates.

Special interest has been paid to the characterization of the aerosols in the underground paths of the Metro line in order to analyze the impact of degrading metal and rubber parts of the system. In this case the specific emission of the Metro system has been characterized, exploiting two HVS multistage impactors which allowed simultaneous samplings inside and outside the tunnel for metals and IPA size distributions. Moreover EC/OC ratios, black carbon as well as morphological a mineralogical assessments via electron microscopy on samples taken inside the tunnel have been used to integrate the mobile cabin data. Detailed results will be presented at the Conference.

A new aerosol conditioning system - Characterisation and first application

M. Laborde[1], B. Rosati[2] , P. Zieger[2], T. Petäjä[3], G. Kassell[4], D. Logan[4], E. Weingartner[2]

Presenting author email: marie.laborde@aerosolconsulting.com

Aerosol particles are known to have the capability of taking up water. As a result, their optical properties (and especially their ability to scatter light) are altered and with it their direct impact on the Earth's radiative balance. Predicting the contribution of condensed water to light scattering remains however a challenge due to the fact that this highly depends on the particle dry size and chemical composition (i.e. the particles hygroscopicity). The relative humidity (RH) dependence of the particle light scattering coefficient $\sigma_{sp}\sigma_{sp}$) is therefore an important measure for climate forcing calculations but also needed for comparing in-situ with remote sensing measurements

This dependence is usually reported as *f(RH)* and is defined as in Eq. 1:

$$f(RH)_i = \frac{\sigma_{sp}(RH)_i}{\sigma_{sp}(RH)_{dry}}$$

Equation 1. Light scattering enhancement factor at a relative humidity

Several studies have successfully measured and modelled the ability of aerosol particles to take up water in various locations (Zieger et al., 2010) using a custom-built humidified nephelometer (WetNeph; Fierz-Schmidhauser et al., 2010). We present here the first results obtained with a newly commercially available aerosol conditioning system. A detailed characterization of this new instrument will soon be performed, including a comparison to the above mentioned custom built WetNeph. A first application in the field in Hyatiäla, Finland is also foreseen and will be presented.

The aerosol conditioning system used in this study (ACS 1000, Ecotech) allows for the humidity to be controlled within ±0.8% (Fig. 1) from ~40% to 90% RH. It is composed of a gore-tex humidifier, a nafion dryer and two integrating, polar nephelometers (Ecotech, Aurora 4000).

Figure 1: RH control of aerosol conditioning system ACS

The aerosol light scattering enhancement at 90% RH was measured (Fig. 2) for over a month in Melbourne, Australia. The figure shows the importance of the particles water uptake on their light scattering.

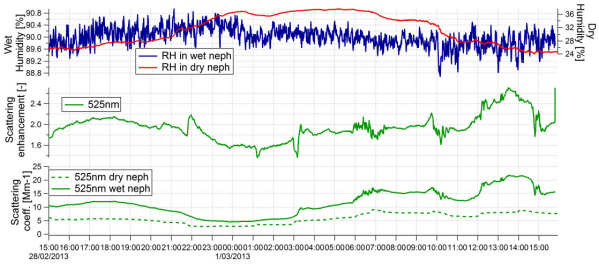

Figure 2: First application of the new humidified nephelometer

Particle number concentration monitor for atmospheric aerosols

L. Hillemann[1], A. Zschoppe[2]

[1]Institute of Process Engineering and Environmental Technology, TU Dresden, 01062 Dresden, Germany
[2]Topas GmbH, Oskar-Röder-Str. 12, 01237 Dresden, Germany
Keywords: particle number concentration monitor, atmospheric aerosol, corona-jet charger
Presenting author email: lars.hillemann@tu-dresden.de

The concentration of particle matter in ambient air is quantified in air quality monitoring networks. The classical mass-based methods are more and more completed by number-based methods. This enables to quantify the concentration of submicron particles, which especially show adverse health effects (Peters *et al*, 1997). For this purpose, an ultrafine particle monitor (UFPM) was designed and constructed to obtain particle number concentrations of atmospheric aerosols.

Fig. 1 shows a schematic diagram of the UFPM. The aerosol sample passes through a corona-jet charger, which charges all particles positively by diffusion charging. Subsequently, the charged particles are classified in a DMA due to their electrical mobility and quantified by a faraday cup aerosol electrometer. During a measurement with the UFPM the voltage in the DMA is increased from 0 to 10 kV in discrete steps within 10 min. The means of the electrical current, measured with the aerosol electrometer at every classifier voltage, are recorded in the vector **I**. The ranges of electrical mobility, corresponding to the classifier voltages, overlap by half its width. The captured range of particle mobility covers particle sizes from 20 to 720 nm in predefined size classes.

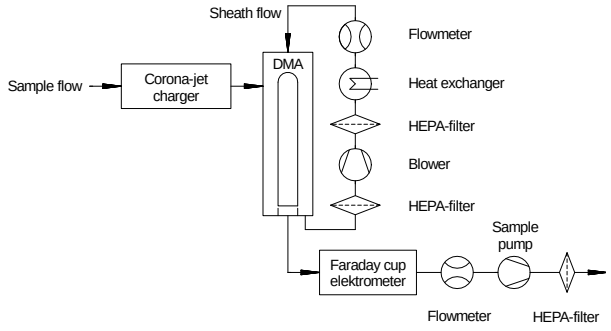

Figure 1: Schematic diagram of the ultrafine particle monitor (UFPM)

The data inversion delivers the connection between the measured electrical current **I** and the particle number concentration **C** by the charge distribution, the transfer function of the DMA and the inlet flow. These functions are summarized in the kernel matrix **K**.

$$\mathbf{I} = \mathbf{KC} \tag{1}$$

A data inversion algorithm, based on the Tikhonov-regularization, was implemented (Tikhonov, 1977).

A method was developed to calculate the kernel matrix from the data of comparison measurements with the UFPM and a reference mobility particle size spectrometer such as a scanning mobility particle sizer. In experimental comparisons, the number concentrations of laboratory and atmospheric aerosols measured by the UFPM were within a range of $\pm 20\,\%$ of the reference concentration determined by a SMPS. The distribution of the counting efficiency of the UFPM measured with atmospheric aerosol is shown as boxplot in Fig. 2. The counting efficiency is mainly between 0.8 and 1.2. The quartiles of the distribution of the counting efficiency of all size classes are between 0.81 and 1.02, the median varies between 0.90 and 0.93.

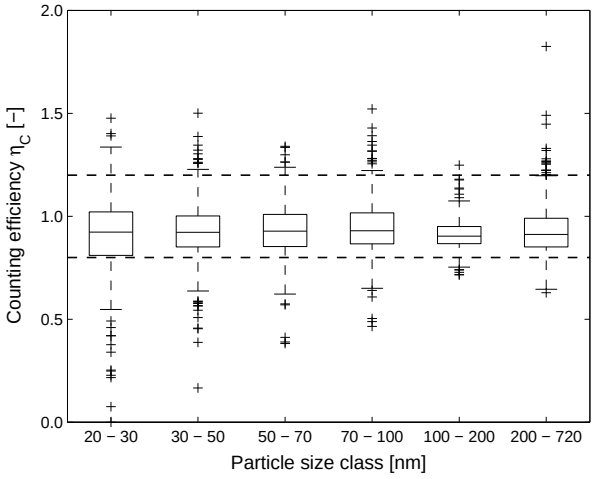

Figure 2: Counting efficiency of the UFPM for atmospheric aerosol

The UFPM is particulary designed to monitor atmospheric particle number concentration in air quality monitoring networks. The contribution will discuss the design and the function of the UFPM. It will focus on the data inversion and the method for the measurement of the kernel matrix data. Results of comparison measurements with the UFPM and a SMPS will be presented to confirm the good agreement of the UFPM to reference mobility particle size spectrometers.

A new visual expansion-type Condensation Particle Counter

B. Bühner, A. Wagner, A. Kürten and J. Curtius

Institute for Atmospheric and Environmental Sciences, Goethe University of Frankfurt, 60438 Frankfurt/M., Germany
Keywords: nanoparticles, instrumentation, CPC
Presenting author email: buehner@iau.uni-frankfurt,de

The particle number concentration is an important fundamental property of aerosol populations and is usually measured with Condensation Particle Counters (CPC). In these instruments nanometer-sized particles are magnified by condensational growth to sizes detectable by light within the range of the visual spectrum. This concept is applied in various commercial and custom-made setups (see McMurry, 2000, and references therein).

One approach for achieving the required super-saturation is realized in "expansion-type" CPCs through fast adiabatic expansion. Different methods have been applied for retrieving the number concentration of the particles after their activation and growth to micrometer-sized droplets. These automated methods usually rely either on the measurement of scattered or transmitted laser light after interaction with the droplet population (e.g. Kürten, 2005). Especially the reliable detection of low particle concentrations with such measurements can, however, be challenging because of noise or drifts in the measured light intensity.

We have developed a new expansion-type particle counter based on the visual detection of individual droplets. The design of the VIPER (Visual expansion-type Particle counter) utilizes a CCD camera and a fully automated image analysis based on a LabVIEW program. A section of the expansion chamber is illuminated by laser light. The laser beam is "shaped" by a cylindrical lens and defines – together with the chamber geometry – a thin optical volume which is used for the particle detection. A series of digital images is taken shortly after the adiabatic expansion and subsequently processed afterwards. The particles visible in the illuminated volume are counted autonomously by image analysis software.

This direct method of observation offers an absolute measurement of individual aerosol particles and is no longer dependent on the interpretation of intensity measurements. As single particles are individually detected rather than the optical properties of a particle ensemble, the result is basically unambiguous. Thus, the method can in principle be independent of calibration. However, the correct geometry of the illuminated volume and the loss of particles due to the expansion have to be taken into account.

The experimental setup of the VIPER is demonstrated to have a reliable performance under various experimental conditions in the laboratory and in the field. The particle size at which 50% of the particles are detected has been determined to be D_{p50} = 8nm (cut-off diameter) with detection of particles beginning at 3nm (using water as the working fluid).

The maximum concentration which can be measured accurately is around 4.4×10^5 cm^{-3}. The lowest measurable concentration is constrained by the counting statistics due to the rather small optical volume. Given this constraint a concentration of 2000 cm^{-3} would be measured with a statistical error of approx. 10 %.

The super-saturation achieved inside the measurement chamber can be controlled by the expansion ratio. Therefore, a thermal conditioning is not required which helps to keep the set-up simple. In addition to that, controlling the expansion ratio has further important advantages: (1) The super-saturation can quickly be adjusted between different expansions to set different lower cut-off sizes in subsequent measurements without time delay. (2) The whole setup can be made isothermal. This would allow the application of VIPER in low temperature environments. Thereby, the potential risk of evaporating particles before the measurement can be avoided.

Detailed instrument characterizations will be presented as well as side-by-side comparisons with other particle counters. We discuss the assessment of different working fluids and the performance of the VIPER CPC during field experiments.

Development of a high volume air-into-liquid aerosol collector for $PM_{2.5}$ and ultrafine particulate matter

Dongbin Wang[1], Payam Pakbin[1], Arian Saffari[1], James J Schauer[2] and Constantinos Sioutas[1]

[1]Department of Civil and Environmental Engineering, University of Southern California, Los Angeles, CA, 90089, USA
[2]Department of Civil and Environmental Engineering, University of Wisconsin, Madison, WI, 53718, USA
Keywords: aerosol collector, VACES, air-into-liquid.
Presenting author email: sioutas@usc.edu

A novel high volume aerosol sampler for $PM_{2.5}$ and ultrafine particulate matter (PM) was developed to collect ambient aerosols directly into a liquid phase, for application areas such as toxicity studies of PM as well as for direct chemical analysis of the collected suspension samples, thus overcoming limitations associated with the conventional filter samplers. This new collector was designed to be coupled with the USC Versatile Aerosol Concentration Enrichment System (VACES) technology described by Kim et al (2001), by integrating an inertial impactor to collect the super micron ambient aerosols after their condensational growth in the VACES, in the form of an aerosol suspension in liquid. The high-flow (200 LPM), low pressure drop (6.5 inches of water) impactor allows prolonged and unattended operation of the system.

Laboratory tests were conducted to evaluate the performance of the impactor. The collection efficiency of the inertial impactor was determined using monodisperse aerosols generated by atomizing suspensions of Polystyrene latex (PSL) particles (1, 1.5, 3 and 6μm) with a constant output nebulizer. Figure 1 presents the collection efficiency of the impactor as a function of particle aerodynamic diameter.

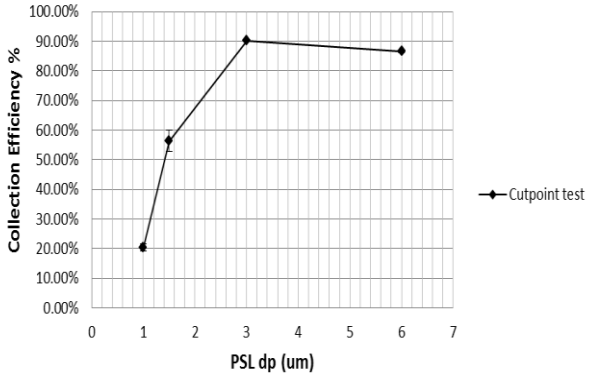

Figure 1. Collection efficiency curve of different PSL particles

Collection efficiency of the VACES-inertial impactor system was evaluated by testing different monodisperse PSL particles in sub-micron range: 42.5, 100, 300, 750nm and 1 μm, and polydisperse aerosols: glutaric acid and ammonium nitrate. The generated particles were first grown in the VACES prior to collection in the impactor. A fluorescence detector was used to measure the fluorescence signal of PSL particles on upstream and downstream filters and residual on the collector inlet and impaction walls, while mass concentration was measured by DustTrak upstream and downstream of the collector for polydisperse aerosols. Overall, the average collection efficiency of this collector was above 90%, as shown in Table 1.

Table 1. Collection efficiency of the new impactor

Aerosol	Efficiency	Inlet	Wall	Suspension
42.5nm	96.40%	4.53%	9.43%	82.44%
100nm	90.33%	2.11%	7.51%	80.71%
300nm	98.95%	1.17%	6.29%	91.49%
750nm	95.15%	2.87%	11.17%	81.10%
1 μm	99.08%	1.79%	9.30%	88.00%
glutaric acid	97.09%	-	-	-
ammonium nitrate	96.56%	-	-	-

Comparison of collection performance between the new impactor and the VACES/biosampler tandem was conducted using PSL particles of 300 and 750nm. Fluorescence signals of suspensions collected by these two samplers were measured and compared Results indicated that the aerosol collection performance was equivalent in both the impactor and biosampler.

Lastly, the whole system was deployed in the field and ambient $PM_{2.5}$ samples were collected both in the new collector and on filter substrates, similar to the test described by Daher et al (2011) to validate that the chemical compositions of suspension samples collected by the new impactor are equivalent to those on filter samples. This analysis is underway and results will be presented soon. Continuity test will be conducted to demonstrate the ability of prolonged and unattended operation.

Online Method for Size-Resolved Chemical Speciation of Nano-Particles

A. Wagner[1], A. Kürten[1], C. Fuchs[1,2], J. Hoker[1], J. Curtius[1]

[1]Institute for Atmospheric and Environmental Sciences, Goethe University, Frankfurt, 60438, Germany
[2]now at: Laboratory of Atmospheric Chemistry, Paul Scherrer Institut, Villigen, 5232, Switzerland
Keywords: nano-particles, instrumentation, mass spectrometry, nucleation.
Presenting author email: acwagner@iau.uni-frankfurt.de

The growth of aerosol particles originating from nucleation is an important atmospheric process. The availability of condensable vapors for this growth is a prerequisite for these particles to become cloud condensation nuclei (CCN). To determine the source and the mechanisms of the aerosol growth, the condensing vapors need to be chemically speciated. However, the chemical analysis of particles in the size range between 2 nm and 20 nm is an experimental challenge and there are only very few instruments which can perform such an analysis under atmospherically relevant conditions. The TD-CIMS (Thermal Desorption Chemical Ionisation Mass Spectrometer, Voisin et al. (2003)) is a unique instrument which is capable performing such measurements online and has already given important insights into some atmospheric processes leading to aerosol growth (e.g. Smith at al. (2010)). However, further studies are necessary, especially with respect to other environments and different particle sizes.

In this study, a new instrument is introduced which allows the size-resolved identification of the chemical composition of particles in the size range below 20 nm. The TD-DMA (Thermal Desorption Differential Mobility Analyzer) collects particles on a substrate and transfers them into the gas phase so that they can be analyzed with a mass spectrometer. The particles first pass through a DMA unit, so that only those with a selected size can reach the substrate. The substrate currently consists of a stainless steel wire to which HV can be applied in order to precipitate the particles. Once enough particles are collected, the substrate can be moved into the sample inlet of a chemical ionization mass spectrometer (CIMS). In this mode of operation the CIMS inlet line is flushed with ultrapure nitrogen and the wire is heated by electrical current which evaporates the particles into the clean carrier gas. This procedure ensures that on the one hand, only the particulate constituents will be analyzed and on the other hand they can reach concentrations which are high enough for chemical speciation.

The advantages of the TD-DMA are as follows: (1) The analysis is performed online. (2) The collection of particles is carried out size-resolved, as particles with different sizes likely have different chemical compositions. (3) The collection and evaporation unit is compact and can in principle be combined with different analyzing instruments. (4) The measurement time required for the particle evaporation is small compared to the overall measurement time. However, during the collection period the mass spectrometer can be used to measure the gas phase composition of the sample air. This feature allows obtaining a full picture of the processes occuring in the gas as well as the particulate phase with one single mass spectrometer.

Lab experiments with a tandem DMA setup have shown that the maximum transmission of the DMA unit is between 45% for 5 nm (see figure 1) and 60% for 15 nm. It could also be demonstrated that close to 100% of the size selected particles can be precipitated onto the substrate. Sulphuric acid particles 15 nm in diameter were successfully collected and subsequently evaporated in the inlet of a CIMS which showed signals characteristic for sulphuric acid.

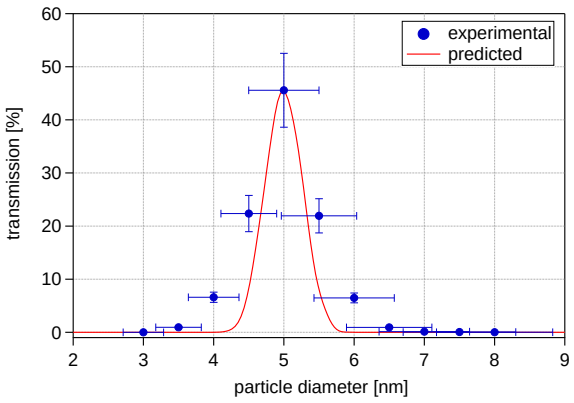

Figure 1: Experimental (blue) and predicted (red) transmission curve for particles with a diameter of 5 nm

The operational principle and the setup of the TD-DMA will be presented in detail. Results on the characterisation of the DMA transmission as well as first quantitative tests with respect to the collection and evaporation of different aerosol species will be discussed.

Development of an automated total carbon analyzer for atmospheric aerosols

Y. Komazaki and Y. Kanaya

Research Institute for Global Change, Japan Agency for Marine-Earth Science and Technology, Yokohama, Kanagawa, 222-0037, Japan

Keywords: carbonaceous aerosol, automated analyser, intercomparison.
Presenting author email: komazaki-y@jamstec.go.jp

Introduction

Increasing attention is being paid to carbonaceous aerosols, a major component in $PM_{2.5}$, owing to the importance of its complex effects over various geographical scales, such as its effects on human health, haze, the hydrological cycle, and climate change. However, the sources, atmospheric processes, and impacts of carbonaceous aerosols are not well understood; moreover, uncertainties in measurement methods tend to be high owing to the complexity of the physical/chemical properties of carbonaceous aerosols as compared with the properties of other components (e.g., inorganic ions and minerals) of $PM_{2.5}$.

Thermal–optical analysis (TOA) is a popular method for determining aerosol EC and OC collected on quartz filters. However, the temperature protocol (e.g., IMPROVE, NIOSH) and optical detection (transmittance, reflectance) adopted in TOA strongly affect the separation of OC and EC.

EC and OC concentrations at Fukue Island in Japan were measured from November to December in 2012 in a short-term campaign using a semi-continuous TOA analyzer (Sunset Laboratory). However, the liquid-based calibrations of the instrument using two thermal protocols, namely IMPROVE-like and Total-Carbon (only in O_2/He mixture), showed a difference of ca. 30%.

The purpose of this study is to develop an automated semi-continuous total carbon (TC, TC = EC + OC) analyzer employing a thermal technique and to minimize the uncertainties in the measurement of carbonaceous aerosol.

Experiments, Results, and Discussions

Based on thermal desorption analysis, a semi-continuous automated analyzer for TC (TC_JA) was developed in this study. One-step heating in 2% O_2/He mixture up to 870 °C was employed to evolve carbonaceous compounds sampled on a quartz filter. TC concentrations were measured as CO_2 through a heated column with an oxidizing catalyst (MnO_2) using an NDIR CO_2 analyzer (LI-840A).

TC concentrations in Yokosuka, Japan, were measured using the semi-continuous carbon analyzer (Sunset Laboratory) and the TC analyzer developed in this study, and comparisons were conducted during the period from Sep 2012 to Feb 2013. A $PM_{2.5}$ sharp-cut cyclone (BGI) and a denuder (Sunset) were employed to remove any volatile organic compounds from the sample air.

Under almost the same thermal Total-Carbon protocols, the TC concentrations measured by the Sunset and newly developed instruments (TC_Sunset and TC_JA) were in good agreement, as shown in Figure 1. In the range below 4 μg/m^3, however, the TC_Sunset/TC_JA ratios were found to be concentration dependent, with higher ratios occurring in the lower concentration range. This result might indicate the better performance of the detection system as a result of the detector, theromogram data system (CDS plus, LAsoft), and/or gas dryer (Perma Pure) using Nafion membrane tubing, which continuously removes only water vapor from the gas streams.

In addition, TC_IMPROVE (OC + EC) measured using the Sunset analyzer was compared with the TC_JA. The concentrations with TC_IMPROVE tended to be higher than those of TC_JA (ca. 30% with a strong correlation). Identification of the exact origins of these differences is underway. These results will help to understand the differences in the liquid-based calibrations at Fukue.

We recommend that measurements by TOA should be undertaken using different protocols, such as IMPROVE-like and Total-Carbon protocols, for the accurate determination of EC and OC.

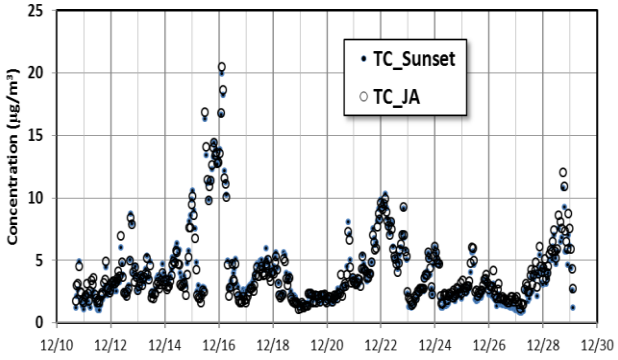

Figure 1 TC concentrations in Yokosuka, Japan, measured using the Sunset carbon analyzer and the TC analyzer developed in this study, Dec 2012

Remotely operated PLUS-octocopter used as an aerosol measurement platform

P. Madl, C. Oberauer and F. Steinhäusler

Division of Physics and Biophysics, Department of Materials Engineering and Physics, PLUS University, Salzburg, A-5020, Austria
Keywords: unmanned aerial vehicle, flying aerosol measurement platform
Presenting author email: pierre.madl@sbg.ac.at

The herein presented design is part of the *BRIDGE* Concept Case Advanced Situation Awareness for proactive risk management. It will fill this gap by providing the user inter alia with real-time data on the extent of airborne pollution inventories.

One of the core-component is a manually controlled unmanned aerial vehicle (UAV), termed PLUS-Octocopter. As shown in Fig. 1, the system consists of a ground-station, a wireless communication link and the sensor-equipped flying platform. The latter houses 8 electric motors, Global Positioning System (GPS) for stabilized flying mode, two different cameras (visual (VIS) / infra-red (IR)) an onboard-computer and several solid state sensors (T, rH, p, β, γ) as well as a particle number counter (P_N) and a particle mass detector (P_M). Table 1 summarizes its core specifications:

Table 1. Technical specifications of the UAV.

UAV	Octocopter
Power supply	20Ah Li-polymer rechargeable batteries
Flying time	>15min, less at windy conditions
Weight	5 kg (incl. LiPo-pack)
add. payload	2.5 kg
Downlink	Radio-controlled @ 2.4 GHz
2D-sensors	2-servo-adjusted camera unit i) VIS camera (0.4 - 1 µm) i) IR-camera (7.5 - 13 µm)
1D-sensors	Atmospheric (T, rH, p) Radiation (β, γ) Particle mass (µg/m^3) Particle number conc. (1/cm^3) Gases (CO, CO_2, C_2H_6, CH_4, N_2O)
DPU	Win-OS ultra small PC
Flight rec.	120 GB shock resistant SSD
GPS	Flight control & auto-homing
Ground	
Downlink	Radio-controlled @ 2.4 GHz
Win-OS Laptop	Visualization of area (IR & VIS) and display of sensor data

UAV-Characteristics: Although the vehicle is controlled via the ground station, the onboard computer is used both as the data processing unit (DPU) for the control signals keeping the system airborne, as well as a flight recorder for logging flight-sensitive parameters; i.e. status of each cell within the LiPo-packs, GPS-data (location, altitude, flight path). At the same time the DPU-hub logs all the sensor data along with the VIS/IR-data streams. The up- and downlink system, which is likewise controlled via the DPU, is achieved using a commercially available high-power WLAN system operating in the 2.4 GHz-band. At any time, and at least at batteries in reserve capacity status, the UAV will be switched into GPS-guided automatic homing mode.

UAV-sensors: Apart from the 2-D-sensors and the standard atmospheric sniffers (see Table 1), the UAV features two aerosol sensors. The P_M-sensor detects mass-fractions <10µm with a sensitivity of <5ng (with the UAV grounded and slightly less in a stationary humming, airborne mode). The P_N-sensor records particle number concentration in three different size classes simultaneously (0.3, 2.5 and 10 µm). Both aerosol sensors require a data acquisition time of 10 sec, which translates into 6 readings per minute. A different set of sensors regard the solid-state pyroelectric sensors to detect gaseous substances. Their detection principle rests on the specific absorption bands in the IR-window in-between 3 to 5 µm (for the various gases listed in Table 1). The entire throughput of the sample air through the sensor-compartment is achieved via a miniature carbon-vein pump at a constant flow-rate of 5 L/min.

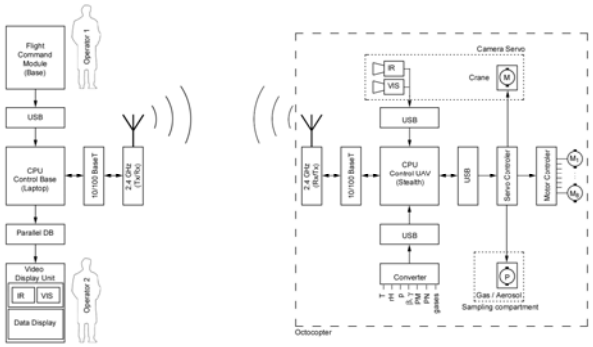

Figure 1. Schematic block diagram of the PLUS Octocopter-system, highlighting ground station and the UAV. *Legend*: Tx, Rx, Transmitter and receiver for the corresponding frequencies; M, Step-motor, M_1-M_8: lifting electric-motors; P, pump; VIS & IR, USB-compatible VIS and IR-camera units, CPU, Central processing unit; USB, Universal Serial Bus; Parallel DB, parallel Data Bus; 10/100BT, bidirectional Ethernet link; T, rH, p, β, γ, P_M, P_N, sensor compartment (see text).

Field of application: the above described system can be used for assisting incident commanders, fire-fighters, environmental air-quality monitoring at stacks, or other emission sources with limited access.

This work was partially supported by the 7th EU Framework Project No. 26.18.17. (BRIDGE).

Establishing to what extent a methodology for identifying pollution sources is appropriate for a specific purpose and expressing the reliability of the results quantitatively is complex.

In order to assess model performances and estimate their uncertainties, intercomparison exercises (IE) have been conducted within the framework of the JRC Initiative on Harmonization of Source Apportionment with Receptor Models (RM).

The present IE involved 20 expert groups from Europe and 2 from South America and was performed using a synthetic database (DB) developed on purpose.

The test DB consisted of 364 $PM_{2,5}$ daily samples including total mass and 38 inorganic and organic species deriving from a simulation of the CAMx PSAT tool for the calendar year 2005 and extracted for a cell corresponding to the city of Milan.

A total of 26 solutions obtained using the following model versions were reported for evaluation: EPA PMF 3.0 (12), EPA PMF 4.1 (1), EPA PMF 5.0 (1), PMF2 (3), EPA CMB 8.2 (4), EPA CMB ROBOTIC (1), FA MLR (1), COPREM (1) and ME-2 (1).

Participants provided the number and label of the identified sources, their contribution estimation (SCE) and uncertainty. In addition, the source/factor chemical profiles, the contribution of the sources to each species and the contribution of each source/factor in each sample were also reported.

Source/factors identified by participants were classified into 9 different source categories: biomass burning, traffic exhaust, road dust, sulphates, nitrates, crustal material, industry and secondary. An 85% of participants reported a number of source/factors close to the "true" number of sources in the synthetic database (±2).

The inclusion of every source/factor into a category was checked by comparing its chemical profile and time trend with all the other members of the same category and with the reference source. The SCEs of the different solutions were compared with the reference source contributions in the synthetic database using the z-score and z'-score indicators (ISO 5725-5) according to the methodology described by Karagulian & Belis, (2012).

More than 80% of the 200 assessed source/factor contribution estimations met the acceptability criterion when compared to the source contributions used in the creation of the synthetic database. Even though, these results are about 10% lower than those obtained in a previous intercomparison using real-world data, a quite satisfactory ability of RM to retrieve the "true" source contributions comes out from this IE.

Keywords: fine aerosol, Negev desert, elements, source areas.
Presenting author email: willy.maenhaut@ugent.be

From January 1995 through December 2004 aerosol samples were collected with a Gent stacked filter unit sampler at Sde Boker, Israel. The samples were collected according to a 2-2-3 day schedule, which resulted in about 150 samples per year. The samples were analyzed for the particulate mass (PM) by weighing, for black carbon (BC) by a light reflectance technique, and for up to 46 elements by a combination of particle-induced X-ray emission (PIXE) and instrumental neutron activation analysis (INAA) (Maenhaut *et al.*, 2001). Here, we report on the fine (PM2) size fraction data for the PM, BC, and the following 9 anthropogenic elements S, V, Ni, Cu, Zn, As, Se, Sb, and Pb.

The annual medians of the PM, BC, and the 9 anthropogenic elements were examined for time trends. The largest changes over the 10-year period were found for S, Ni, Se, Sb, and Pb and they were -34%, -25%, -47%, +26%, and -40%, respectively. Substantial changes were also noted for the PM and Zn, i.e., of -18% and -12%, respectively, whereas no changes were noted for BC and the other elements. The decreases for S and the PM are consistent with those observed by Karnieli *et al.* (2009) for the July and August data from the same site.

The seasonal variation was also examined. The largest variation was seen for S, which exhibited 1.6 times larger concentrations in summer than in the other 3 seasons. As to the other elements, a similar seasonality was observed for As with 1.4 times enhanced concentrations in summer, and to a lesser extent also for the PM and Zn. That the PM follows S is not surprising as sulphate (estimated as 3 times S) accounted, on average, for 36% of the PM2 mass. For V, Ni, and Sb there was a clear tendency for lower concentrations in summer than in the other seasons. Pb exhibited its highest concentrations in fall and winter and virtually no seasonality was seen for BC, Cu, and Se.

S was substantially correlated with the PM ($r = 0.65$), whereas its correlation coefficients with BC and the 9 elements were all lower than 0.5. V and Ni were very highly correlated with each other ($r = 0.94$) and substantially ($0.5 < r < 0.7$) with BC, Sb, and Pb. The correlation between V and Ni, together with the average V/Ni ratio of 2.3±0.5 clearly point to heavy oil burning as the predominant source of both elements. Since BC at the site is thought to originate predominantly from the incomplete combustion of fossil fuels, it is not surprising to see that it is correlated with V and Ni. Cu was best correlated with BC ($r = 0.53$) and the correlation coefficients of Zn, As, and Se with the other elements, BC, and the PM were all lower than 0.5.

Trajectory statistics (Lupu and Maenhaut, 2002), using 10-day back trajectories with arrival at 300 m above ground, was applied to assess the source areas of the PM, BC, and the 9 elements. The trajectories came predominantly from the northwest, but there were seasonal differences in the transport pathways, with westerly ones becoming important in winter and northerly ones important in summer. The concentration field map for S is shown in Figure 1. It appears that the prevailing source region for S was southeastern Europe (i.e., Turkey, Bulgaria, Romania, Ukraine, and southern Russia). As had the southeastern part of European Russia as its prevailing source area, while the source picture for Zn was rather unclear. The other 6 anthropogenic elements and BC seemed to originate mainly from regional sources (i.e., Jordan, Syria, Iraq, and Saudi Arabia).

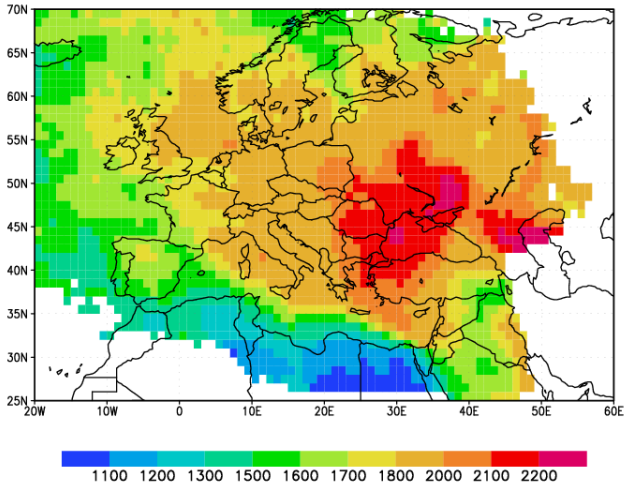

Figure 1. Fine S concentration field (ng/m^3, with the concentration scale shown at the bottom) as computed with trajectory statistics.

Emissions from the marine transport sector contribute significantly to air pollution globally (Corbett & Fischbeck, 1997). Around 15% of global NOx and 5-8% of global SOx emissions are attributable to oceangoing ships (Eyring et al., 2005). Because nearly 70% of ship emissions are estimated to occur within 400 km of land, ships have the potential to contribute significantly to air quality degradation in coastal areas.

Shipping emissions are currently increasing, and even more so in the future due to the globalization of manufacturing processes and the increase of global-scale trade (USEPA, 2009). This increased flow of commercial ships into and out of ports does not only affect major ports, but also medium and small-scale ones. Although shipping contributes significantly to the international transportation sector, its emissions are not well quantified and are one of the least regulated anthropogenic sources.

In this context, the European Environment Agency initiated a project to investigate the current impact of the ship emissions on the ambient air levels of primary and secondary aerosols, and how the predicted future growth of ship traffic and the geographical expansion of waterways and ports, possibly combined with international regulations, will affect the atmospheric composition. In order to design and implement effective regulation to minimise environmental impacts of these emissions, detailed knowledge is necessary on their effects on climate and on their contribution to atmospheric pollution.

An in depth literature review was carried out focusing on the assessment of the impacts of shipping emissions and activities on urban air quality in coastal areas. The initial conclusion extracted from this review is that studies addressing this topic are relatively scarce, and that therefore there is a need to encourage this type of assessment in European coastal (and potentially, inland) areas. In particular, quantitative studies are especially scarce.

In addition to the literature review, the contribution of shipping activities to the degradation of European air quality and regional climate change was assessed by means of sensitivity chemistry transport simulations with the CHIMERE model based on the emission projections of the Global Energy Assessment.

The literature review evidenced that shipping emissions contribute to ambient PM levels in European coastal areas with 1-7% of PM_{10}, 1-14% of $PM_{2.5}$ (reaching a maximum of 20% in Genoa, Italy) and at least 11% of PM_1 (data for this size fraction available only for 1 location). Thus, it is evident that the impact of shipping activities increases with decreasing particle size. For the sake of comparison, contributions reported for non-European harbours (USA) were <5% of $PM_{2.5}$ in Los Angeles and 4-6% of $PM_{2.5}$ in Seattle. Spatially, shipping contributions to urban air quality degradation are higher in Mediterranean cities than in Atlantic coastal areas. However, it must be highlighted that results were obtained using different approaches and methodologies in the different regions, and thus may not be directly comparable.

The data available on gaseous pollutants is even more scarce than for PMx. Contributions from shipping to ambient NO_2 levels range between 7 and 24%, with the highest values being recorded in the Netherlands and Denmark. Increases in SO_2 concentrations were only reported in Sweden, as relative increases with respect to background concentrations and not in absolute terms.

Finally, current research evidences that shipping emissions impact not only the levels and composition of airborne particles and gaseous pollutants, but that they also may enhance new particle formation in urban areas and contribute to other forms of air quality degradation.

The modelling exercise evidenced that, to date, ships are responsible for about half of the NO_2 and SO_2 concentrations found over sea surface. In the future, SOx emissions are expected to be reduced, so that the contribution of ships to SO_2 over sea surface will decrease to about 1/3, whereas their contribution to absorbing BC will be higher than for the present-day.

In coastal areas, ships are responsible for about 7-8% of human exposure to particulate sulphate and 4% of the exposure to $PM_{2.5}$ and ozone peaks. The model results offer a good insight into the geographical variability of the impact, which is consistent with the estimates derived from ambient air monitoring.

Hourly elemental composition and source identification of fine and coarse particulate matter in the high polluted industrial area of Taranto (Italy)

F. Lucarelli[1], G. Calzolai[1], M. Chiari[1] and S.Nava[1]

[1]Department of Physics and Astronomy, University of Florence and National Institute of Nuclear Physics (INFN), Sesto Fiorentino (Florence), 50019, Italy

Keywords: PIXE, hourly composition, source apportionment, steel plant
Presenting author email: lucarelli@fi.infn.it

Taranto, an ancient Italian town lying on the Ionic Sea coast, is nowadays one of the most industrialized towns in the South of Italy. An industrial area, that includes the biggest steel plant of Europe, one of the biggest Italian refinery, a power plant and a big cement industry, is located in the northern suburbs of the town. During the last year pollution problems of this area have come under the spotlight and have become a very compelling issue for the policy makers.

In the frame of an extensive environmental investigation, promoted by the Italian Health Ministry, the ISPESL (Istituto Superiore per la Prevenzione e la Sicurezza del Lavoro) and the CNR (Consiglio Nazionale della Ricerca), aerosol samples were collected with high time resolution and analysed by PIXE. The project included two sampling campaigns (February–March and June 2004), in two different sites: Tamburi (site A in the following), an urban district in Taranto adjacent to the industrial area, and Statte (site B), a small town located 7 km N-NW of Taranto. Site A is a dense populated quarter subject to a heavy pollution flux; site B is located along the direction of prevalent winds from the industrial area.

The fine (< 2.5 μm) and coarse (2.5-10 μm) fractions of particulate matter were simultaneously collected in the two sampling sites by means of two ‘‘streaker’’ samplers (PIXE International Corporation). PIXE analyses were performed with a 3 MeV proton beam from the 3 MV Tandetron accelerator of the INFN-LABEC laboratory (Calzolai et al., 2006). These analyses allowed the assessment of the concentrations of several elements (Na, Mg, Al, Si, P, S, Cl, K, Ca, Ti, V, Cr, Mn, Fe, Ni, Cu, Zn, Br, Sr and Pb), including important industrial tracers, with hourly time resolution.

Although the vast majority of results in literature are limited to time resolution of the input samples of typically 12 or 24 h, most particulate emissions as well as their atmospheric transport and dilution processes change within a few hours and daily samples are not capable of tracking these rapid changes. Furthermore, source apportionment receptor models need a series of samples containing material from the same set of sources in differing proportions and increasing the time resolution of the measurements typically provides samples that have greater between-sample variability in the source contributions than samples integrated over longer time periods.

In this study the high time resolution of the adopted approach allowed us to follow in detail changes in the aerosol elemental composition due to both the time evolution of the industrial emissions and the time changes in meteorological conditions and thus transport pathways. Moreover, the location of the sampling sites, along the prevalent wind direction and in opposite position with respect to the industrial site, allowed us to follow the impact of the industrial plume as a function of wind direction.

The most significant feature of this data set is the presence of very high hourly concentrations of Fe (up to 15 μg/m^3 in the fine fraction and 12 μg/m^3 in the coarse one) and Mn (up to 170 ng/m^3 and 115 ng/m^3 in the fine and coarse fractions, respectively), which are typical tracers of steel smelter emissions. Their time trends are high correlated and show sharp peaks, typical of industrial emissions, which are in opposite phase in the two sampling sites (Fig. 1).

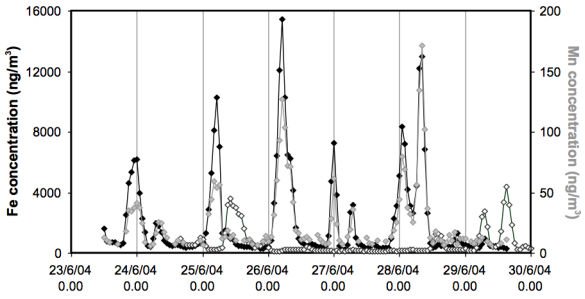

Figure 1. Hourly time trends of fine Fe (black) and fine Mn (white) in site A, and fine Fe (grey) in site B.

Positive Matrix Factorisation (PMF) has been applied to the data to assess the main aerosol sources, and in particular the impact of industrial emissions. Results of these analyses will be shown.

Presenting author email: petra.karkulin@post.cz

The ambient aerosol source composition is particle size dependent (Dodd, 1991). Therefore, to improve the accuracy of aerosol source apportionment, size segregated aerosol measurement with high time resolution is required (Han, 2005; Peré-Trepat, 2007). The objective of presented study was to identify sources of size resolved ambient aerosols in industrial city Ostrava in Czech Republic, Central Europe.

Measurements were conducted from 26th Jan to 21st Feb 2012 in Ostrava city in the north-east part of the Czech Republic. The heavy industrialized city, accumulation of steel industry and coke plants, counts among the worst air quality region in EU.

A Davis Rotating-drum Uniform-size-cut Monitoring (DRUM) was used to sample with 1-h time resolution aerosol particles of aerodynamic diameter D_p for three size modes A (10 μm > Dp > 1.15 μm), B (1.15 μm > Dp > 0.34 μm) and C (0.34 μm > Dp > 0.1 μm). Aerosol masses were calculated from five minute data by Aerodynamic Particle Sizer, APS (3321, TSI) and Scanning mobility Particle Sizer, SMPS (3963, TSI). To evaluate middle-scale $PM_{2.5}$ variability in an urban airshed, $PM_{2.5}$ measurement by 7 laser photometers DustTrak, DT (8520, TSI) in a network arrangement was conducted. Complete meteorology wind speed (WS) wind direction (WD), temperature (T), relative humidity (RH), global radiation (GR), precipitation (P) were also concurrently recorded.

A bilinear receptor model, EPA PMF 4.2.0.0, was used to resolve the possible sources for 60 minutes mass integrates for three sizes m as measured by APS and SMPS and elemental composition for 28 elements sampled by 3DRUM analyzed by S-XRF.

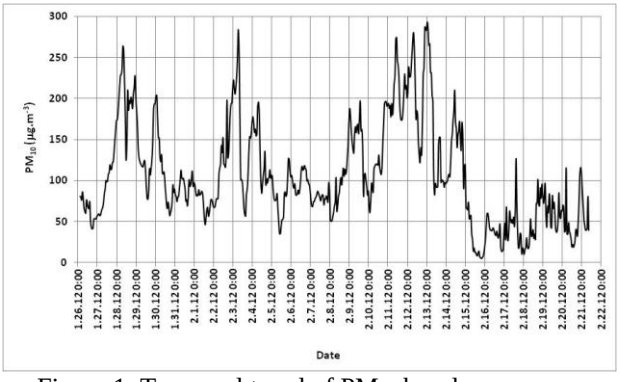

Figure 1. Temporal trend of PM_{10} hourly averages.

According to the different meteorological condition and PM_{10} levels the measuring campaign was separated into two periods, smog and after smog. The smog period characterized low T (median=-14.8 °C), WS (median=0.7 $m.s^{-1}$), WD prevailing from NE and high PM_{10} (median=108 $\mu g.m^{-3}$) lasted from 26th Jan to 14th Feb. The after smog period (15th – 21st Feb) was characterized by grow of T (median=-1.7 °C), WS (median=1.1 $m.s^{-1}$), WD prevailing from NW to SW and precipitation, which resulted in PM_{10} decrease (median=40.1 $\mu g.m^{-3}$) (Figure 1.). The median of three size fraction (A, B and C) during smog episode and after is quoted in the Table 1.

Table 1. The three fraction median value for smog and after smog episode in Ostrava 26th Jan-21st Feb 2012.

Size fraction	Smog	After smog
	median ($\mu g.m^{-3}$)	
A	22.1	11.5
B	39.1	10.8
C	47.6	15.4

The $PM_{2.5}$ inter-DT differences in the course of measurement were not statistically significant. We may conclude, that the monitoring station was well positioned and the measurements eligible at least for a middle scale of urban airshed.

The PMF resolved from five to six possible sources related to the size fraction. The sources of B and C fraction corresponded to each other from 83 % (5 sources from total number of 6 sources). The A fraction sources matched with the two fraction sources from 60 % (3 sources from total number of 5 sources). The antrophogenic sources industry, combustion and traffic (exhausted and nonexhausted emission) contributed most to PM_{10}.

It is well known that the particle size plays a major role in determining the particle penetration in the respiratory system and therefore in threatening human health.

Despite this fact, data on PM1 composition and sources are still relatively rare. This work aimed at a detailed physical and chemical characterisation of PM1 to obtain the mass closure and to perform a source apportionment study using receptor modelling. Episodes with very high PM1 pollution levels were analysed in detail to identify processes/sources affecting this fine PM fraction.

Moreover, a critical comparison to the results obtained during the previous PM1 campaigns carried out by our group at the same location about 10 years ago (Vecchi et al. 2004; Vecchi et al., 2008) will be also shown.

PM1 was sampled at an urban background station in Milan, Italy, during winter 2011-2012. Milan is the greatest urban area in the Po Valley, a well-known hot-spot pollution area in Europe, especially during wintertime. Parallel PM1 sampling was carried out during daytime and nighttime (07-16, 19-04) on PTFE and quartz fibre filters using two low-volume samplers for a total of about 300 samples. Mass concentration was determined by the gravimetric technique and all the PM1 samples were chemically characterised for elements, inorganic ions, levoglucosan, EC/OC and water soluble organic compounds. BC determination was also carried out on both PTFE and quartz fibre filters by a polar photometer (Vecchi et al., 2010; Vecchi et al., 2012). Moreover, BC concentrations in PM1 were monitored with a 5 minute resolution by a MAAP. Ancillary information on atmospheric dispersion conditions was available by ^{222}Rn measurements and the main meteorological parameters (temperature, pressure, RH, solar radiation, wind speed and direction) were also monitored at the sampling site.

PM1 data were analysed by receptor modelling using Multilinear Engine ME-2 and 5 factors were identified. The most relevant contributions to PM1 were from ammonium nitrate and biomass burning (about 30% each) followed by ammonium sulphate (about 20%), traffic (about 15%) and industry (about 5%).

Keywords: source apportionment, traffic, particulate matter, source profiles.
Presenting author email: pxp024@bham.ac.uk

Road traffic is one of the key sources of particulate matter (PM) concentrations in urban areas, and a good understanding of the contribution of traffic emissions to PM mass is imperative for policy action. Receptor models such as the Chemical Mass Balance (CMB) and Positive Matrix Factorization (PMF) are routinely used for quantitative estimation of source contributions to PM. The CMB model, based on the principle of mass balance, requires locally-relevant profiles for reliable source contribution estimates (SCEs).

The aim of this study was to assess the response of the CMB-MM model to molecular marker profiles for traffic derived using different sampling approaches, i.e. dynamometer and twin-site sampling (Schauer *et al.*, 1996). The traffic estimates thus obtained were cross-compared using other proposed methods as described in Figure 1.

24-hour samples were collected using high-volume samplers at roadside, urban background and rural sites in Birmingham and London (UK) in 2007 and 2011 respectively. Chemical analysis was carried out using GC-MS as described in Yin *et al.* (2010).

Using ambient measurement-based molecular marker data from the roadside and background sites in London, a composite traffic profile for $PM_{2.5}$ OC was created. Based on previous studies and information about key sources in the area, a total of six profiles were used including vegetative detritus, wood combustion, coal combustion, natural gas, crustal dust and traffic (diesel, gasoline and smoking engine). Ambient data was analysed using the CMB8.2 software for attribution of $PM_{2.5}$ OC mass to different sources. The marker species for the sources were monitored using the MPIN matrix and cross-compared with other published studies and the r^2 and χ^2 were observed to be between 0.96-1.00 and 0.08- 3.00 respectively. $PM_{2.5}$ estimates were obtained using OC to $PM_{2.5}$ source conversion ratios previously published in Yin *et al.* (2010).

The model resolved the CMB mass reasonably well with both composite and dynamometer profiles with 88.8-117.1% of the $PM_{2.5}$ mass resolved across all datasets. In terms of resolution of the traffic source, while there was overall agreement between the SCEs from the different profiles, the t-stat values for the composite profile were consistently lower than the dynamometer profile runs. Comparisons with mass closure and the EC-tracer calculations lead to the conclusion that the composite profiles estimates the traffic source contribution better than the dynamometer profile. However, it is important to bear in mind that the traffic profiles generated using ambient data have higher uncertainties and the chemical species can be subject to oxidation in the atmosphere, both of which can impact upon the model output.

Analysis is currently underway to prepare traffic source profiles using tunnel data which will then be compared against twin-site profile and dynamometer profiles.

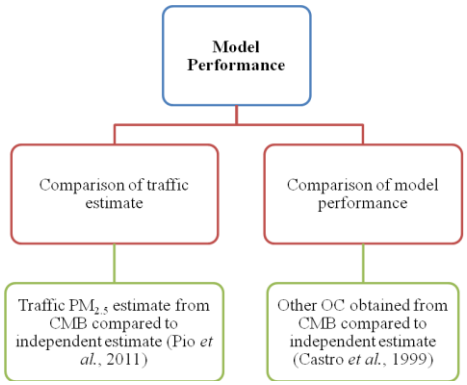

Figure 1: Assessment of model performance using independent estimates

PMF source apportionment for fine and coarse PM in Athens, Greece: Evolution of source contributions over the last decade

K. Eleftheriadis[1], E. Diapouli[1], A. Karanasiou[2], S. Vratolis[1], V. Vasilatou[1], M. Gini[1], D. Saraga[1], S. Pateraki[1], Th. Maggos[1]

Particulate air pollution remains a significant environmental problem in big urban centres in Europe and around the world. The development of effective control policies calls for the identification of the main particulate matter (PM) sources, as well as the quantification of their contribution to elevated concentration levels. The city of Athens has been known to face severe air pollution problems due both to the presence of multiple particle sources and to the meteorological conditions and topography that promote pollutants build-up. The presence of significant natural sources further complicates the efforts to apply effective mitigation measures and to ensure compliance with air quality guidelines. The objective of the present work was to identify the major PM sources in the Athens area, quantify their relative contribution to coarse and fine particle concentrations and examine their evolution over the last decade.

Source apportionment by positive matrix factorization (PMF) analysis was performed on two $PM_{10}/PM_{2.5}$ datasets from 2002 and 2012. Both datasets covered warm and cold period. The 2002 measurement campaign included 24-hr gravimetric measurements from three urban residential sites. The collected teflon filters were analysed for a number of elements by electrothermal atomic absorption spectrometry (Cd, Pb, V, Ni, Mn, Cr, Cu, Fe and Al) and flame atomic absorption spectrometry (Ca, Mg, K and Na), as well as for major anions (Cl^-, NO_3^- and $SO4^{2-}$) by ion chromatography. In addition, black carbon (BC) data were obtained by means of an aethalometer (AE-9, Maggee Sci). The 2012 campaign was conducted at two urban background sites. 24-hr gravimetric measurements were performed with two different filter substrates (teflon and quartz) in order to allow for a more extensive chemical characterization of the aerosol fractions. Elemental composition was again quantified by electrothermal and flame atomic absorption spectrometry. Ionic species (Na^+, Mg^{2+}, Ca^{2+}, K^+, NH_4^+, SO_4^{2-}, NO_3^-, Cl^-) were quantified by ion chromatography, while elemental (EC) and organic (OC) carbon were also measured by thermal-optical methodology.

Two-dimensional Positive Matrix Factorisation (PMF) has been applied to each dataset. Details on input data preparation are provided in Karanasiou et al. (2009). Two PMF models were used, PMF2 (Version 4.2) and EPA PMF 3.0, and the obtained results were compared. Analysis was performed for different numbers of factors and the best solution was chosen based on goodness of fit parameters (Q value and the explained variation of the matrix F) as well as by examining the obtained factors profiles with respect to the possibility of associating them with specific source. In addition, multiple values of Fpeak (in the range -2.0 to 2.0) were examined in order to explore different rotations of the solutions.

In general the two models applied showed good agreement of results. Vehicular traffic was found the main contributor to fine particle concentrations, with marine aerosol also playing a major role. Fossil fuel combustion and traffic contributions were similar. Coarse particles concentrations seemed unaffected by all combustion-related sources and were attributed to a large extent to natural sources (sea salt, soil). (Figure 1)

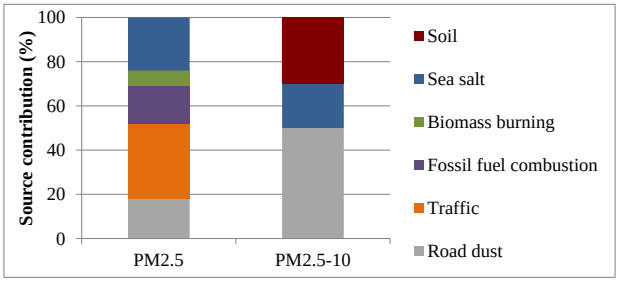

Figure 1. Relative contribution (%) of each source to PM concentration levels (Year 2002).

PMF analysis on the 2012 dataset is still in progress but initial results indicated a differentiation in PM source contributions over the last decade. This is also evident by the reduced concentration levels, attributed to a decrease in anthropogenic emissions either because of efficient mitigation measures (new-technology "cleaner" vehicles, traffic regulations etc.) and/or lower anthropogenic activity due to the financial crisis of the last two years. The final results are expected to provide an interesting insight into the present air pollution situation in the city and the potential "new" major contributors to the observed daily exceedances of air quality guidelines.

This work was supported by the European Commission LIFE+ Environment Policy and Governance programme.

Session: Atmospheric Aerosols
New particle formation

Role of organics in particle nucleation as viewed from a positive ion spectrometer

Formation of new particles from trace gases (nucleation) has been recognized as the main source of aerosols in the atmosphere. It is estimated that nucleation can be responsible for up to 50% of the total cloud condensation nuclei (CCN) concentration (Merikanto et al., 2009). However, the formation of new particles in the atmosphere is still a poorly understood process despite its importance. In recent years sulfuric acid (H_2SO_4) has emerged as the key player in atmospheric nucleation. In many field campaigns a good correlation between the concentration of H_2SO_4 and the rate of particle nucleation was found. Laboratory experiments have shown that binary H_2SO_4-H_2O homogeneous nucleation cannot explain the observations in many regions of the atmosphere. Ion-mediated nucleation (IMN) is discussed as a potential strong source of aerosol formation and as a mechanism of influence of cosmic rays on clouds and climate. Based on model simulations Yu et al. (2008) conclude that IMN is significant on a global scale. Thus, it is very important to determine which trace species participate in the first steps of the nucleation process and which mechanisms govern the nucleation.

Experiments were performed in the CLOUD chamber which allows the study of nucleation rates under highly controlled conditions of temperature, humidity and trace gas concentrations. This 26 m^3 stainless-steel chamber is equipped with state-of-the-art instruments can be exposed to a π^+ beam coming from CERN's proton synchrotron to simulate the effect of the galactic cosmic rays on the new particle formation process. On the other hand a 20kV/m electric clearing field can be engaged to enforce an ion-free environment.

We investigated new particle formation of sulfuric acid (H_2SO_4) in the presence of compounds such as ammonia, dimethylamine ($(CH_3)_2NH$), α-pinene ($C_{10}H_{16}$) and pinanediol ($C_{10}H_{18}O_2$). The nucleation process was induced either by ozonolysis of α-pinene or OH radical reactions produced by UV-photolysis of ozone or HONO.

Here we present results obtained with the atmospheric pressure interface time-of-flight mass spectrometer (APi-TOF, Tofwerk and Aerodyne Research) operated in the positive ion mode (Junninen et al., 2010). This instrument samples directly the ions present in the CLOUD chamber through a critical orifice and measures their mass-to-charge ratio at a resolution higher than 5000 Th/Th and a mass accuracy lower than 10 ppm. Due to the high resolution of the instrument the composition of the evolving positive charged clusters could be measured for the various systems: H_2SO_4–NH_3, H_2SO_4–DMA and H_2SO_4–oxidized organics (OxOrg). In the case of the H_2SO_4–NH_3 system we observed $(H_2SO_4)_n \cdot (NH_3)_{n+1} \cdot H^+$ positive ions for low *n* and one extra molecule of ammonia for higher *n*. In the presence of DMA ammonia was substituted by DMA but the composition and stoichiometry remained essentially the same. However, the time evolution of the cluster formation was quite different for the two systems. In the case of H_2SO_4–OxOrg clusters were found in the m/z range from 200 Th up to 1500 Th. Highly oxidized organic species were observed. In all those positively charged clusters, whose chemical composition could be identified, no H_2SO_4 was observed. These results with the positive ion spectra obtained in the laboratory will be compared to measurements in the ambient atmosphere during nucleation events.

We thank CERN for supporting CLOUD with important technical and financial resources, and for providing a particle beam from the CERN Proton Synchrotron. Western Australia was originally covered by natural eucalyptus forests, but land-use has changed considerably after large scale deforestation from 1950 to 1970. Thus, the ground-water level rose and brought dissolved salts and minerals to the surface. Nowadays, Western Australia is known for a great plenty of salt lakes with pH levels reaching from 2.5 to 7.1. The land is mainly used for wheat farming and livestock and becomes drier due to the lack of rain periods. One possible reason could be the formation of ultrafine particles from salt lakes, which increases the number of cloud condensation nuclei and thus potentially suppresses precipitation.

Several field campaigns have been conducted between 2006 and 2011 with car-based and airborne measurements, where new particle formation has been observed and has been related to the Western Australian salt lakes (Junkermann et al., 2009). To identify particle formation directly above the salt lakes, a 2.35 m³ PTFE chamber was set up above several lakes in 2012. Inside the chamber, photochemistry may take place whereas mixing through wind or advection of already existing particles is prevented. Salt lakes with a low pH level lead to strongly increased aerosol formation. In two chamber experiments also aerosol filter samples have been taken. The chemical analysis of the anions by ion chromatography showed a 8 to 17 times higher concentration of Cl^- than SO_4^{2-}. Thus, the particle formation seems to be influenced by halogens.

As salt lakes have been identified as a source for reactive halogen species (RHS; Buxmann et al., 2012) and RHS seem to interact with precursors of secondary organic aerosol (SOA), they could be producers of halogen induced secondary organic aerosol (XOA) (Ofner et al., 2012).

As reference experiments, laboratory based aerosol smog-chamber runs were performed to examine XOA formation under atmospheric conditions using simulated sunlight and the simplified chemical composition of a salt lake. The mixture included $FeSO_4$, NaCl and Na_2SO_4. After adding α-pinene to the simulated salt lake, a strong nucleation event began (Figure 1) in the absence of ozone comparable to the observed events in Western Australia in 2012. First results from the laboratory based aerosol smog-chamber experiments indicate a halogen-induced aerosol formation above Australian salt lakes. To validate this hypothesis, additional measurements above several salt lakes of Western Australia will be conducted in spring 2013 with combined physical and chemical investigations. The particle number size distribution will be recorded by a mobile DMPS system and for further chemical analysis filter and impactor samples will be taken.

Secondary organic aerosols (SOA) are an important component of tropospheric aerosols. A large fraction of secondary organic aerosols has biogenic sources. The contribution of monoterpenes (MT), isoprene, and sesquiterpenes (SQT) to BSOA formation after atmospheric oxidation are well known. Since aerosols play a role for climate by direct (light scattering and absorption) and indirect effects (cloud albedo, rain probability, cloud lifetime), SOA provides couplings between vegetation, air chemistry and climate. Currently these couplings are believed to provide overall a negative feedback (Kulmala et al., 2004, Goldstein et al., 2009).

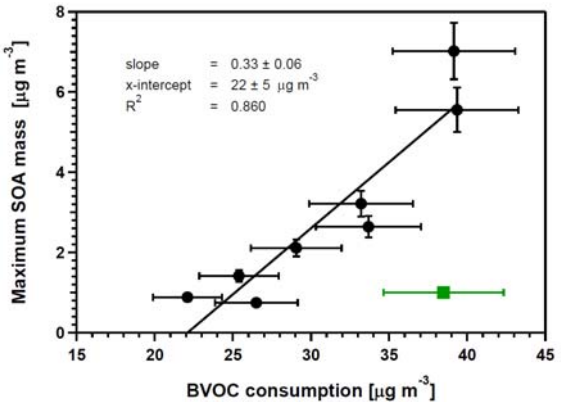

Figure 1, Maximum SOA mass versus consumption of C_{17}–BVOC dominated emissions. Black circles: data obtained at low contribution of GLV. Green square data point obtained on day 0 at high GLV emissions.

However, already SQT indicate that it is probably not sufficient to only consider the constitutive MT and isoprene emissions (Arneth and Niinemets, 2010). Plants tend to change emission patterns and strength, when they are facing stress (insect and pathogen attacks, heat, drought). Typical stress induced emissions are SQT, methylsalicylate (MeSa), and green leave volatiles (GLV). It is not unlikely, that fractions of forests always are exposed to biotic stress e.g. by insect or pathogen attacks, causing latent or episodic SIE emissions. On top heat or drought periods will modify the emissions. This would modify constitutive and SIE emissions episodically.

We determined the incremental mass yields of SOA formation from SIE caused by biotic stressors (Table 1). To simulate future climate effects we applied heat and drought on top. The experiments were performed with individual trees or small stands in the Jülich Plant Atmosphere Chamber JPAC (Mentel et al., ACPD 2013). Before the experiments trees were stored outside, near a forest, to simulate natural (stress) conditions. The trees were transferred to the JPAC for studies under controlled conditions (T, r.h.).

The SOA formation potential of SIE from common trees of Temperate and Boreal forests (Pine, Spruce, Birch, and Beech) were larger than those due to constitutive MT emissions: 17 ± 1% for SQT, 20 ± 3% for MeSa, and 30 ± 4% for C_{17}-BVOC.

Table 1. Incremental SOA yields for SIE and MT.

BVOC source	Action	Major BVOC	Mass yield
Boreal Stand	Aphids	SQT/MeSa	22 ± 2%
Diff. source		MeSa	20 ± 3%
Spruce	Aphids & heat	SQT	17 ± 1%
Temperate Stand	Aphids& drought	C_{17}-BVOC GLV	33 ± 6 %
Grey poplar	Ozone pulse	SQT/MeSa	20 ± 6%
Pine	None	MT 80%	5.3 ± 0.5%
Spruce	None	MT 90%	4.2 ± 0.7%
Diff. source		α-pinene	5.2 ± 0.5%
Holm oak	Heat	MT	6.0 ± 0.6%

In contrast to these SIE classes, GLV emissions have the potential to decrease SOA mass and number (Fig. 1), similar to isoprene (Kiendler-Scharr et al.,

Nanoparticle Growth Mechanisms During New Particle Formation

Atmospheric new particle formation (NPF) is a key source of ambient ultrafine particles that may contribute substantially to the global production of cloud condensation nuclei (CCN). While NPF is driven by atmospheric nucleation, its impact on CCN concentration depends strongly on atmospheric growth mechanisms since the growth rate must exceed the loss rate due to scavenging in order for the particles to reach the CCN size range. We have made chemical composition measurements of 20 nm diameter particles during NPF in urban and remote locations using the Nano Aerosol Mass Spectrometer (NAMS). These measurements provide a quantitative assessment of important growth channels. We find several common features among NPF events in different locations and different times of year, and other features that are location/time specific. These features will be discussed in the context of our most recent field campaigns in the US and Europe.

With the improved time resolution of NAMS for these measurements (Pennington et. al, 2012), we are able to distinguish and quantify chemical species that are associated with nucleation vs. growth. At the onset of NPF (nucleation), we find that the composition of 20 nm particles changes even though the total aerosol mass concentration does not. These changes provide insight into the nucleation process since the chemical species that condense onto pre-existing "large" particles are likely to be similar to those that assist nucleation. In this regard, the species found to condense onto pre-existing particles during this time period include sulfuric acid, ammonia/amine and in some locations high O/C ratio carbonaceous matter. The change in nanoparticle composition coincides with an increase in the sulfuric acid gas phase concentration, which indicates the onset of NPF.

As the mode diameter increases and the aerosol mass concentration grows through the NAMS size range, other chemical species can increase relative to those involved in nucleation. While sulfuric acid condensation contributes to particle growth, it usually represents much less than half of the mass growth. The sulfur mole fraction determined by NAMS is taken as a quantitative measure of sulfate in the aerosol. (Bzdek et al., 2012) The sulfate mass fraction of growing particles (determined from NAMS measurements), along with the particle growth rate (determined from particle size measurements), can be used to back-calculate the gas phase sulfuric acid concentration. The sulfuric acid concentration calculated in this manner matches within experimental error the sulfuric acid concentration measured with a chemical ionization mass spectrometer, confirming that sulfuric acid uptake is collision limited.

During particle growth, the sulfur and nitrogen mole fractions are highly correlated, suggesting that cationic nitrogen (ammonia, amines) is taken into the particle to neutralize the condensing sulfuric acid. In some locations, the ratio of these two elements is such that sulfate in the particles is only partially neutralized (N/S<2). In other locations, sulfate appears to be completely neutralized (N/S>2).

We define "excess" nitrogen as N-2S where N is the nitrogen mole fraction and S is the sulfur mole fraction. We find that excess nitrogen is associated with particle *growth* but not *nucleation*. Excess nitrogen indicates that nitrate (either inorganic and/or organic) is an important growth species for NPF.

Carbonaceous matter is another important growth species. Depending on the location and time of year, the carbonaceous matter associated with particle growth can have an O/C ratio characteristic of fresh or slightly aged SOA.

Finally, we find that differences in the overall particle growth rate from one NPF event to another at a specific location and time of year are caused by variations in the growth rates of all major chemical species, not just one individual species.

Abstract

A novel gas- and particle phase twin chamber has been constructed and tested for its use under real atmospheric conditions. It allows investigation of particle formation mechanisms as well as of the impact of certain parameters on the present conditions. It applies laboratory tools but uses ambient concentrations and conditions. In a first set of experiments particle formation in the urban area of Frankfurt have been conducted comparatively by either enhancing ozone in one of the chambers or by reducing the solar radiation intensity. Both parameters revealed significant effects on number and mass concentration resulting in a remarkable potential aerosol number and mass currently not produced. This has important implications for future emission budget calculations, local traffic and pollution strategies and for human health.

Introduction

New aerosol number and mass formation in the atmosphere includes a variety of precursor gases and processes with some of them known and intensively studies and others so far unknown or unexplained. This derives of the basic problem that there is currently no instrument that can accurately chemically analyse clusters and smallest particles in the ambient. However a notable fraction of these particles can affect human health and can grow to sizes beyond around 70 nm in diameter, at which it may act as cloud condensation nuclei and modifies the regional radiation budget. Because of this a better understanding of the chemistry and the controlling processes for the particles formation is required.

Methods

In order to bypass the analytical problem of small particle composition a novel twin chamber transparent to light was constructed. Both chambers consisted of ETFE foil, cylindrical in shape and acted as vertical laminar flow chambers with a total volume of 400 L and a residence time of (26.4±0.3) min. Both chambers were positioned in that way that they faced similar sunlight intensity and temperature and used the comparative method. Therefore one chamber was used as a reference (no. 2), while the conditions in the first one were modified to test the impact of certain parameters.

Experimental

First ambient experiments have been conducted at urban conditions (Campus Riedberg, Frankfurt/Main) during October and November. Intercomparison experiments using both chambers unmodified displayed no significant difference in the measurements of both chambers. Next, we enriched the present ozone level in chamber 2, while in a second period the second chamber was darkened to study the influence of OH chemistry.

Both parameters clearly displayed notable effects under urban conditions. Enhanced ozone (up to 70 ppb_v) increased both, i.e. particle number concentration and particle mass above 10 nm in diameter within 26 min residence time substantial (more than 40%, see Fig. 1). On the contrary, darkening of one of both chambers led to a decrease of number and mass concentration although temperature in the particular chamber was reduced due to the coverage with aluminium foil. Investigation of organic gases by proton transfer reaction-mass spectrometry revealed several potential candidates for precursors.

In total the new movable twin chamber displayed its functionality and capability to study ambient particle formation under different atmospheric conditions.

Presenting author email: miikka.dalmaso@tut.fi

Understanding the source strength of tropospheric aerosol production is key to successfully predicting aerosol concentrations and their effect on human health and climate (Kulmala et al., 2004). Aerosol sources generally add aerosol particles or gas-phase aerosol precursors into atmospheric volumes already containing a significant number of pre-existing aerosol particles. This pre-existing aerosol acts as a sink for fresh aerosol particles as well as gaseous aerosol precursors.

Aerosol source processes are generally described as a source rate of aerosol particles into a given size range. Source rates from aerosol production processes such as combustion or secondary gas-to-particle conversion are often obtained in idealized conditions with no pre-existing aerosol present. Alternatively, the production rate is reported in context of realistic ambient concentrations but without characteristic information of the pre-existing aerosol.

The sink processes, caused by condensation and coagulation during the early steps of aerosol lifetime, can significantly alter the aerosol size distribution on timescales that are shorter than those implemented in conventional models predicting tropospheric aerosol concentrations. Parameterizations to take these effects already exist (eg. Lehtinen et al.,2007; Anttila et al, 2010), but they do not take into account effects caused by the size dependence of the particle growth (Vuollekoski et al., 2012) and the changes to the time dependence of the size distribution evolution caused by this.

In this study, we explore the different mechanisms that cause pre-existing aerosol to affect new aerosol sources. We use two models to study the effect of pre-extising aerosol on the source strength of atmospheric aerosol production processes. The molecular resolution model MOREAD, developed from the model by Lehtinen and Kulmala (2003), is used to quantify the effect of nanoparticle dynamics on the source rate of secondary nanoparticle production, and specially how these dynamics affect parameterizations of the formation rate of such particles. We also applied the 0d box model CHAMMO to study the carry-on effect of the pre-existing particles on the survival rate of particles to climatically significant sizes.

In addition to pure aerosol dynamics, pre-existing aerosol affects the particle formation process and the perceived dependencies on precursor vapors in the case of multiple chemical compound participating in the particle production. We studied the formation of secondary particles from sulphuric acid and VOC oxidation, and present results the describe particle formation dependencies in presence of sinks for nucleating and condensing vapours as well as additional sinks, such as dilution.

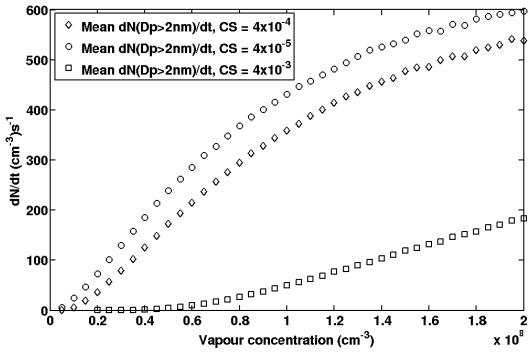

Figure 1: The perceived particle formation rate in a model aerosol with a prescribed formation rate of 1000 $cm^{-3}s^{-1}$ under varying background aerosol concentrations

Our model showed a strong influence of background aerosol on perceived particle formation rate even if the formation rate is technically derived very close to the actual formation size (see Fig. 1). The background aerosol is also key to the survival of fresh aerosol to CCN size; additionally, the relative chemical and condensation sink determine the dependency of particle formation rate on VOC precursor and oxidant concentration. We will illustrate these effects with field data, which shows clearly reduced particle formation activity with increasing background aerosol.

Keywords: Neutral sulphuric acid nucleation, new particle formation, Jungfraujoch

Aerosol nucleation from trace vapours is a ubiquitous process in the Earth's atmosphere and has been observed at many different places (Kulmala et al., 2004). It is thought that sulphuric acid is a key species in the formation process of small clusters and particles. A correlation between the particle formation rate and the concentration of sulphuric has been frequently observed during ground-level field campaigns. However, data coverage on the sulphuric acid concentrations at higher altitudes is relatively scarce, although, these regions are very important on a global scale. In addition, it is not clear if and what other compounds (besides water) are participating in the formation of aerosol particles in these regions.

During January and February 2013 the **Nu**cleation, **Cl**oud and **A**erosol **C**haracterization **E**xperiment (NUCLACE) took place at the high alpine research station Jungfraujoch (JFJ) in Switzerland. The JJF station is located at 3580 meters altitude and mainly influenced by free tropospheric air during this time of the year. One of the goals of the NUCLACE campaign was to investigate the role of ions on the formation of new particles. However, in this study we focus on the measurement of the sulfuric acid concentration as well as on the detection of neutral clusters and their composition with state-of-the-art instruments.

For this purpose, two Chemical Ionization Atmospheric Pressure interface Time-Of-Flight Mass Spectrometers (CI-APi-TOFs) were used (Jokinen et al., 2012). Within the inlets of both instruments nitrate primary ions are generated which can ionize neutral sulphuric acid and clusters through a proton transfer reaction or by clustering. The primary and the product ions are detected with a high resolution time of flight mass spectrometer. The combination of these two techniques allows low detection limits (at ppq levels) and the identification of ion species through their exact mass. Although both CI-APi-TOF instruments have the same principle they differ in the design of their ion source. The CI-APi-TOF from the University of Frankfurt utilizes a corona discharge needle (Kürten et al., 2011) while the CI-APi-TOF from the University of Helsinki (Jokinen et al., 2012) utilizes a soft x-ray ion source. In addition, the geometry of the ion drift regions and the inlet geometries differ slightly. Additionally, the operation of the CI-APi-TOFs at JFJ turned out to be challenging due to the low pressure and strong temperature variations inside the building where the instruments were located. Therefore, an intercomparison of the two instruments is important (see figure 1). Furthermore, it turned out that an on-site calibration needed to be performed to take into account the conditions at the measurement site. For this, a calibration unit similar to the one described by Kürten et al. (2012) has been brought to JFJ. With this set-up a known concentration of H_2SO_4 can be generated and measured by one CI-APi-TOF at a time.

We will report on the overall comparison of the two CI-APi-TOFs with respect to the sulfuric acid monomer concentrations. In addition, the instruments will be compared regarding the detection of different neutral clusters. Details about the calibration will also be presented.

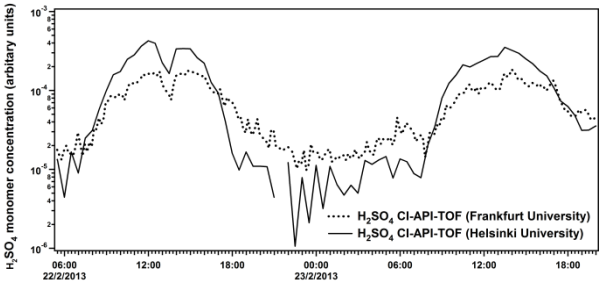

Figure 1. Observed diurnal variation of the sulphuric acid concentration measured by the two CI-APi-TOFs from Frankfurt and Helsinki.

We thank the International Foundation High Altitude Research Stations Jungfraujoch and Gornergrat (HFSJG), which made it possible to carry out the experiments at the JFJ. Also, we thank tofTools team for their support.

Session: Aerosol Modelling
Modelling aerosols in different environments

CFD prediction of the spatial distribution of particulate matter deposition indoors

J. Grau-Bové[1], L. Mazzei[2], M. Strlič[1]

[1]UCL Centre for Sustainable Heritage, University College London, WC1H 0NN, London, United Kingdom

Presenting author email: josep.grau-bove.11@ucl.ac.uk

The development of mathematical models for aerosol transport and deposition in the size range $0.1\mu m$ - $10\mu m$, associated with atmospheric pollution, has been largely motivated by health and indoor comfort concerns. Consequently, the main interest of this models has been the prediction of particle concentration in the free volume of rooms, and they are typically validated with measurements of decay rates in the centre of an experimental chamber [1]. However, in some environments such as museums, archives or historic houses, in which valuable objects are on display, the main interest is not only to know the suspended particle concentration but, especially, to know the fate of these particles, i. e. the deposition rates and the spatial distribution of deposition. [2].

Model description

A model for particle transport and deposition has been implemented in a commercial CFD code. The disperse and continuous phases are resolved following an Eulerian-Eulerian approach. Since the Stokes number is well below 1, one-way coupling is assumed for the velocity fields. Following a comparison of turbulence models, the $k-\varepsilon$ has been chosen as the most suitable. The diffusive and convective terms of particle conservation equations have been modified to account for different phenomena. The diffusive term includes Brownian diffusion and turbulent diffusivity. The convective term adds a vertical component to the velocity field which describes gravitational settling. The semi-empirical deposition equations developed by Lai and Nazaroff [3], which are functions of the Schmidt number and require the wall shear stress as an input, have been implemented as boundary conditions for the particle concentration field. Their solution has been extended to surfaces with arbitrary face angles.

Validation

Since our main interest is in the spatial distribution of deposition, validation requires a comparison of the computational results with deposition values obtained at different points in a space. Published experiments offering data with such characteristics [4] have been simulated, and the numerical results have shown good agreement with experimental values. Figures 1 and 2, as an example, show the simulated distribution of deposition in the floor of a room after an accidental release of 5 g of particles with a normally distributed size, which corresponds with the reported experimental values. An on-going monitoring campaign involving monitoring of deposition and of suspended concentration will allow for validation of the model with a full-scale case study, enabling it to be used as a predictive tool for spatial distribution of deposition in indoor environments.

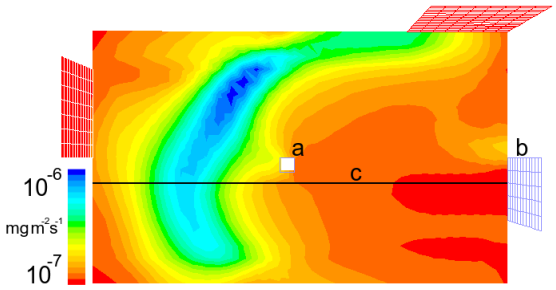

Figure 1: Instant deposition flux on the floor. t = 100 s, inlet velocity, v = 0.6 m/s, (a) is the particle inlet, which emits particles vertically, (b) is the air inlet and (c) is the line used to produce Figure 2.

2009). Increased GLV emissions support positive feedback in case GLV emissions are related to heat, however exert a potential negative feedback when related to drought. Our results clearly indicate that different stress conditions can affect biogenic SOA production: Stress induced changes of BVOC emission patterns and strength strongly impact SOA formation causing increased (SQT, MeSa, C_{17}-BVOC) or decreased (GLV) SOA formation.

Results of our study indicate the importance of SIE for the existence of feedbacks between climate and vegetation via SOA formation. Biotic stress supports negative feedback and this may be effective already today. But heat and drought can turn the negative feedback proposed by Kulmala et al. (2004) and Goldstein et al. (2009) into a positive feedback in Temperate Forests dominated by *de-novo* emitters. Since it is likely that climate change will affect SIE from vegetation, SIE and their SOA formation potential have to be considered in future climate scenarios.

In numerical simulations of atmospheric models, often a reduced model has to be used due to computation time or resource limitations. The use of a reduced model, however, induces errors to the simulation results. These errors are referred to as the approximation errors.

In this study, we consider the approximation errors caused by coarse discretizations of aerosol particle number and volume size distributions in a sectional aerosol model such as SALSA (Kokkola et al., 2008). We model the approximation error as an additive noise process in the simulation model and employ the random forest (Breiman, 2001) regression algorithm for constructing a computationally low cost predictor for the approximation error. In this way, the overall simulation problem is decomposed into two separate and computationally efficient simulation problems: solution of the reduced model and prediction of the approximation error realization. Given the trained random forest model, the accurate model can be approximated by the sum of the reduced model and the predicted approximation error realization.

The proposed approach is tested for handling the approximation errors due to a reduced coarse sectional representation of aerosol size distribution in the cloud droplet activation parameterization by Abdul-Razzak and Ghan (2002). Here a set of approximation error realizations between the accurate and reduced cloud droplet formation parametrizations is first constructed. Second, these approximation error realizations and the corresponding input variables of the parametrizations are used as the training data for the random forest algorithm and the random forest predictor is constructed and used in the simulations.

In this study, the approximative and sufficiently accurate parametrizations consisted of 7 and 70 size sections for the aerosol particle number and volume size distributions, respectively. The cloud droplet number concentration (CDNC) samples simulated with the accurate parametrization as functions of the CDNC samples computed both with the approximative and approximation error corrected parametrizations are shown in Figure 1. The mean squared and mean relative errors of the CDNC samples corresponding to the approximative and approximation error corrected parametrizations are shown in Table 1. The results show a significant improvement in the accuracy of the simulation compared to the conventional simulation with a reduced model. The approach proposed in this study is rather general and the extension of it to different physical simulation models is a straightforward task.

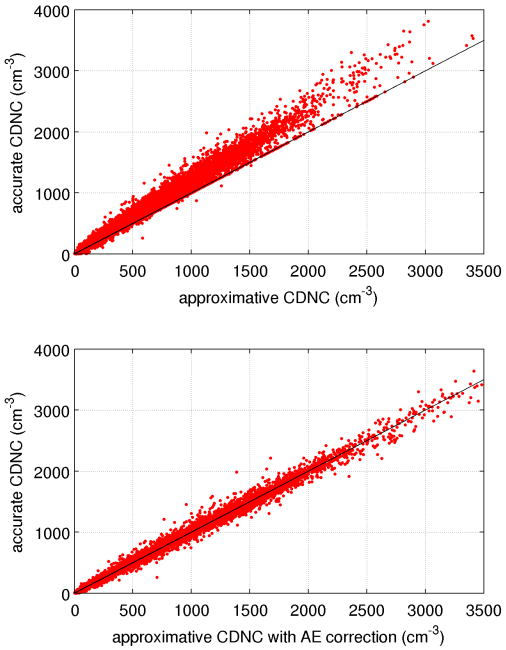

Figure 1. The cloud droplet number concentrations (CDNC) computed with the accurate parametrization as functions of approximative (up) and corrected (down) CDNC values. The solid black lines in the figures represent the identity lines.

Table 1. Mean squared errors and mean relative errors of the approximative and corrected CDNC values.

Parametrization	Mean squared error (cm^{-6})	Mean relative error (%)
Approximative	1.70×10^{4}	20.3
Approximation error corrected	1.27×10^{3}	8.4

Introduction

Knowledge of the physical state and morphology of internally mixed organic/inorganic aerosol particles is still largely uncertain (Song et al 2012). The wide range of concentrations and properties of organic compounds found within aerosol particles in the atmosphere suggest that liquid-liquid phase separation equilibrium ('LLE') might occur in certain ambient conditions. Predicting the equilibrium composition in multicomponent inorganic-organic aerosol particles using thermodynamic models has remained a challenge. Traditionally the most complex, and seemingly accurate, models rely on minimisation of the Gibbs energy of the system.

Currently available thermodynamic methods that account for partitioning between two liquid phases are computationally expensive and do not account for the vast number of organics expected to contribute to the condensed phase. Whilst empirical parameterisations based on organic:sulphate and O:C ratios have been constrained to specific systems (Bertram et al 2011), there is no general consensus on how to account for LLE across a broad range of scenarios. In this study, we reformulate the problem such that it can be solved using a robust and efficient iterative method and thus derive a generic simplified method for predicting coupled VLE and LLE in atmospheric aerosol particles. Comparisons with more complex benchmark models are made (figure 1) along with a discussion as the wider significance of LLE in relation to additional uncertainties in other properties.

Using the activity coefficient model AIOMFAC (Zuend et al 2008), partitioning coefficients between two liquid phases are derived based on the assumption of a continuum of forces that represent molecules that interact by London Dispersion forces (hydrocarbons) and molecules that interact by dipoles/hydrogen-bonding/electrostatic charges. Organics of atmospheric interest are assumed to form a continuum between H-bonding/dipole interactions at one extreme and purely London Dispersion forces at the other, so all these compounds partition between the two phases (assumed aqueous and hydrocarbon in this study). In this method the composition space is explored to discover the least miscible components (solvents) based on predictions from the AIOMFAC activity coefficient model.

Results

To test the applicability of the simplified model a set of coupled VLE-LLE partitioning calculations are compared with the results of Zuend et al (2010) for a system with an ammonium sulphate core and 4 organic compounds are multiple relative humidity (RH) (figure 1). Unrestricted with regards to the number of compounds used within the calculations, we then attempt to assess the potential importance of LLE in ambient aerosol using output from a gas phase degradation model with 2727 compounds. Here we use the results described by Barley et al (2010) in which the Master Chemical Mechanism was used to simulate the gas phase composition of air masses over multiple environments. The potential importance of LLE is discussed in relation to existing uncertainties in the properties of organic components.

Organic compounds can amount to 50% or more of atmospheric aerosol mass (Jimenez et al., 2009) and therefore have an important role in determining the climate and air quality effects of particulate matter. However, currently the contribution of secondary organic aerosol (SOA) formation both to aerosol total mass and particle growth from nucleation size to climatically relevant sizes is poorly understood (Riipinen et al., 2012). In this work, we shed some light on the formation of atmospheric SOA as we use well-constrained new particle formation experiments in a Teflon chamber together with aerosol microphysics modelling to demonstrate that low-volatile organic compounds formed in chamber studies may have gone undetected in previous experiments due to their very rapid partitioning onto chamber walls.

Our measurements were performed in a 4 m^3 Teflon chamber, in which three semi-volatile organic gases of distinctly different volatilities were injected. In the experiment, 20 ppb of these organic gases was repeatedly injected at 30 min intervals. Between the injections, a high-resolution proton transfer reaction mass spectrometer (PTR-TOF-MS) measured the gas-phase concentration of the compound and revealed that the equilibrium between the gas-phase and the chamber walls was reached within a few minutes of each injection. Such rapid equilibrium suggests that detection of very low-volatility compounds, which partition almost exclusively to chamber walls, is extremely difficult in chamber experiments and may therefore have gone unnoticed in several previous studies.

We tested this hypothesis further in a chamber experiment of α-pinene ozonolysis in the presence of an ammonium sulphate seed aerosol. In this experiment, new particle formation and subsequent growth of the nucleation mode was observed shortly after the injection of α-pinene and ozone. The formation of new particles indicates presence of gas phase compounds of very low volatility.

We attempted to simulate the observed growth with the aerosol microphysics model SALSA (Kokkola et al., 2009) by using the frequently used volatility bins and stoichiometric coefficients (Pathak et al., 2007) in the volatility basis set (VBS) framework, which have been derived from previous chamber studies. Using this set-up, the model was clearly unable to simulate the observed growth of the nucleation mode. To reproduce the growth of these small particles we optimized the values of stoichiometric coefficients for different volatility classes by minimizing the difference between the observed and modelled total number concentration in different particle size classes. The optimization resulted in approximately two orders of magnitude higher coefficient for the lowest volatility bins. When these optimized stoichiometric coefficients were applied in SALSA, the observed new particle growth event was reproduced with good fidelity as can be seen in Figure 1.

Our results indicate that very low-volatile organic compounds capable of contributing to nucleation mode growth form in the first-generation reactions of α-pinene oxidation. In previous chamber experiments these compounds have gone undetected because they are depleted to the chamber walls before being detected by measurement devices. Our findings call for new experimental approaches that can constrain the SOA formation yields in chambers in a more reliable way.

Since 2000, 13 CLACE (Cloud and Aerosol Characterization Experiment) measurement campaigns have been performed at the High Altitude Research Station Jungfraujoch (JFJ, Switzerland, 3580 m asl). Of these, 5 focussed on the activation of aerosol to form warm clouds (i.e. liquid-phase). Additionally, comprehensive measurements of aerosol composition and physical properties have been performed at the Jungfraujoch since 1995. The Jungfraujoch is suitable for this purpose since it is in the free troposphere most of the time, and is also influenced by the continental air over Europe. Combined with the fact that the Jungfraujoch is within clouds for 40% of the time, this makes it an ideal site to study aerosol-cloud interactions.

In earlier studies, the cloud droplet activation of aerosol particles has been investigated by performing field measurements of activation (Henning et al., 2002). A recent study (Hammer et al., 2013) investigated the link between the measured cloud droplet number concentration and the cloud condensation nuclei (CCN) number concentrations that were derived from laboratory measurements. These measurements allowed a determination of the prevailing effective peak supersaturation ($SS_{eff.peak,\ retrieved}$) in ambient clouds, which was responsible for the activation of aerosol particles to cloud droplets.

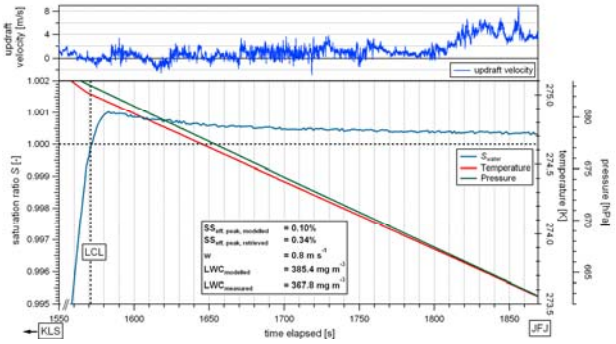

Figure 1. In the upper panel the measured updraft velocity is shown with a time resolution of 20 Hz. The lower panel shows an air parcel back trajectory for air masses starting at KLS and reaching the JFJ. The evolving saturation ratio (blue), temperature (red) and pressure (green) are shown (lower panel). LCL is the lifting condensation level.

The measured aerosol and cloud parameters such as activation diameter, cloud droplet number concentration and effective peak saturation were compared with values predicted by a cloud parcel model. The model, ZOMM (Zurich optical and microphysical model; Luo et al., 2003; Hoyle et al., 2005) simulates the microphysics of aerosols and cloud particles in air parcels including a fully kinetic calculation of water transfer between the gas and liquid phases. The model was initialised with conditions valid for the Kleine Scheidegg (KLS, 2061 m asl) which is located 4 km to the north of the JFJ, at lower altitude.

Figure 1 shows an example of a model simulation, following such an air parcel trajectory. All input parameters (dry aerosol size distribution, temperature, pressure, initial water vapour mixing ratio) were measured at the JFJ. The updraft velocity measured at the JFJ with an ultrasonic anemometer (Metek USA-1) is time-shifted so that it is time-synchronized with the predicted trajectory. It is expected that the air masses approaching the JFJ are experiencing turbulence, which can influence the temperature and thus the saturation ratio. The highest value on the trajectory of the saturation ratio is the maximum peak supersaturation ($SS_{eff.peak,modelled}$) which can be compared with the $SS_{eff.peak,retrieved}$. However, a difference between the predicted (0.10%) and retrieved (0.34%) value is evident. We will present possible explanations for this difference, including the effect of implementing a hygroscopicity parameter. In addition, sensitivity studies were carried out to assess the influence of turbulence on the $SS_{eff.peak,modelled}$.

This work was supported by MeteoSwiss in the framework of the Global Atmosphere Watch program. We thank the International Foundation High Altitude Research Station JFJ and Gornergrat for the opportunity to perform experiments on the Jungfraujoch.

Dependence of Aircraft Smoke Number on Black Carbon Size Distribution

M.E.J. Stettler[1], J.J. Swanson [1] and A.M. Boies[1]

[1]Department of Engineering, University of Cambridge, CB2 1PZ, United Kingdom
Keywords: combustion aerosols, aircraft emissions, soot generator, aerosol filtration.
Presenting author email: ms828@cam.ac.uk

Current methods used to estimate aircraft black carbon (BC) emissions for the purposes of air quality and climate impact studies rely on an outdated correlation and underestimate by a factor of 2-3. In this study, we show that the correlation between the BC mass concentration and smoke number is strongly dependent on the geometric mean of the particle size distribution. To test the correlation a new method to produce BC particles with a variable geometric mean diameter on the range 20-60 nm is employed to simulate BC particles emitted by aircraft gas turbine engines.

Aircraft engine exhaust is currently regulated on the basis of a filter smoke number (SN) – the observed change in reflectance of the filter after sampling a specified mass of exhaust. Estimates of aircraft BC emissions rely on an empirical correlation between SN and BC mass concentration (C_{BC}) derived using BC particles with geometric mean diameter (GMD) between 80-100 nm (Girling et al., 1990). Recent measurements of BC particles in aircraft exhaust have shown that aircraft soot can be characterized as having lognormal particle size distribution with a GMD between 20-40 nm (Kinsey et al., 2010).

A co-flow inverse diffusion flame provides a steady source of BC particles with variable GMD in the range 20-60 nm and geometric standard deviation between 1.5-1.7. The particle size distribution is characterised with a Scanning Mobility Particle Sizer (SMPS) and particle mass as a function of mobility diameter (d_m) is measured using a Centrifugal Particle Mass Analyser. Calculated BC mass concentrations are verified with gravimetric analysis. SN measurements are taken according to the standard aircraft test procedure (SAE, 1997). Correlations between SN and BC concentration are derived for 20, 30 and 60 nm GMD. Filtration efficiency of the specified SN filter as a function of d_m is measured.

In Fig. 1, the particle mass distributions for GMD~20 nm, GMD~30 nm and GMD~60 nm are superimposed on the filtration efficiency, indicating that filtration efficiency increases with d_m such that a smaller proportion of the BC mass is collected on the filter for a smaller GMD.

In Fig. 2 the correlation between SN and BC mass concentration is shown to be a function of d_m – for a smaller GMD a greater C_{BC} is required to produce the same SN, suggesting that current estimates underestimate aircraft BC mass emissions by up to a factor 2-3. These revised correlations improve estimates of aircraft BC emissions compared to measurements but do not account for uncertainty in the regulatory SNs.

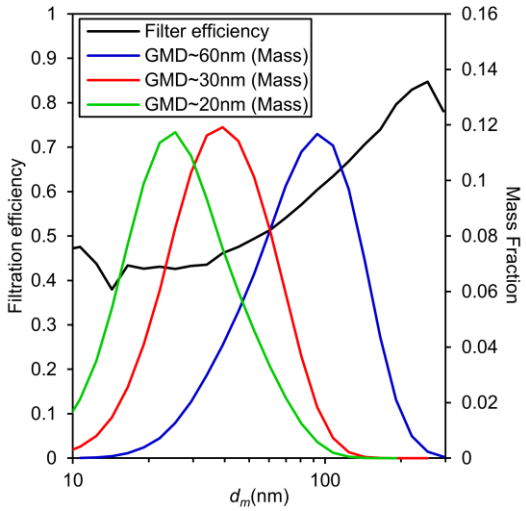

Figure 1. Filtration efficiency of the SN filter with mass distributions for GMD~20, GMD~30 and GMD~ 60 nm soot.

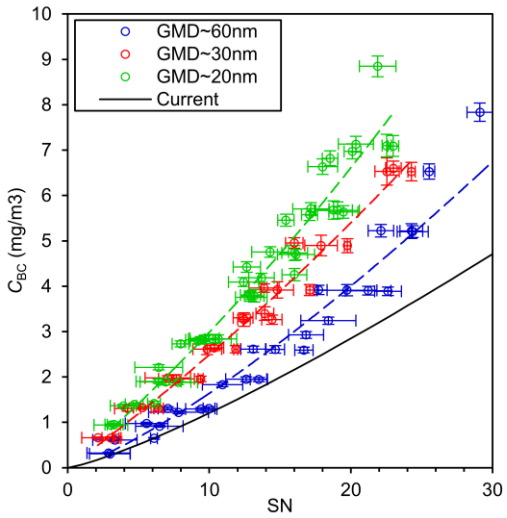

Figure 2. Correlation between C_{BC} and SN.

Sulphuric Acid Aerosol Formation in Industrial Processes – Simulation and CPC measurement at a Pilot Plant

L.Brachert[1], S. Sinanis[1] and K. Schaber[1]

[1]Institute for Technical Thermodynamics and Refrigeration, Karlsruhe Institute of Technology, Karlsruhe, 76131, Germany

Keywords: Sulphuric Acid Aerosol, Coagulation, CPC, Homogeneous nucleation

Presenting author email: leonie.brachert@kit.edu

The formation of sulphuric acid aerosols is a phenomenon which emerges frequently in industrial processes. An important domain is for example the absorption-based flue gas cleaning in power plants (wet flue gas desulfurization). Problems such as corrosion and the occurrence of a distinct "blue plume" may arise due to the aerosol formation. The problem evolves in particular in the presence of $DeNO_X$-systems with selective catalytic reduction (SCR). The resulting aerosol droplets remain sub-micron even after coagulation and are difficult to precipitate.

The simulation tool AerCoDe has been developed at the Institute for Technical Thermodynamics and Refrigeration to predict aerosol formation initiated by heterogeneous (Wix, 2008) as well as homogeneous nucleation (Wix *et al*, 2010). In sulphuric acid – water systems homogeneous nucleation has to be considered. The reason for this is the occurrence of high supersaturations as a result of the extreme phase equilibrium of this binary system. The simulation yields high number concentrations up to 10^{10} 1/cm³ (Wix *et al*, 2010). The number concentration is slightly lower when the parameterisation of Vehkamäki et al (2003) is used to take the formation of hydrate clusters into account (Figure 1). The resulting number concentrations are high even for low inlet concentrations of H_2SO_4 combined with very small diameters (<20 nm) of the aerosol droplets.

Additional polydisperse coagulation calculations show the rapid decrease in number concentrations to 10^8 1/cm³. Due to the higher number concentrations and smaller droplets the coagulation has a larger influence on the number concentration for small sulphuric acid concentrations in the flue gas (Figure 1).

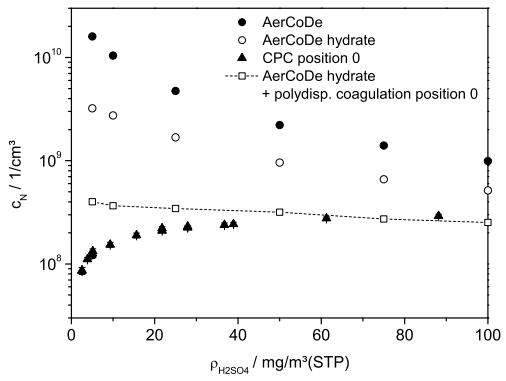

Figure 1 Total number concentrations in the absorption column outlet as a function of the H_2SO_4 inlet concentration. Simulation with AerCoDe and CPC measurements

The experiments at the pilot plant and the measurements with the condensational particle counter (CPC) confirm the high number concentrations in the order of magnitude of 10^8 1/cm³ (Figure1 and 2). At lower sulphuric acid concentrations remains a gap between simulations and experiments which can be explained partly by deposition and by the cut-off of the measurement device at smaller droplet sizes.

Experiments with varying number concentrations of soot particles in the pilot plant demonstrate the occurrence of homogeneous nucleation even in the presence of ~$5*10^6$ 1/cm³ foreign nuclei (compared to ~$2*10^4$ 1/cm³ in low soot mode). As a result, high number concentrations of sulphuric acid aerosol droplets with very small droplet diameters are present even at high soot concentrations.

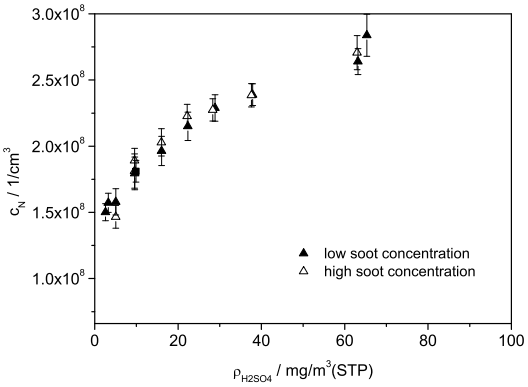

Figure 2 Total number concentrations in the absorption column outlet at low and high soot concentrations (CPC measurements)

Inactivation of Aerosolized Spores in Combustion Environments Using Filled Nano-composite Materials: Study with Two Surrogates of Bacillus Anthracis

S.A. Grinshpun[1], M. Yermakov[1], R. Indugula[1], X. He[1], T. Reponen[1], E. Dreizin[2], M. Schoenitz[2], S. Zhang[2], Y. Aly[2]

Keywords: bioaerosol, combustion, viability, inactivation.
Presenting author email: sergey.grinshpun@uc.edu

Bio-threat agents may be aerosolized should a bio-weapon facility be accidentally or intentionally targeted. Some aerosolized microorganisms (e.g., bacterial spores) may survive the associated heat and chemical stresses and pose a major threat. Novel halogen-containing reactive materials (referred to as Filled Nano-composite Materials, FNM) are being developed with the added capability to inactivate viable microorganisms during their release to the atmosphere. A state-of-the-art laboratory facility was designed and built in our earlier efforts to evaluate the biocidal effects of heat and various compositions released during combustion.

The objective of this research was to determine the efficiency of combustion products of existing and newly-developed materials to inactivate aerosolized spores of two well-established surrogates of *Bacillus anthracis*: *Bacillus subtilis var. niger* (also referred to as *Bacillus atrophaeus* or BG spores) as well as *Bacillus thuringiensis* (Bt spores). The spores dispersed in dry air flow were exposed for sub-second time intervals to hydrocarbon flames seeded with different reactive powders. The bioaerosol particles interacted with the combustion products in a controlled high-temperature environment. The concentrations were determined for viable spores exposed to combustion (C_{exp}) and non-exposed spores ($C_{control}$); the ratio of $C_{control}/C_{exp}$ defined as Inactivation Factor (IF) was calculated for each tested reactive material and each of the two *Bacillus* species. The tests were performed with Al powder (dispersion = 3-4.5 μm) regarded as the reference material and two novel iodine-containing FNMs, Al·I_2 and Al·B·I_2, which release iodine when the base material (Al or Al·B) is melting in the powder combustion process.

The IF data are presented in Fig. 1 for BG and Bt exposed to combustion products at air temperatures of 192 to 210°C (above the iodine boiling point, 184°C). Both iodine-containing materials exhibited IFs higher than Al by two to three orders of magnitude, producing IF = 733 (Al·I_2) and 2,654 (Al·B·I_2) for BG and IF = 918 (Al·I_2) and 10,895 (Al·B·I_2) for Bt. The inactivation level provided by Al·B·I_2 was significantly higher than that of Al·I_2 for both species. The species effect on IF was statistically significant only for Al·B·I_2. Similar tests performed at exposure temperatures slightly below 184°C also showed an iodine-enhanced inactivation although generating much lower IF-levels (because only a small fraction of the released iodine remained in the gaseous phase in the exposure chamber). Overall, the results suggest a great biocidal potential of combustion products generated by the two tested iodine-containing FNMs.

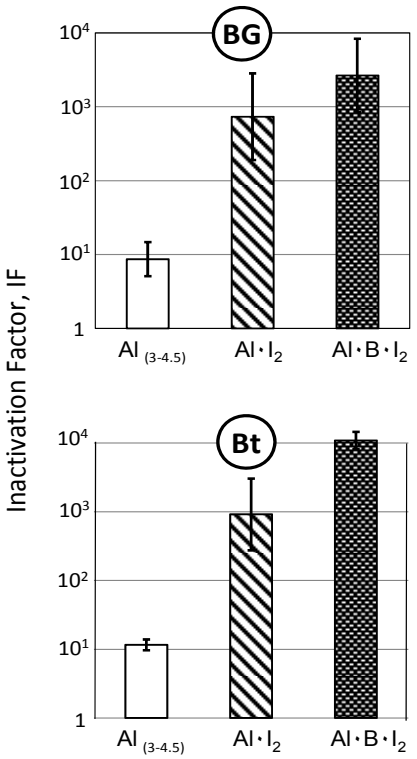

Figure 1. Inactivation factors for the aerosolized BG and Bt spores measured for $Al_{3\text{-}4.5}$ and two Al-based iodinated FNMs.

This study provided foundation for the hypothesis about a synergistic effect of dry heat and chemical products released during the FNM combustion. The heat-induced stress is considered as a tool to damage the spore protein coats and affect the spore outer membrane, cortex, and inner membrane, which, in turn, is expected to enhance the penetration of the "lethal" chemical products. This hypothesis is being tested in a separate investigation.

This research was funded by the U.S. Defense Threat Reduction Agency (DTRA). The authors extend their appreciation to Dr. Su Peiris of DTRA for her support and encouragement.

Size distribution and light scattering properties of standard test fire aerosols

Introduction

Aerosol particles in smoke, produced by combustion processes, are widely used by fire alarm systems for early fire detection. Most existing smoke detectors belong to one of the two types: ionisation or photoelectric detectors. The photoelectric type detectors are taking over the market share from the ionization detectors because the ionization detectors use radioactive sources that lately get banned in many countries.

The detection of smoke in a photoelectric detector is based on the detection of the light scattered by the aerosol particles present in the smoke. In order to better understand and/or to improve the performance of the photoelectric detectors, the properties of the fire produced aerosol particles determining their optical scattering has to be measured.

Aerosol properties of 7 different standard EN54 test fires (see Table 1 for details about the fires) were measured in a fire laboratory. The particle number size distribution and it's time evolution were measured by a scanning mobility particle sizer (SMPS, TSI) and a white-light optical particle counter (WELAS digital 2000, Palas). The angular and time dependence of the differential scattering coefficient at 660 nm wavelength was measured by a home developed instrument: The aerosol is brought into a closed chamber where a laser diode illuminates the particles that can be found in the sampling volume. The scattered light is then detected simultaneously by avalanche photodiodes at 7 different angles.

Table 1. The different standard EN54 test fires

Name	Type of fire
TF1	flaming wood
TF2	smouldering wood
TF3	smouldering cotton
TF4	flaming polyurethane foam
TF5	flaming *n*-heptane with 5% toluene
TF6	flaming ethanol
TF8	flaming decalin

Results

Figure 1 shows the time evolution of the particle number size distribution for a flaming wood fire. Shortly after the ignition of the fire at 14:05 very small particles around 25 nm mobility diameter were formed. As the fire got larger, the previously mentioned mode disappeared suddenly, particles with a mean diameter around 150 nm became dominant and the particle number concentration has increased fast. At 14:13 the flame has died out, and therefore the concentration has started to decrease, however the width and the mean size of the size distribution has continued to increase.

Both the aerosol size distribution and scattering properties of the different fire types show a significant variability, e.g. the mean diameter of the number size distribution had values between 60 and 300 nm.

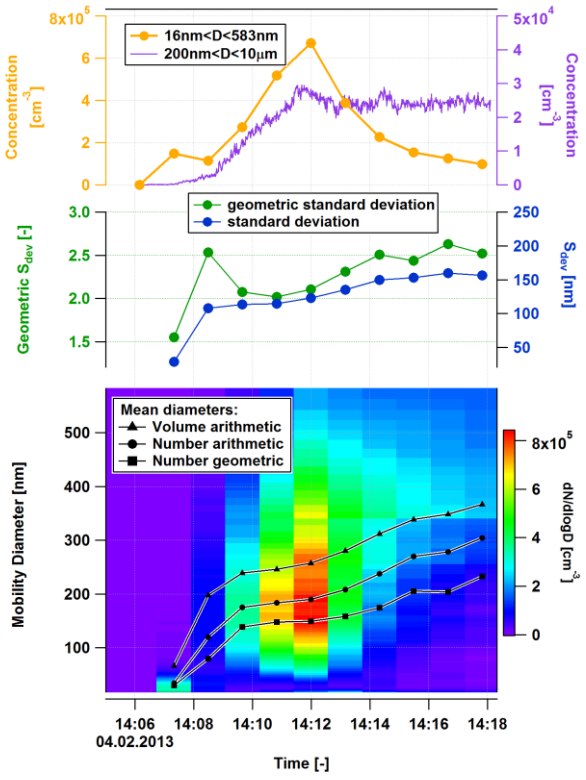

Figure 1. Size distribution properties for TF1 standard test fire

The overlapping size range between the mobility diameter and the optical diameter based size distribution measurement will be used to merge the two size distributions together. The angular light scattering will be compared to theory.

On-site estimation of secondary organic aerosol production potential from wood burning appliances

A. Keller[1], J. C. Corbin[2], A. A. Mensah[2], B. Sierau[2], H. Burtscher[1]

[1]Institute for Aerosol and Sensor Technology, University of Applied Sciences Northwestern-Switzerland, 5210 Windisch, Switzerland

[2]Institute for Atmospheric and Climate Science, ETH Zurich, 8092 Zurich, Switzerland

Keywords: SOA (Second. Organic Aerosols), Wood Combustion, Emissions, Measurement (characterization).

Presenting author email: alejandro.keller@fhnw.ch

Organic aerosol (OA) can be the dominant component of ambient particulate matter (Szidat *et al.*, 2007). However, not all OA is present at the emission point. An important fraction, called secondary organic aerosol (SOA), forms after emitted organic gaseous carbon (OGC) undergoes atmospheric chemistry in a process that can take hours or even days to complete. Small combustion installations (SCI) that burn solid fuel produce important amounts of SOA (Grieshop *et al.*, 2009; Heringa *et al.*, 2011). Their SOA production potential depends, among other things, upon the type of technology and the operating conditions.

SOA is, thus, an important fraction of atmospheric PM that should be considered in emission control legislation. This poses a challenge for air quality regulatory agencies. Smog chamber experiments, for instance, are hardly appropriate for type approval testing or as a standard system for emissions control. We have tested a more compact solution: a continuous-flow reactor-tube with a residence time of only a few seconds. We will show that this setup is enough to oxidize OGC emissions from SCI and transform them into SOA, resulting in a SOA production potential between 0.01 and 1.28 g/Kg-CO_2 (Keller and Burtscher, 2012). These values depend upon the combustion phase and are comparable to previous published data from smog-chamber experiments. Changes in the dilution of the sample, tested up to a factor of 1:8, do not seem to influence the results. Field measurements show that larger automatic installations (e.g. boilers > 70kW) can achieve a very good combustion with no measurable OGC emissions and have, accordingly, no measurable SOA production potential either.

We will also present data from the chemical analysis of the resulting SOA by means of an Aerodyne aerosol mass spectrometer (AMS) run by ETH Zurich. This instrument shows that conditioning the emissions in our UV reactor results in a highly oxidized OA. The oxidation degree is higher than previously published data from field campaigns or smog chamber experiments (see, e.g., figure 1). This difference does not come into conflict with the purpose of our reactor. We do not want to predict an ambient outcome, which is influenced by atmospheric conditions and the contribution of other local sources. Instead, we want to provide a system that can estimate the maximum SOA production potential of wood burning appliances.

This research was supported by the Swiss Federal Office for Energy (SFOE), the Swiss Federal Office for the Environment (FOEN) and the IMBALANCE project of the Competence Center Environment and Sustainability (CCES) from the ETH Zurich and the Swiss National Fund (SNF).

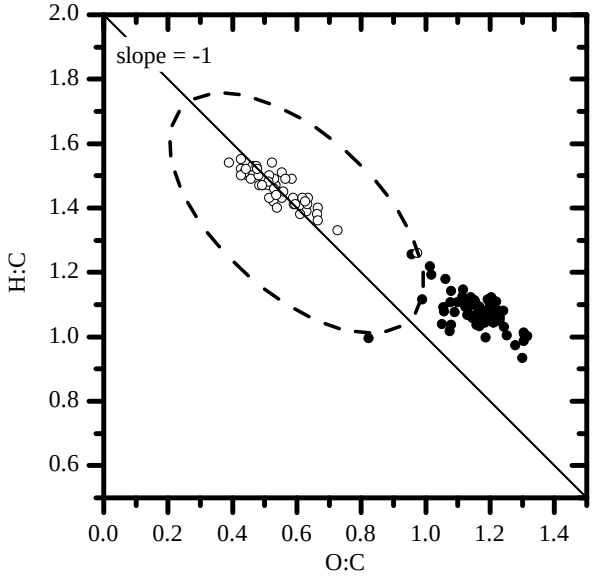

Figure 1: Van Krevelen diagrams of the elemental ratios of organic aerosol emitted during the warm combustion cycles of a log-wood stove measured by AMS run by ETH Zurich. Open circles represent the raw emissions whereas bullets represent the result of conditioning these emissions in the UV reactor tube. The dashed ellipse shows the area comprising ambient data from the MILAGRO C-130 aircraft campaign over and near Mexico City (Heald *et al.*, 2010).

Reference particles for toxicology studies of biomass combustion generated ash particles

T. Torvela[1], O. Uski[2], A. Lähde[1], J. Grigonyte[1], T. Karhunen[1], T. Koponen[1], M.-R. Hirvonen[2], J. Jokiniemi[1,3]

Presenting author email: tiina.torvela@uef.fi

The health risks of biomass combustion have been widely recognized (Mills *et al.*, 2009). However there is contradictory understanding of the factors that cause the adverse effects on human health. There is also a lack of knowledge regarding the relevant dose of particular pollutants causing the adverse health effects (Pope & Dockery, 2006).

In order to understand the toxicological responses, the properties of the exposing particles must be clearly defined. Pure substances or chemicals have been used in toxicological analyses as reference. However the size, crystallinity and solubility, for example, are major determinant factors for the toxicological response (Becker *et al.*, 2003). The properties of reference particles that are typically used in these studies differ, in general, from the ones of the pollutants. Therefore, it can be difficult to correlate toxicity of the references and the pollutants.

The ash of efficient combustion is mainly composed of alkali metal sulphates and chlorides, containing also various amounts of transition metal oxides such as ZnO (Sippula *et al.* 2009). The particle diameter is typically below 100 nm and thus fulfils the definition of nanoparticles (NPs, EC 2011). However, these efficient conditions are not typical for biomass combustion. In incomplete combustion condensed organic compounds are likely to participate in the particle formation. There are indications that organic compounds are capable of inducing radical alterations to the rheological behaviour, such as solubility, of the particles. Therefore the behaviour of the particles in contact with cells in a biological medium becomes more unpredictable.

In this study we have synthesized NPs containing ZnO, alkali salts and carbon in order to respond to the need for biomass combustion reference particles for toxicological studies. The NPs were designed to be similar in size, shape and chemical composition to the ash particles released from biomass combustion. Moreover, the physicochemical and rheological properties of the particles were characterised in order to identify the factors affecting their bioavailability. The effects on the cell viability of mice macrophage cells caused by the synthesized NPs were also evaluated.

The NPs were manufactured with chemical vapour synthesis (CVS, Moisala *et al.* 2006), using liquid Zn acetate dehydrate and alkali salts in water as a precursor solution. Purified air was used as carrier gas. The precursor was dispersed to gas with an ultrasonic atomizer and lead through a high-temperature (1000-1400°C) vertical flow reactor, and diluted rapidly with ambient temperature air to quench the chemical reactions. Particles were then analysed with on-line and off-line methods.

The resulting particles (Fig. 1) were characterised for size distribution, chemical composition, crystallinity, single particle morphology, thermal behaviour, surface properties, IR absorbance and rheological properties e.g. zeta potential and solubility. Cytotoxicity of the synthetic NPs was determined by a dose-response study which was carried out using mice RAW264.7 macrophage cells. The detected toxicological responses were compared to the real biomass combustion generated ash particle responses as described by Jalava *et al.* (2012).

Presenting author email: andrei.bologa@kit.edu

Wood combustion in small scale boilers is widely used for domestic heating. The boiler capacity, combustion conditions, fuel quality, etc. strongly influence on particle emissions from the facility. Due to progress of combustion technologies particle emissions from small scale wood combustion has decreased with respect to mass concentration. However, fine particles, which are associated with various diseases, still contribute significantly to the PM-burden in many cities, especially during winter heating period.

In Germany the Ordinance for Small Scale Combustion (1.BImSchV) regulates the level of particle emissions from biomass combustion facilities. According to the ordinance, starting from 01.01.2015, the particle mass concentration in the exhaust gas from modern small scale wood combustion boilers should be decreased from 100 mg/m_N^3 to 20 mg/m_N^3. So, a significant part of wood-fired boilers will require the improvement of combustion conditions and /or the use of the exhaust gas cleaning equipment.

The purpose of the current work is the study of fine particle emissions from small scale wood chips combustion boiler for different operation conditions and development of recommendations for enhancement of the efficiency of the gas cleaning equipment.

The long-term experimental studies were carried in the Karlsruhe Institute of Technology. The test facility consisted of a 100 kW wood chips boiler (Fa. HDG Bavaria) which was equipped with automatic system for fuel delivering into the combustion chamber. The wood-chips combustion boiler was tested during 2 measurements companies, every ca. 1000 h.

For control of fine particles emissions from the exhaust gases a novel form CAROLA© space charge electrostatic precipitators (ESP) were applied. The ESPs are designed by the CCA – Carola Clean Air GmbH.. The boiler and the electrostatic precipitators were operated in automatic non-stop regime.

The exhaust gas from the boiler was delivered into the test set-up gas duct which allowed the control of the operation conditions, such gas flow velocity and temperature, exhaust gas composition and particle mass concentration (measured by the corresponding equipment from Fa. Wöhler) and particle number concentration (measured by the Scanning Mobility particle Analyser (SMPS), Fa. TSI). Among the measurements, also the chemical analysis and the REM-analysis of the collected material were carried out.

The studies show that the exhaust gas composition strongly depends on the combustion stage and it is characterised by the increase of the CO concentration by the start-up and burn-out stages.

During the 1000 h of boiler operation round 100 gravimetric measurements were carried out. The analysis of the results shows that the exhaust gas temperature and the particle mass concentration strongly depend on the fuel quality, type of burnt material and wood humidity. With increase of humidity, particle mass concentration in the exhaust gas flow increases. Reduced particle emissions (round 50-60 mg/Nm³) correspond to the wood humidity ca. 12-14%. The increase of humidity up to 23-25% results in the increase of particle mass concentration in the exhaust gas up to 150 mg/Nm³.

The results of SMPS measurements show (fig.1) that the mean particle size is 160-180 nm. The aerosol is three-modal, what probably corresponds to different combustion condition stages in the boiler with automatic delivering of wood into the combustion chamber.

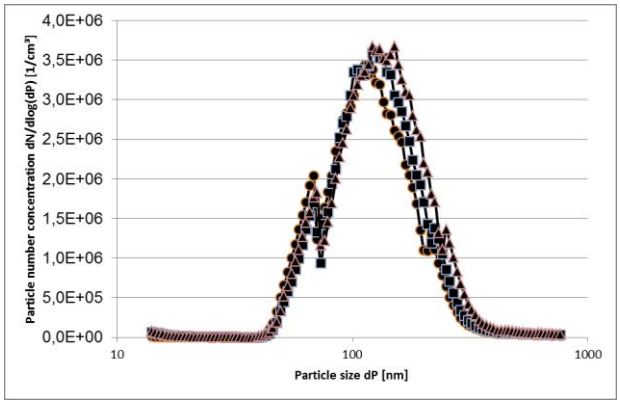

Figure 1. Example of particle size distribution in the exhaust gas flow, dilution factor 10

Among the discussion of the data of long-term observations of fine particle generation by wood combustion, the results of the reduction of fine emissions by the ESPs will be also presented. Detail results of the study of the electrostatic precipitators are the topic of the 2nd abstract presented by the EAC-2013.

The use of the novel ESP's strongly decreases particle mass and number concentration. The mass collection efficiency of the electrostatic precipitators is in-between 70% to 90% depending on combustion conditions.

Effects of severe congestion on PAH emissions from a heavy vehicle diesel engine

M. Vojtisek-Lom[1,2], M. Pechout[1], M. Mazač[1] and J.Topinka[3]

Keywords: diesel engine, particulate matter, polyaromatic hydrocarbons, PAH, urban, congestion
Presenting author email: michal.vojtisek@tul.cz

Summary

The effects of severe congestion on heavy diesel particulate matter (PM) emissions were investigated in a laboratory experiment. Extended idling of a conventional diesel engine and subsequent operation at full load were found to produce higher levels of PM and polyaromatic hydrocarbons (PAH) and an order of magnitude higher levels of carcinogenic PAH compared to idling just after loaded operation and to stabilized operation at full load.

Introduction

Despite advances in engine technology, vehicular traffic remains to be one of the key sources of fine and ultrafine PM in urban air. This work investigates the effects of severe congestion, common for transit truck traffic in Prague and elsewhere, on PM emissions.

Experimental (see Fig. 1 for schematic)

A diesel engine (certified to 0.3 g/kWh PM) with a mechanical injection pump coupled to an engine dynamometer was run alternately at intermediate rpm and full load, and at idle rpm and 1-2% of rated power to simulate slow "creep". Raw exhaust was diluted at nominally 10:1 dilution ratio and sampled by a Hi-Vol sampler (EcoTech 3000) with a $PM_{2.5}$ impactor. A second Hi-Vol sampler was used to provide dilution air. Dilution ratio was verified by CO_2 concentrations measurements. Samples of PM taken on fluorocarbon coated and quartz filters were extracted and PAH content analysed by HPLC with fluorescence detection.

Results and Discussion

Emissions of benzo[a]pyrene, 7 carcinogenic PAH (cPAH) per US EPA (benzo[a]anthracene, chrysene, benzo[b]fluoranthene, benzo[k]fluoranthene, benzo[a]pyrene, dibenzo[a,h]anthracene, indeno[1,2,3-cd]pyrene), US EPA 16 PAH, and total particulate mass, expressed as mass per kg of fuel, are plotted in Fig. 2.

It appears that BaP and cPAH after tens of minutes of idling were an order of magnitude higher than during first several minutes following a higher load.

It also appears that BaP and cPAH during operation at full load were an order of magnitude higher during first several minutes after prolonged (one-hour) idling compared to "stabilized" operation at full load.

It thus seems that prolonged idling may substantially increase emissions of carcinogenic PAH not only during, but also after the idling episode.

Toxicity of extracts of particulate matter sampled from exhaust gases of heavy diesel vehicles under real-world urban operation is currently being evaluated.

EC/OC comparison exercise with same thermal protocols after temperature offsets correction

P. Panteliadis[1], T. Hafkenscheid[2], B. Cary[3] and W. Maenhaut[4]

[1]Department of Air quality, Public Health Service Amsterdam, 1018WT, The Netherlands
[2]National Institute for Public Health and the Environment, Bilthoven, The Netherlands

Presenting author email: ppanteliadis@ggd.amsterdam.nl

The department of Air Quality of Public Health Service Amsterdam has been organizing laboratory comparison exercises for the past few years on thermal-optical elemental carbon / organic carbon (EC/OC) analysers. To our knowledge, all laboratory comparisons performed in Europe up to 2012 considered results derived from different protocols applied per participant, usually NIOSH (Birch & Cary, 1996) or EUSAAR2 (Cavalli et al., 2010), limiting comparability of the performance of each laboratory. The scope of the 2012 comparison exercise was to evaluate results based on an identical, to the extent possible, instrument set-up for all participants. By definition the same protocol should then be applied. Yet, the debate over NIOSH and EUSAAR2 is still ongoing in Europe and a selection of one out the two would have been complex. As an alternative, we decided for the use of both protocols by each participant, providing additional information that could point out possible differences between the two protocols.

Each protocol facilitates several thermal steps and instrument-specific deviations of the desired temperature can alter the sample treatment and bias the analysis result. Since the introduction of a temperature calibration kit by the analyser manufacturer (Sunset Laboratory Inc, OR, US) in early 2012 it is possible to overcome these deviations. All participants agreed on performing the calibration and compensating for the temperature offsets before the comparison exercise analysis.

A total of 20 1.5 cm^2 punches, derived from 5 PM sampled quartz filters, and two sucrose standard solutions were delivered to each of the 17 participants. Duplicate analyses per filter and triplicate per solution were performed applying each protocol. Next to the EC and OC concentrations, raw data and thermograms were provided and additional analysis factors were investigated, namely, split time, transit time, pyrolytic carbon, temperature offsets and thermal peaks distribution. All analyses were performed on transmittance mode (TOT) while the majority of participants also provided reflectance (TOR) results.

In the comparison of EUSAAR2 derived thermograms (Figure 1), notable differences were observed in peak distribution, especially after the 4th, suggesting possible pre-oxidation on a number of analysers. The split point separating EC from OC fell in a range of about 100 seconds. Similar observations were made on the respective NIOSH thermograms. Figure 2 shows all paired EC results for EUSAAR2 and NIOSH indicating that reported EC concentrations may vary for

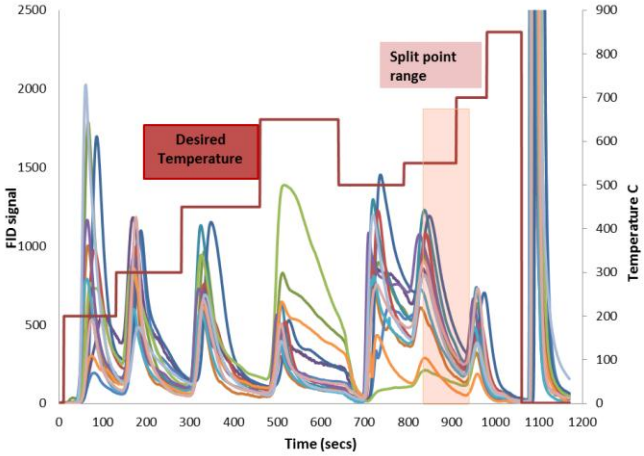

Figure 1. Thermograms of TOT ECOC analysis on PM loaded quartz filter, by EUSAAR2 for all participants.

the same filter in regard to the protocol applied. No differences were observed for total carbon (TC) where $TC_{NIOSH} = 0.99 \cdot TC_{EUSAAR2}$ (R^2=0.98) for loaded PM filters and $TC_{NIOSH} = 1.00 \cdot TC_{EUSAAR2}$ (R^2=0.98) for sucrose solutions was found.

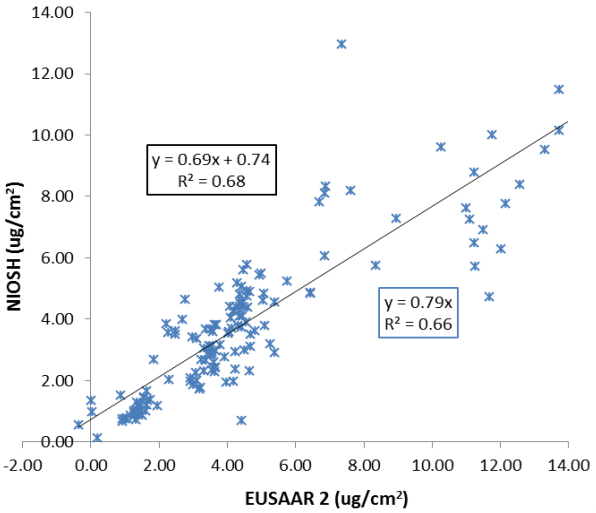

Figure 2. Comparison of EC concentrations by TOT EUSAAR2 and NIOSH on PM loaded quartz filters (N=150).

The fossil fraction of carbon in PM2.5: Variations on seasonal and diurnal time scales

U. Dusek[1], M. Monaco[1], A. Kappetijn[1], H. A. J. Meijer[2], S. Szidat[3], and T. Röckmann[1]

[1]IMAU, Utrecht University, Utrecht, the Netherlands

Keywords: organic carbon, elemental carbon, radiocarbon, 14C, fossil fuel, source apportionment, PM2.5
Presenting author email: u.dusekt@uu.nl

Measurement of the radioactive carbon isotope ^{14}C in aerosols can provide a direct estimate of the contribution of fossil fuel sources to aerosol carbon (e.g. Szidat et al., 2007). In aerosol science, measurements of $^{14}C/^{12}C$ ratios are usually reported as fraction modern ($F^{14}C$). The radiocarbon signature gives a clear distinction between 'modern' carbon sources ($F^{14}C$ around 1.1-1.2 for biomass burning and around 1.05 for biogenic secondary organic aerosol) and 'fossil' carbon sources ($F^{14}C$ =0 for primary and secondary formation from fossil fuel combustion). Due to the high cost of ^{14}C analyses very few long-term studies have been conducted to date. The data that will be presented offer a unique insight into the seasonal variation of source contributions to the carbonaceous aerosol in a highly industrialized region.

High volume filter samples of PM2.5 have been collected roughly twice per month from February 2011 – July 2012 at Cabauw, a rural location in the Netherlands surrounded by major urban centers and highways. This site is representative of regional background aerosol contamination in the Netherlands. We report measurements of $F^{14}C$ for total carbon (TC), organic carbon (OC), water insoluble OC (WIOC) and thermally refractory carbon (RC) as a proxy for elemental carbon.

The fraction modern of OC lies between 0.65 - 1 and shows only a moderate seasonal variation, with highest values in the spring and lowest values in the summer. EC is generally dominated by fossil carbon, but shows a distinct seasonal variation with higher contribution of modern sources from November – Mai. This contribution is normally attributed to wood combustion, see Figure 1, but this is questionable for the filter samples taken in spring. The modern contribution is low when air masses arrive from the ocean and high for air masses with European continental origin, pointing to a main source outside the Netherlands. Water soluble organic carbon is dominated by modern sources throughout the year.

For TC concentrations between 1.2 and 8 $\mu g/m^3$, f_m(TC) increases with TC concentration. A Keeling plot implies that synoptic scale variation in f_m(TC) are mainly due to a modern source, imposed on a regional background with a relatively high contribution from fossil sources. TC concentrations > 8 $\mu g/m^3$ are associated with pollution events and can have much higher fossil contributions.

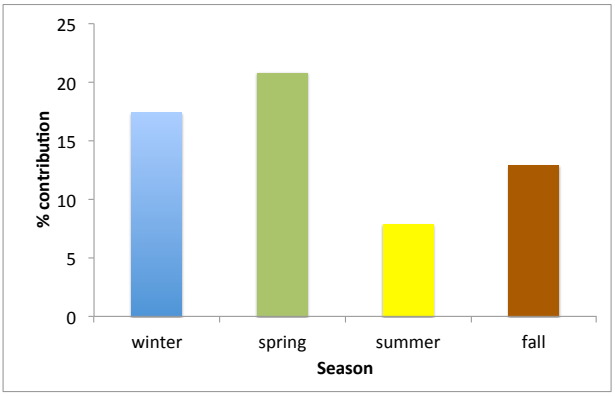

Figure 1. Contribution of biomass burning to refractory carbon in different seasons. Up to approximately 5% can be explained by not ideal separation of OC and RC

Measurements of diurnal variations in $F^{14}C$ can give an indication of the importance of regional emissions, such as traffic, or SOA production from biogenic emissions. For selected time periods during spring and summer 2012, we took separate day and night filter samples that were analyzed for ^{14}C in TC, OC, WIOC, and RC. In all carbon fractions the fossil contribution was higher in day time than in night time. This is consistent with the traffic density in the region, which is higher during day time (7 am to 7 pm) than during night time. Contrary to the synoptic scale variation dominated by modern carbon, the shorter term variations in the regional aerosol seem dominated by fossil sources. Condensation of semi-volatile carbon in the cooler night time might contribute to this trend.

Using a simple model, the contributions of fossil emissions, biomass burning, and biogenic emissions will be estimated for all carbon fractions. The seasonal variation in the source contributions will be presented and discussed.

Presenting author email: j.staelens@vmm.be

Due to the short atmospheric lifetime of ultrafine particles (UFP) and their strong dependence on local sources, ambient particle number concentrations and size distributions may vary significantly on short spatial and temporal scales. Because UFP are a primary pollutant that is rapidly transformed by physicochemical processes (dispersion, coagulation, deposition, etc.) and emitted mainly by mobile sources, they show a very high spatial variation. The particle number concentration is known to be elevated near roads and to decrease with increasing distance to the road primarily as a result of dispersion. Therefore, UFP measurements at a single urban background air quality monitoring station may not be indicative of the actual exposure in the communities surrounding this station.

To address this problem and to more accurately estimate human exposure and subsequent health impacts of UFP, more intensive measurements on finer spatial scales are needed. Therefore, UFP measurements were carried out at eight urban background or hotspot sites in the city of Antwerp (Belgium).

UFP instrument comparison

As different types of UFP instruments were used, first a 3-week field comparison was carried out in January 2013. Four types of UFP instruments were involved: (i) a particle counter with water as condensation liquid (TSI-3783 or EPC, n = 5), (ii) a differential mobility analyzer with an electrometer and corona discharger to ionize the sampled aerosol (TSI-3031 or UFP monitor, n = 3), (iii) a scanning mobility particle size spectrometer (SMPS) with butanol condensation particle counter and a Kr-85 source (Grimm CPC-5420 with L-DMA, n = 3), and (iv) a second type of SMPS with a butanol particle counter and a Ni-83 source (TSI-3772 with L-DMA, n = 1).

All devices were set up in measuring stations or trailers at an urban background site next to a moderately busy road. The results indicate good comparability of the instruments per type of instrument. The particle number concentration measured by the five EPC instruments was strongly correlated ($R^2 > 0.98$). More particles were detected in the high inlet flow mode (3.0 L/min) than with a lower inlet flow (0.6 L/min). The number of instruments sampling from a single TSI sampling system influenced the results as well. Without inlet screen assembly the average number concentration by the EPC instruments differed less than 12% from each other.

For the three UFP monitors good correlation ($R^2 > 0.91$) was generally observed between the size-specific particle number concentrations, except for the highest size channel (>200 nm). For the lowest size channel (20-30 nm) the difference between the UFP monitors was up to 30%, but the total number concentration differed less than 10%. For the three Grimm SMPS devices there was a strong correlation ($R^2 > 0.95$) between the size-specific particle number concentrations and also the total number concentration (10-1094 nm) was very comparable, with a difference of on average less than 3%.

Spatiotemporal UFP variation

In February 2013, the UFP number concentrations and size distributions were simultaneously measured (i) at three sites with an increasing distance (10, 30 and 55 m) to a major traffic road and (ii) at four other urban sites in Antwerp. At each of these seven sites an EPC was set up together with a UFP monitor or an SMPS. To relate the UFP measurements to the local traffic conditions, traffic intensity was monitored at all sites. Diffusive samplers were used to monitor weekly NO_x concentrations. In the road gradient study also black carbon concentrations were measured.

The research questions of this 4-week study were (i) to determine the effects of a busy traffic road on particle number, size distribution, black carbon and NO_x concentrations into adjacent neighbourhoods, (ii) to determine the small-scale spatial variability of particle number concentration and size distribution within an urban area, (iii) to examine how this variation is affected by the site location (source vs. receptor), traffic intensity and meteorology, and (iv) to analyze particle number data with high time resolution in order to determine regional vs. local contributions to particle number levels.

This study is part of the Joaquin project (Joint Air Quality Initiative; www.joaquin.eu) that is supported by INTERREG IVB North-West Europe.

Long term trend and weekly cycles of PM_{10} in the Po valley

A. Bigi, G. Ghermandi

Department of Engineering "Enzo Ferrari", University of Modena and Reggio Emilia, Modena, I-41125, Italy
Keywords: long-term trend, PM_{10}, Po valley
alessandro.bigi@unimore.it

In order to assess changes and variability in daily PM_{10} concentration in the Po valley, 35 pluri-annual time-series have been analysed. Data have been collected at 35 different sampling sites within the Po valley, including both traffic and background sites, either urban, suburban or rural. The dataset comprise pollution data up to January 2012 acquired within the Regional Environmental Agency monitoring networks; all data are referred to actual sampling condition, as required by 2008/50/EC.

Series with at least 10 years of data have been tested for long term trends in the deseasonalised monthly means, in annual quantiles and in binned monthly concentration. In the former test data have been deseasonlised by STL (Cleveland *et al*, 1990) technique and temporal trend has been estimated *via* GLS model on the STL trend component. Trend significance has been estimated by model-based resampling. Trend for the 25th, 50th and 95th annual quantiles has been estimated by Theil-Sen method; significance of annual quantiles trend has been tested by non-parametric resampling. In order to assess a seasonal long term trend, PM_{10} daily concentration for each month have been binned by 15μg/m³ increments and the frequency of each bin in each month over the sampling period has been computed. The trend in these frequencies for each month have been estimated by Theil-Sen method and significance has been tested by non parametric bootstrap, similarly to annual quantiles.

Weekly pattern at each site have been estimated, in order to assess pollution condition and anthropogenic sources influence at each station. Weekly cycle has been investigated through the study of PM_{10} anomalies. Being the data highly non normal, the analysis of deviations used a Kruskal-Wallis test. The significance of the weekly cycle has been double checked by group deviations in 6- and 8-days-week, and performing a Kruskal-Wallis test for these series of anomalies. Also the weekend effect magnitude for each site has been computed, i.e. the difference between the mean PM_{10} anomaly of Saturday through Monday and the mean PM_{10} anomaly between Wednesday through Friday.

A cluster analysis has been applied in order to highlight stations sharing similar pollution conditions over the reference period. Clusters have been built by hierarchical method, computing the dissimilarity matrix by Euclidean distance and using Ward's method to aggregate the data.

Finally, at the sites where both $PM_{2.5}$ and PM_{10} are sampled, a comparison of the weekly patterns for the two pollutants has been performed.

Results

Here are some of the main findings of the study:

- most sites exhibited significant decreasing trends in monthly, annual and seasonal data
- decreasing trends can be high (up to ~4.5% / year)
- many decreasing trends are higher over the period 2002 - 2011 compared to 1998 - 2011
- most of the decrease is due to lower autumn-winter high concentrations
- a significant weekly cycle is present in almost all of the sites; consistent results are shown by the analysis of weekly cycle magnitude
- clustering is driven mostly by the geographical position than by site classification

Finally the study shows how multiple and proper analysis methods are necessary in order to assess the significance of a pattern on atmospheric pollutant data.

Fugitive particle emissions from steel making: source characteristics and local air quality impact investigated with a mobile laboratory

F. Drewnick[1], F. Freutel[1], S.-L. von der Weiden-Reinmüller[1], J. Fachinger[1] and S. Borrmann[1,2]

[1]Particle Chemistry Department, Max Planck Institute for Chemistry, Mainz, 55128, Germany

Keywords: steelworks emissions, source characteristics, pollutant mapping, mobile laboratory.
Presenting author email: frank.drewnick@mpic.de

Industrial stack emissions are largely regulated and therefore typically reasonably well known. However, much less is known on the characteristics and local impact of fugitive emissions which can originate from multiple sources in industrial facilities. The focus of this study is the investigation of fugitive particulate emissions from sources on integrated steel plants, both in terms of emission characteristics and of their impact onto the air quality in the area around such sites.

The highly time resolved measurements within this study were performed using the mobile aerosol research laboratory MoLa (Drewnick *et al.*, 2012). MoLa provides state-of-the-art instrumentation to determine aerosol number (d_p > 2.5 nm) and mass (PM_1, $PM_{2.5}$, PM_{10}) concentrations, particle size distributions (d_p = 6 nm – 32 µm) and chemical composition of the sub-micron aerosol. In addition several trace gases and all relevant meteorological variables are measured.

For determination of fugitive emission source characteristics, stationary measurements of the ambient aerosol were performed within the steelworks several tens to several hundred meters downwind of the individual facilities. The distribution of air pollutants in the vicinity of the plant and their impact onto local air quality were determined by applying a combination of stationary and mobile measurements, both downwind the steelworks and in the unpolluted background.

In order to extract the best possible information from the Aerodyne HR-ToF-AMS mass spectra different approaches have been used. In addition to the determination of the standard species, PMF was applied to separate the organic aerosol into fresh combustion-related and oxygenated (i.e. aged) fractions. Thorough analysis of the high-resolution mass spectra provided information on aerosol components like iron, rubidium and zinc halogenides as well as lead, all not included in the standard analysis procedure of the instrument.

Measurements downwind of blast furnaces, coke ovens, a BOS (basic oxygen steelmaking) plant, ore and coal stockyards and a vehicle movement area were used to determine the respective fugitive emission source characteristics. Due to the close proximity of multiple sources on an integrated steel plant, miniscule variations in wind directions can cause the advection of background air or of emissions from other sources to the measurement site, resulting in systematic biases in integrating measurements. Therefore, the combination of highly time-resolved wind and pollutant measurements is necessary to reliably determine the source contribution to the locally observed ambient aerosol.

A total of more than 1300 km of mobile measurements in the vicinity of two steel plants was performed to determine the concentration distributions for multiple aerosol and trace gas variables in the respective areas. After removal of data contaminated by local sources (e.g., vehicles in front of MoLa) pollutant concentrations along the driving tracks were calculated. Using an extrapolation and interpolation algorithm that accounts for the different transport characteristics parallel and perpendicular to the wind direction, two-dimensional distribution maps were calculated for every pollutant measured with MoLa (e.g., Fig. 1). For days where wind directions did not change strongly over the time of the measurement this procedure provided valuable information on the impact of the steelworks emissions onto the local air quality in the vicinity of the plant.

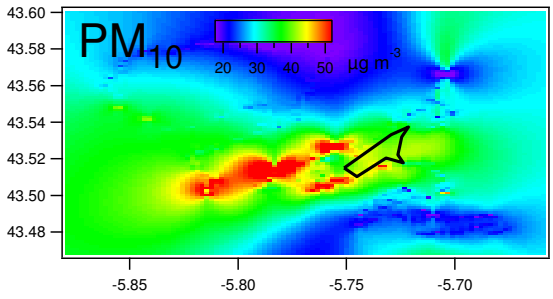

Figure 1. Distribution of PM_{10} in the vicinity of a steel plant. Two separate sources of PM_{10} on and near the steelworks (black framed area) can be distinguished.

Additional stationary measurements in the unpolluted background and within the emission plume were performed. These data were used to determine the background aerosol characteristics as well as the temporal variability of the steelworks impact onto various locations.

Keywords: elemental composition, schools, vehicle emissions
Presenting author email: g.ayoko@qut.edu.au

Although both the size and chemical composition of ambient particles are important parameters in determining their toxicities, their relative contributions are unclear (Heal et al., 2012). Children are particularly at risk to the detrimental health effects that have been linked to long term exposure to airborne particles (See e.g. Ruckerl et al., 2011). However, there is currently limited understanding of the health effects in children due to long term exposure to airborne particles. Schools are locations within an urban environment where children experience significant exposure to vehicle emissions, and to date there is limited information assessing children's exposure at school. This study is a part of a large project aimed at gaining a holistic picture of the exposure of children to traffic related pollutants. In the current paper, results from the investigation of the elemental composition of airborne particle at urban schools are presented.

Airborne Particulate Matter (PM) with aerodynamic diameters equal to or less than 1.0 (PM_1) and equal to or less than 2.5 micrometer ($PM_{2.5}$) were collected in 25 schools in Brisbane, Australia. $PM_{2.5}$ and PM_1 samples were both collected for 24 hours (8am to 8am) for one week at each school. Filters were subsequently analysed by Ion Beam Analysis (IBA) for their elemental compositions at ANSTO. Twenty-one elements (Na, Al, Si, P, S, K, Ca, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Br, Sr, Cd and Pb) were analyzed. Gravimetric analysis was performed on preconditioned filters on a 5 point balance.

The gravimetric results revealed that the on average the PM_1 fraction made up 82 ± 18% of the $PM_{2.5}$ fraction by mass at the schools. Therefore the majority of the sampled particles were in the PM_1 fraction. In Figure 1 the average concentrations across all the school are given. Overall, elements with crustal origins such as Al, Si, K, Ca, Ti, Mn and Fe were found predominantly in the $PM_{2.5}$ fraction. Whereas elements that are more associated with anthropogenic emissions, such as Cr, Pb, Ni, V, Cu and Zn were found predominantly in the PM_1 fraction. Comparison to previous work at roadside location in Brisbane (Friend et al., 2011) revealed that Cr, Ni, Br and Pb had statistically significantly higher $PM_{2.5}$ concentrations at the schools than the roadside indicating an influence from school traffic and other anthropogenic sources.

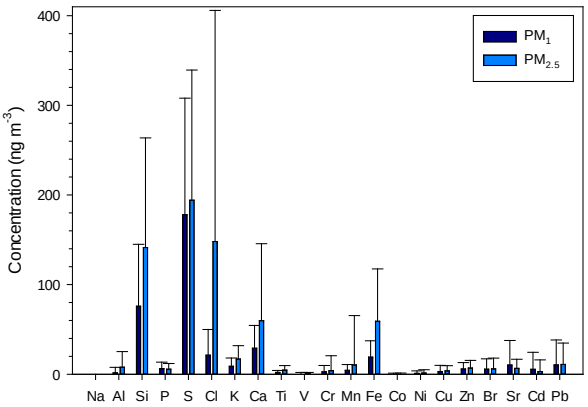

Figure 1: Average concentration of each element across all schools for the both size fractions. Error bars represent 1 standard deviation.

The more toxic heavy metals were found to be in the smaller particle sizes indicating that the PM_1 fraction may have greater detrimental health effects than the $PM_{2.5}$ fraction. Therefore, the results from this study point to PM_1 as a potentially better fraction to use when investigating the health effects of airborne particles. Further work is required to confirm this hypothesis.

The harbour areas are economic centres and transport hubs, that bring together different transport modes (sea, road, railway transport) and, often, include relevant industrial activities. Emissions of ships and of harbour-related activities could have potential negative impact on air quality especially for fine and ultrafine atmospheric particles (Contini at al., 2011; Healy et al., 2010).

At the beginning of 2012 it was started the research project CESAPO (Contribution of Emission Sources on the Air quality of the POrt-cities in Greece and Italy), within the framework of Interreg Greece-Italy 2007/2013, having among its objectives the quantification of the contribution to atmospheric particles of emission sources in two important Mediterranean port-cities: Patra (Greece) and Brindisi (Italy) using state-of-the-art modelling and experimental approaches. Here, an overview of the experimental results obtained in Brindisi will be presented. The area studied is influenced by several emissions: an industrial area, three power plants, an airport and an harbour with a freight traffic and total goods movement that accounted for more than 9.5 million tons and over 520,000 passengers in 2011. Experimental activities in CESAPO were based on an intensive observation period (IOP) of 5 months (June-October 2012). During the IOP the data of 10 fixed monitoring stations (the regional network managed by ARPA Puglia) and those from two additional stations specifically installed during the project inside the harbour area were collected. A station was used to characterize the chemical composition of PM2.5 (metals, major water soluble ions and carbon content) and PAHs (in the gaseous and aerosol phases) and the other was devoted to high temporal resolution (1 second) measurements of PM2.5 mass, number concentrations of submicron particles and diurnal spatially integrated gaseous concentrations using a remote sensing DOAS system (Premuda et al., 2011).

Results of source apportionment based on PM2.5 composition, using the Positive Matrix Factorization (EPA PMF3.0), and on high temporal resolution measurements will be presented and compared with other harbour areas in Italy and Europe. Preliminary results indicate that average PM10 and PM2.5 concentrations in the harbour area are smaller than those observed in the urban area but SO_2 concentrations associated to oil combustion and shipping emissions were larger. The secondary non-sea-salt-sulphate was essentially ammonium sulphate and accounted for about 32% of PM2.5. The detailed contributions of ship traffic and of harbour activities (loading/unloading of ships) were analysed using high temporal resolution measurements. The two contributions appear to be of the same order of magnitude and sporadic in nature being due to numerous short concentrations peaks (durations variable between 10 and 100 minutes) in PM2.5 and in the number of sub-micron particles. An example of peaks to due ships is reported in Figure 1. These peaks were analysed using a statistical methodology that takes into account the wind direction and the actual ships traffic to quantitatively characterize the contribution of vessels traffic and of harbour activities.

Session: Aerosol-based Nanotechnology
Fabrication of nanostructured materials

Rapid synthesis of multi-layered & multi-functional polymer nanocomposite films

C.O. Blattmann, G.A. Sotiriou and S.E. Pratsinis

Particle Technology Laboratory, Department of Mechanical and Process Engineering
ETH Zurich, CH-8092 Zurich, Switzerland
Keywords: polymer nanocomposite, multi-functional, thin film.
Presenting author email: blattmac@student.ethz.ch

Polymer nanocomposites consist of a polymer matrix with nano-sized fillers. They may exhibit different properties than the pure polymer or a polymer with micron-sized fillers (Hagleitner, 2001). This change comes forth due to the unique material properties of nanoparticles as well as their increased specific surface area. An increase in mechanical durability (Camenzind, 2010), greater thermal stability (Kashiwagi, 2005) is common. Incorporation of superparamagnetic, plasmonic or phosphorescence properties is also possible by adjusting the filler material (Sotiriou, 2013). Agglomeration of the fillers, however, seriously hinders this task (Schulz, 2008). Nanocomposite homogeneity is achieved usually at the expense of lower filler loading even though fillers are surface functionalized prior to their embedding in the polymer (Suter, 2011). With this step their loading can be enhanced (e.g. up to 20%) while maintaining dispersion homogeneity (Schulz, 2008). This, however, increases the cost and complicates the processing.

Here a new route for synthesis of nanocomposite polymer films was invented. Superparamagnetic, phosphorescent and plasmonic polymer nanocomposites were made by directly depositing and integrating flame-made Fe_2O_3, Eu/Tb-doped Y_2O_3 and Ag nanoparticles, respectively, into a poly-methyl methacrylate (PMMA) matrix. Such properties allow the polymer film to serve as a sensor, actuator, display or electromagnetic shield (Sotiriou, 2013). Such a multitude of functionalities in one film is desired in miniaturized devices such as lab-on-a-chip (Suter, 2011).

The entire manufacturing procedure consists of dry synthesis of nanoparticles by flame-spray pyrolysis (Strobel, 2007) while directly depositing them on a cooled substrate and subsequently spin-coating with a polymer solution (Sotiriou, 2013). By varying the particle deposition parameters, *in-situ* flame annealing conditions and the spin-coating speed, the particle film thickness and filler loading (i.e. vol%) can be selected.

The nanoparticle loading in the polymer films is determined by thermogravimetric analysis. These loadings are higher than conventional methodologies without affecting film flexibility. Figure 1A shows the response of such a film to an external magnet. Imaging of this nanocomposite film by electron microscopy reveals a homogeneous layered particle distribution throughout the polymer (Figure 1B).

A free-standing thin flexible film (Fig. 1A) can be achieved by coating the deposition substrate with a sacrificial layer prior to manufacturing. Furthermore multi-layered structures with the same and/or different nanoparticles are easily achieved (Sotiriou, 2013). The substrate for deposition consists of a pre-existing polymer nanocomposite film. This allows one to easily incorporate sequentially additional functionalities.

Overall the multitude of polymer – nanoparticle combination possibilities achievable by scalable flame-spray pyrolysis (Strobel, 2007) and high filler fractions with homogeneous distribution distinguish the current nanocomposite synthesis technique.

Electrostatic charging during electrospray deposition of polymer granular coatings

Eszter Bodnár[1], Nikolas Sochorakis[1], Jordi Grifoll[1], Joan Rosell-Llompart[1,2]

[1]Chemical Engineering Department, Universitat Rovira i Virgili, Tarragona, E-43007, Spain
[2]Catalan Institution for Research and Advanced Studies (ICREA), Barcelona, E-08010, Spain
Keywords: electrospray; spray coating; polymer particles; electrostatic charging
Presenting author email: eszter.bodnar@urv.cat

Electrospray is a liquid atomization technique which has been applied to form thin coatings over solid substrates from a wide range of starting solutions (Jaworek, 2007). Highly charged droplets are formed, which repel each other, forming a spray which travels towards a collection electrode. When the droplets contain non-volatile solutes, either a continuous film or a granular coating made of dry residues can be collected.

The electrode configuration and the applied needle voltage (needed for a stable cone-jet mode) determine the electric field and the spray geometry, which in turn define the collection area of the film on the conductive substrate. Therefore, such films are generally considered to be uniform and to grow linearly with deposition time. However, in this study, we have noticed that granular polymer films grow wider during the deposition process.

We have studied the film growth dynamics and the degree of uniformity of the film thickness, as a function of factors which influence the rate of charge accumulation during coating, such as needle-plate separation and ambient relative humidity (RH).

The granular polymer films shown in Figure 1, for example, show radial variations not only in thickness but also in film morphology (size segregation of primary and satellite particles). At the 6.4 mm location, the buried layer of residues from satellite droplets (S) must have been collected earlier than the top layer of residues from primary droplets (P).

Figure 2 shows that these films grow wide faster at low than at high RH. We believe that electrostatic

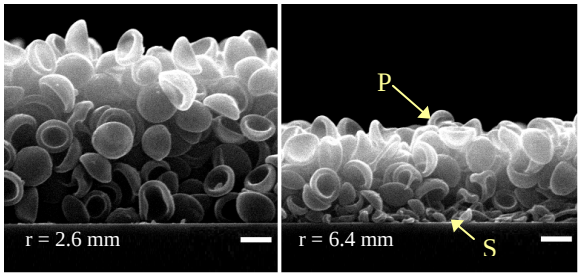

Figure 1. Cross section views by SEM of an ethyl cellulose granular film at different radial locations, collected at 10% RH. Scale bar 1 μm.

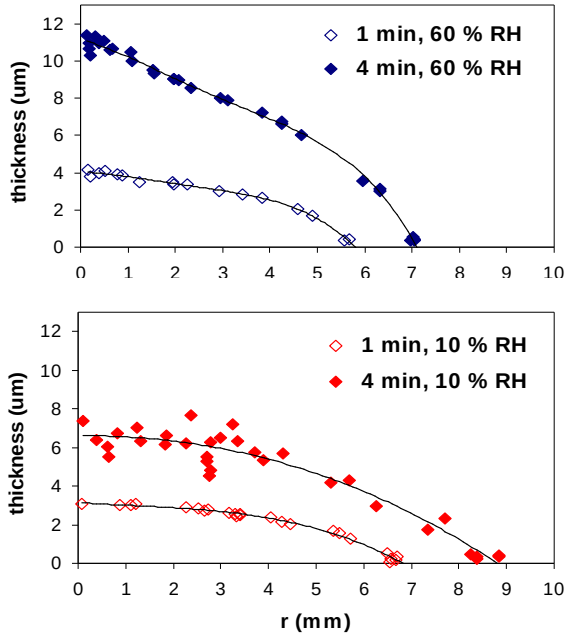

Figure 2. Thickness radial profiles of deposited ethyl cellulose films at fixed inter-electrode separation.

charges accumulate on the film during collection of polymer particles, and contribute a repulsive electric force (pointing towards the droplet emission zone) which acts to slow down the droplets and the dry particles that define the electrospray plume. As a result, the lifetime of the dry particles in the spray is increased, and the spray widens by electrostatic expansion before its particles reach the collector.

This model explains the observed trends of the radial profile of film thickness versus RH (Fig. 2) and inter-electrode separation (not shown here).

This research was funded by Ministerio de Educación y Ciencia (Spain) (CTQ2008-05758/PPQ and DPI2012-35687) and Generalitat de Catalunya (2009SGR-01529).

The technological potential of graphene fosters studies on its deposition to form thin films on a variety of substrates (Blake *et al*, 2008). Spraying is a physical process extensively used to fabricate films and coatings because of its flexibility in the chemical composition of materials that can be deposited. Electrospray, a liquid atomization method that leads to highly charged, nearly monosized micro- and nano-droplets, has been applied to create thin films and coatings (Jaworek, 2007; Modesto-Lopez & Biswas, 2010). Because of its electrostatic control, electrospray deposition (ESD) results in a nearly 100 % deposition efficiency on conductive substrates.

Previously we have reported the deposition of multilayer graphene nanosheets onto silicon and quartz substrates using an electrospray ion-assisted (EIA) method (Modesto-Lopez *et al*, 2012; Uecker et al, 2010). The films comprised multilayered graphene and large agglomerates. In our EIA approach the ions facilitate the deposition of graphene onto dielectric substrates, which is otherwise difficult to achieve with conventional ESD. Films of varying thicknesses can be obtained by adjusting the deposition time and the concentration of graphene in the precursor suspension.

The objective of this study is to deposit single layer graphene films using the EIA method. We also investigate the relationships between coating morphology and EIA process parameters. Suspensions of commercial graphene flakes (Grupo Antolin, Spain) were diluted to 0.005 wt% in dymethylformamide, and were electrosprayed onto Si and quartz substrates. Electrospray was performed in the cone-jet mode. The films were characterized with atomic force microscopy (AFM) and micro-Raman spectroscopy. Figure 1a shows an AFM image of a film collected for 10 min onto Si from an electrospray operated at a liquid flow rate of ~1 µL/min. The film is comprised of relatively large graphene flakes of uniform thickness (clear areas) over the Si substrate (darker areas). Such thickness is approximately 1.1 nm as shown in the profile of Figure 1b, which corresponds to the green line in Figure 1a.

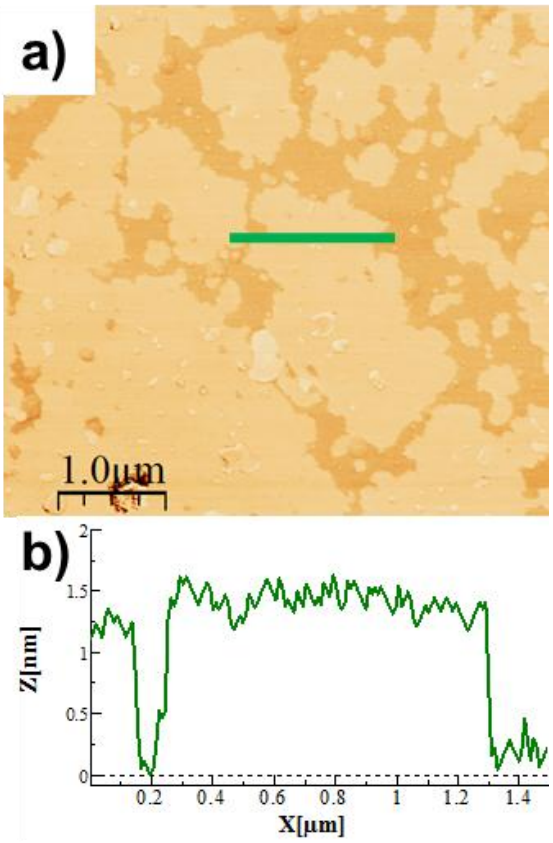

Figure 1. a) AFM phase image of a graphene thin film deposited for 10 min onto a Si substrate, b) cross-section profile from topographic image (green line shown in a)).

Large-Area Patterning of Three-dimensional Nanoparticle Structure Arrays via Ion Assisted Aerosol Lithography (IAAL) and Multi-tip Spark Discharge

K.-Y. Ha[1], H.-S. Choi[1], K.-N. Jung[1], K.-H. Han[1,2], J.-K. Lee[1], and M. Choi[1]

[1]Global Frontier Center for Multiscale Energy Systems, Division of WCU Multiscale Mechanical Design, School of Mechanical and Aerospace Engineering, Seoul National University, Seoul, 151-744, Korea
[2]Present address: Samsung Electronics, Gyeonggi-do 443-742, Korea.
Keywords: nanoparticle assembly, spark discharge generator, nanofabrication.
Presenting author email: hky0220@snu.ac.kr

A great deal of attention has been paid recently to the development of novel methods for fabricating nanoscale structures. In order to implement practical nanodevices using the unique features of nanostructures, large-area patterning technique is necessary. In particular, three-dimensional nanoparticle assembly method based on ion-assisted aerosol lithography (IAAL) has been reported (Kim et al. 2006, Lee et al. 2011, and Han et al. 2012) as an effective way to produce multi-dimensional assembly of nanoparticles in a parallel fashion at atmosphere.

For the case of the IAAL using a single-tip spark discharge generator, charged nanoparticles generated by spark discharge move along an electric field not by diffusion process. Thus, there exists the limitation of realizing large-area patterning along with precisely controllable uniformity. In this regard, the nanoparticles have to be injected over as wide an area as possible for the large-area patterning. We present here large-area fabrication of three-dimensional nanoparticle structure arrays using a multi-tip spark discharge generator based on the pin-to-plate type at atmospheric pressure (Figure 1).

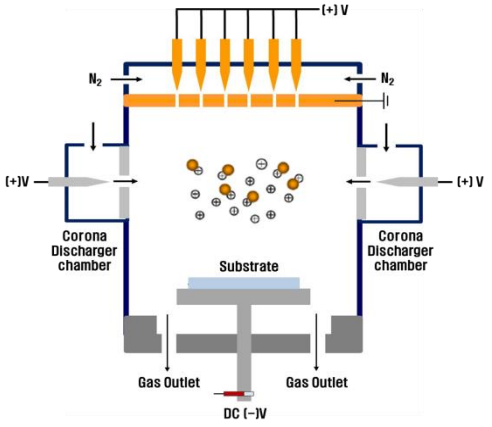

Figure1. Schematic of a multi-tip spark discharge generator

The interval and number of the tips in a multi-tip spark discharge generator are designed to minimize nanoparticle agglomeration and induce high concentration of nanoparticles. The distance between a plate and a sample is set to minimize losses of nanoparticles at the wall, as well as ensure uniformity of resulting nanostructures on a substrate.

With consideration of these conditions, large-area patterns of ordered nanostructures in the size of 50 by 50 square millimeter were fabricated on the substrate in a massive parallel way (Figure 2). In addition, the shape of the nanoparticle structures was variously controlled by changing the size of nanoparticles with the same prepattern formed on a substrate. Tuning the size of nanoparticles can be obtained by varying the parameters such as the electric circuit, the gap between pin to plate, and the flow-rate of nitrogen gas.

This large-area patterning technique using IAAL and multi-tip spark discharge generator will open the door to apply three-dimensional nanoparticle structures with a variety of shapes to diverse nanodevices including optoelectronics, sensing, and electronics.

Introduction

Optical properties of noble metal nanoparticles, such as gold and silver, are dominated by coherent oscillations of conduction electrons, which give rise to localized surface plasmon resonances. The wavelength of the resonances depends on the particle size, shape and dielectric environment.

In our previous study (Harra *et al*, 2012), the plasmon resonance wavelength of spherical single-component silver particles was tuned by controlling their size (50–130 nm). Even though the coverage of the silver particles on the substrate was relatively low ($< 10\,\%$), the overlapping of the particles caused the extinction spectra of the prepared surface samples to broaden to longer wavelengths (> 500 nm).

In plasmonic applications, such as colored coatings and nonlinear optical materials, it is preferable to be able to tune the extinction while maintaining a narrow and well-defined resonance band. In this study, we demonstrate such control by using a multilayered structure consisting of silver-decorated silica nanoparticles.

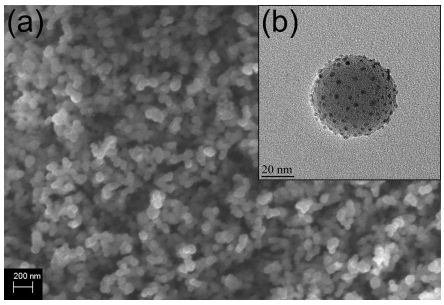

Figure 1: (a) An SEM image of the decorated particles on a glass substrate after a collection time of 30 min and (b) a TEM image of a single particle.

Experimental

Aerosol techniques were used to synthesize the silver-decorated silica nanoparticles. The synthesis process composed of chemical vapor synthesis of larger silica particles and their subsequent decoration with smaller silver particles by an evaporation–condensation method. A layer of decorated particles was deposited on a glass substrate and coated with a thin layer of glass by electron beam evaporation. This process was repeated several times in order to obtain a multilayered structure.

The synthesized particles were characterized with a scanning mobility particle sizer and a transmission electron microscope (TEM), whereas, the plasmonic glass samples were studied with a UV-VIS spectrophotometer and a scanning electron microscope (SEM).

Results and discussion

Figure 1a shows an SEM image of a glass substrate covered with a porous layer of nanoparticles after a collection time of 30 minutes. The individual particles consisted of approximately 50 nm silica spheres decorated with a few nanometer silver particles, as shown in a TEM image (Fig. 1b).

Figure 2 shows extinction spectra of the multilayered nanoparticle structures containing 1–4 layers. The plasmon resonance band, typical of silver at around a wavelength of 400 nm, remains well-defined and relatively narrow, while the extinction grows linearly as the number of layers increases. The inserts show how the yellow color of the multilayered samples intensifies as well.

This study shows that the dielectric silica in the decorated particles reduces unwanted contacts between metal particles, thus, a well-defined extinction spectrum can be maintained. In addition, multilayered structures can be used to improve the mechanical and chemical stability of the nanoparticles in plasmonic materials.

Semiconductor nanowires are key building blocks for the next generation of light-emitting diodes (Qian *et al*, 2005), solar cells (Wallentin et al, 2013) and batteries (Chan *et al*, 2008). To fabricate functional nanowire-based devices on an industrial scale requires an efficient methodology that enables the mass production of nanowires with perfect crystallinity, reproducible and controlled dimensions and material composition, and low cost. So far there have been no reports of reliable methods that can satisfy all of these requirements. Here we show how aerotaxy, an aerosol-based growth method (Deppert and Samuelson, 1996), can be used to grow nanowires continuously with controlled nanoscale dimensions, a high degree of crystallinity and at a remarkable growth rate.

In our aerotaxy approach, catalytic size-selected Au aerosol particles induce nucleation and growth of GaAs nanowires with a growth rate of about 1 micrometre per second, which is 20 to 1,000 times higher than previously reported for traditional, substrate-based growth of nanowires made of group III–V materials (Borgström *et al*, 2007, Joyce *et al*, 2009, Ramdani *et al*, 2010). We demonstrate that the method allows sensitive and reproducible control of the nanowire dimensions and shape—and, thus, controlled optical and electronic properties—through the variation of growth temperature, time and Au particle size. Photoluminescence measurements reveal that even as-grown nanowires have good optical properties and excellent spectral uniformity. Detailed transmission electron microscopy investigations show that our aerotaxy-grown nanowires form along one of the four equivalent 〈111〉B crystallographic directions in the zincblende unit cell, which is also the preferred growth direction for III–V nanowires seeded by Au particles on a single-crystal substrate. The reported continuous and potentially high-throughput method can be expected substantially to reduce the cost of producing high-quality nanowires and may enable the low-cost fabrication of nanowire-based devices on an industrial scale (Heurlin *et al*, 2012).
