Abstract

In this thesis, the existence and properties of luminous infrared objects in PACS (Photoconductor Array Camera and Spectrometer) images taken by the Herschel Space Observatory are investigated. Their coordinates are measured and aperture photometry is performed on them by using a pipeline called FPS-AP (FITS PREPARATOR for SEXTRACTOR and APERTURE PHOTOMETRY) that has been written for this thesis. A cross-correlation with the NASA/IPAC Extragalactic Database (NED) for each object, infrared colors for filter measurements at $70\mu\text{m}$, $100\mu\text{m}$ and $160\mu\text{m}$, and estimates for star formation rates (SFR), redshift and total infrared luminosity (L_{TIR}) for a sub-sample of these objects is provided. The majority of this sub-sample can be classified as luminous infrared galaxies (LIRGs), with a significantly high star formation rate (SFR), confirming the expectation of the nature of these sources.

Abstract

In dieser Arbeit wird die Existenz und Eigenschaften von leuchtkräftigen IR Objekten in PACS (Photoconductor Array Camera and Spectrometer) Aufnahmen des Herschel Space Observatory untersucht. Deren Koordinaten wurden vermessen und Apertur-Photometrie wurde mit Hilfe einer Pipeline namens FPS-AP (FITS PREPARATOR for SEXTRACTOR and APERTURE PHOTOMETRY) betrieben, welche für diese Arbeit geschrieben wurde. Weiters werden alle detektierten Quellen mit NED abgeglichen, IR Farben für Messungen in den Filtern bei $70\mu\text{m}$, $100\mu\text{m}$ und $160\mu\text{m}$ bereitgestellt, und Abschätzungen für Sternentstehungsraten (Star Formation Rate - SFR), Rotverschiebung und totale Infrarot Leuchtkraft (L_{TIR}) werden für ein sub-sample präsentiert. Die Mehrheit des sub-samples kann als leuchtkräftige infrarot Galaxien (LIRGs) klassifiziert werden, mit einer signifikant hohen Sternentstehungsrate (SFR), wodurch die Vermutung über die Natur der Quellen bestätigt wird.

1 Introduction

1.1 Infrared Measurements in History and Today

Roughly two centuries ago, in the year 1800, infrared radiation was discovered by Frederick William Herschel (Herschel, 1800).

As the story goes, he was experimenting with sunlight in several filters, when one day, he left a thermometer just outside of the optical path of sunlight hitting a prism. By coincidence this happened next to red part of the spectrum, heating the instrument, leaving Herschel only with one conclusion, that there must be a part of solar radiation, that is not perceivable to the human eye.

Nowadays, the infrared regime of wavelength, ranging between the red part of the optical spectrum and sub-millimeter parts of light, is a crucial tool in astronomy if one wants to learn more about the cold universe.

Only small and few windows in the atmosphere exist that allow infrared radiation to reach us.

Telescopes have to be brought to places where the influence of water vapor is small to none, as this is one of main reasons why this part of radiation is blocked at sea level.

The second big factor of influence is thermal radiation by the instrument itself, hence cooling is of an important matter.

Observers are left with the problem of getting the telescope to higher elevation, preferably space, although this is the most expensive option. The other one would be placing the observatory on top of a mountain above ~2000 meters, where at least a lot of the earth's atmosphere is located underneath it.

The Infrared Space Telescope (IRAS) (Neugebauer et al., 1984) has been the first space telescope for the mid and far infrared wavelength regime. Launched in 1983, it was operational for ~10 months, before its coolant consisting of liquid helium was depleted. It measured with a 60cm mirror roughly 300.000 IR sources across the whole sky at low resolution in the wavelengths 12 μm , 25 μm , 60 μm and 100 μm . This catalog is still of great importance to infrared astronomy today.

The next IR mission was called ISO (Infrared Space Observatory) (Kessler et al., 1996) and was operational from late 1995 to mid 1998. It measured at wavelengths between 2.4 μm and 240 μm at a spatial resolution between 1.5'' to 90'' with its 60 cm mirror and 4 instruments, consisting of an infrared camera, a photopolarimeter, and 2 spectrometers.

A third IR mission called Spitzer Space Telescope (SST) (Mainzer et al., 2003) was fully operational from 2003 to 2009. After it ran out of coolant in 2009, it was kept in operation at a higher temperature of ~31 Kelvin, and still keeps delivering scientific results until today. The coverage of wavelength ranges from 3 μm to 180 μm detected via its 3

detectors consisting of an infrared camera (IRAC), a spectrograph (IRS) and a multiband photometer (MIPS).

These missions delivered a lot of important scientific data to the astronomical community about the cool universe. Therefore large international agencies and organizations such as ESA still introduce so called corner stone missions such as the Herschel Space Observatory (Pilbratt et al., 2010) which was operational from 2009 to 2013 (see section 2 for detailed information).

By analyzing its data we are able to add to the knowledge base in this range of wavelength.

In this thesis, we present a method for the determination of star formation rates (SFR hereafter) from Herschel PACS images at 70 μ m (blue filter, B hereafter), 100 μ m (green filter, G hereafter) and 160 μ m (red filter, R hereafter). The images were obtained by the MESS-group (Mass-loss of Evolved StarS) (Groenewegen et al., 2011) and were originally meant for research on \sim 140 objects with circumstellar envelopes (CSE). A lot of yet unknown IR - luminous objects showed up on those frames, nurturing further interest and research into the nature of these findings. In order to amass more information for these sources, a semi-automatic pipeline-like approach, with heavy use of the capabilities of the programming language Python and the source-finding program SExtractor (Bertin & Arnouts, 1996) was chosen. The resulting Python script named `fps-ap` (FITS PREPARATOR for SExtractor and APERTURE PHOTOMETRY) consists of \sim 1500 lines of code, and has automatically found and cross-matched roughly 900 objects throughout all frames with the NASA/IPAC Extragalactic Database (NED) (Mazzarella & NED Team, 2007). Subsequently, the sample was processed manually for further analysis, resulting in SFR (Star Formation Rate) estimates according to Calzetti et al. (2010) from monochromatic measurements of model fitted ULIRGS (Ultra Luminous IR Galaxies), L_{TIR} estimates according to Galametz et al. (2013) and photometric redshifts for 22 objects. About 150 B-G colors and 170 B-R colors were calculated for the rest of the sample with at least two detections for the same object in their respective frames. A complete set of measurements for B,G, and R filters has been available for 52 sources from this sample.

1.2 Physical Background

Star forming regions are areas in galaxies where giant molecular clouds of gas collapse to form stars. According to McKee & Ostriker (1977) the interstellar medium (ISM) consists of a 3-phase medium, mainly driven by supernovae. This model describes the ISM of a galaxy by taking into account a dynamical evolution of star formation, cooling and stellar death, among other influencing factors.

By adding disturbances via explosions of massive stars, a cloud of cold gas can become Jeans-unstable (Jeans, 1902) and collapse under its own weight.

1.2.1 The Jeans Mass

Theoretically, the Jeans-Mass can be derived (see Dorfi, 2013) by taking the continuity equation,

$$\frac{\partial \rho}{\partial t} + \nabla(\rho u) = 0 \quad (1)$$

the Euler equation,

$$\rho \left(\frac{\partial u}{\partial t} + u(\nabla u) \right) = -\nabla P + \rho g \quad (2)$$

and the Laplace equation.

$$\frac{\partial^2 \psi}{\partial x^2} = 4\pi G \rho \quad (3)$$

By adding small perturbations to the variables $\rho = \rho_0 + \rho_1$, $P = P_0 + P_1$, and $u = u_0 + u_1 = u_1$, (assuming $u_0 = 0$) equations (1), (2) and (3) become

$$\frac{\partial(\rho_0 + \rho_1)}{\partial t} + \nabla((\rho_0 + \rho_1)u_1) = 0 \quad (4)$$

$$(\rho_0 + \rho_1) \left(\frac{\partial u_1}{\partial t} + u_1(\nabla u_1) \right) = -\nabla(P_0 + P_1) + (\rho_0 + \rho_1)g \quad (5)$$

$$\frac{\partial^2(\psi_0 + \psi_1)}{\partial x^2} = 4\pi G(\rho_0 + \rho_1) \quad (6)$$

After linearization, which means that after expanding these equations, we eliminate all terms of higher order, we are left with

$$\frac{\partial \rho_1}{\partial t} + \nabla(\rho_0 u_1) = 0 \quad (7)$$

$$\rho_0 \frac{\partial u_1}{\partial t} = -\nabla P_1 + \rho_0 g \quad (8)$$

$$\frac{\partial^2 \psi_1}{\partial x^2} = 4\pi G \rho_1 \quad (9)$$

It is worth mentioning, that here the so called "Jeans-Swindel" took place, when we assumed $\psi_0 = \text{const.}$ Furthermore, we can use $g = -\nabla\psi_1$. We introduce a simple equation of state $P_1 = \rho_1 c_s^2$, where c_s^2 is the isothermal speed of sound. By taking the divergence of the linearized Euler equation we can use the continuity equation to write the resulting form

$$\frac{\partial^2 \rho_1}{\partial t^2} - c_s^2 \nabla^2 \rho_1 - 4\pi G \rho_0 \rho_1 = 0 \quad (10)$$

which is solvable with a wave Ansatz $P_1 = A e^{i(kx - \omega t)}$, and leads to the following dispersion relation

$$-\frac{1}{c_s^2} \omega^2 + k^2 = \frac{4\pi G \rho_0}{c_s^2} \quad (11)$$

for solutions growing with time, we examine $\omega^2 \leq 0$ and get

$$k^2 = \frac{4\pi G \rho_0}{c_s^2} = \left(\frac{2\pi}{\lambda_J} \right)^2 \quad (12)$$

by taking a sphere with λ_J as its diameter we finally get the Jeans Mass

$$M_J = \frac{1}{6} \pi \rho_0 \left(\frac{\pi c_s^2}{G \rho_0} \right)^{\frac{3}{2}} \quad (13)$$

assuming an ideal gas we can use $P = \frac{\mathcal{R}}{\mu} kT$ and get

$$M_J = \frac{\pi^{\frac{5}{2}}}{6} \left(\frac{\mathcal{R}}{\mu G} \right)^{\frac{3}{2}} T_0^{\frac{3}{2}} \rho_0^{-\frac{1}{2}} \quad (14)$$

In the end, we are left with a rather simple correlation between mass, temperature, and density.

1.2.2 Initial Mass Function

Stars usually form in associations, following an Initial Mass Function (IMF). That means that within a given interval of mass, a certain number of stars are produced from a cloud of hydrogen. One of the best known IMFs has been described by Salpeter (1955).

$$\xi(M) \approx 0.03 \left(\frac{M}{M_{\odot}} \right)^{\alpha} \quad (15)$$

where $\alpha = -1.35$ in the Salpeter formulation. There are several other values for α for different parts of the IMF (see Kroupa, 2001; Chabrier, 2003). As this is just an informal part of an overview, we will settle for the fact of its existence, and the circumstance that it tells us, that massive stars get created to a certain amount in certain intervals of mass.

So called OB-Associations consist of stars from a single star formation process, with some massive members and lots of smaller ones. As these massive stars have a short lifespan of a few million years, they end quickly as supernovae, feeding the local ISM, thus keeping up the dynamical processes in the ISM.

1.2.3 Supernova Remnants

As said before in section 1.2, supernovae (SN) are the main sources of energy input into the ISM with typical energies of $E_{SN} = 10^{44}$ [J] and SN-rates of $\tau_{SN} = \frac{2-3}{100}$ [yr^{-1}] in our galaxy. According to Dorfi (2014) there is a simple theoretical way of describing the evolution of a supernova remnant (SNR). Without going into further detail, the development of a SNR can be divided into three phases.

The first phase treats the movement of the shock front emitted from the star as free expansion, meaning that the ejected material does not 'care' about the ISM it runs over.

The second phase starts when the mass of the ISM swept up by the shock front becomes comparable to the mass ejected from the star. At this point the so called Sedov-Taylor phase (Sedov, 1959) will partake in the expansion by heating the inner part of the SNR through a reverse shock, reflected by the shock front. This is the pressure driven part of the expansion.

In the third phase radiative cooling takes place and the SNR expands due to inertia. The lifetime of a SNR is finite and short, as it will lose its identity in the ISM after typically about $\sim 10^5$ yrs.

1.2.4 Star Formation in IR Galaxies

IG (IR Galaxies) with $L_{TIR} \simeq 10^{11} L_{\odot}$ and ULIRGS (Ultra Luminous IR Galaxies) with $L_{TIR} \simeq 10^{12} L_{\odot}$ are some of the most luminous groups of objects in the universe, along with quasars. While the origin of the source of energy in these objects is being discussed controversially in lots of papers, we still can assume that it is reasonable to include the following processes. First of all, we saw that star formation needs a disturbance in the ISM, which can be provided by shock waves via a SNR. For a starburst to take place, which is characterized as a strong rise in star formation over a period of time in a galaxy, a larger scale of disturbance is needed. This can be mainly provided by interaction between galaxies called mergers and includes the formation of tidal arms or synonymous tidal tails. On the other hand, there is reason to believe that active galactic nuclei (AGN) can also be of great importance to providing energy in this process. Therefore the bright IR objects found and discussed in this thesis are likely to be part of these groups.

1.3 Overview

In short, the processes in section 1.2 explain the dynamical evolution of the ISM very superficially, and by far not completely. McKee & Ostriker (1977) use more processes like cooling among others in their paper. However, they still rely in their basic conception on these ideas sketched above. Apart from that, the important part is that star formation plays an important role during the lifetime of a galaxy.

The rate at which stars are formed can be measured in various ways, because of different physical processes that come into play during this development.

A star that forms, emits radiation that interacts with its environment. As this environment usually consists of dense clouds of gas it makes direct optical observation rather difficult. The hydrogen atom is one of the most contributing elements in the cooling process in the universe, by absorbing and re-emitting radiation and through ionization.

One tracer of star formation can be $H\alpha$ at 656,2793 nm (Domínguez Sánchez et al., 2014) in the red part of optical wavelength regime. Another indicator is O/H (Moustakas et al., 2006). This is the ratio between abundances of oxygen and hydrogen. Its value mainly is a measure for metallicity and therefore traces the star formation process indirectly, because regions with a lot of star formation will get enriched with heavy elements more quickly than others. The theoretical idea behind this is that the most massive stars will die in the vicinity of their birthplace, expelling heavy elements locally into the ISM, which in turn, will be converted into new stars, triggered by the instability the shock waves of the SNe create. Therefore a rise in metallicity can be measured and correlated to star formation.

Unfortunately the O/H ratio can only be measured through spectroscopy, which is a time consuming and therefore expensive way of observation, and thus, not available for large amounts of objects. In the end, the most promising part of the spectrum for detecting star formation lies in the infrared (IR) bands. The advantage of these wavelengths is that they are able to pass through dust and dense clouds of gas more easily than the optical light. Calzetti et al. (2010) showed that there is a strong correlation between the star formation rate and light emitted at 70 μ m and 160 μ m, among other wavelengths in the IR.

2 The Herschel Space Observatory

The Herschel Space Observatory (Pilbratt et al., 2010) was a 3400 kg infrared telescope launched into space by ESA via an Ariane 5 rocket in May of 2009 and was operational until April of 2013, longer than its planned lifetime of 3 years. The total dimensions of the telescope were 7.5 x 4 x 4 meters. It was brought into an orbit around Lagrange point 2 (L2), about 1.5 million km away from earth, in order to minimize influencing radiation. The optical system consisted of a Cassegrain setup with a 3.5m main mirror, and a 0.3m secondary mirror, detecting wavelengths from 55 μ m to 672 μ m through 3 instruments that needed active cooling in the form of ~2300 liters of liquid helium at 2.15 Kelvin. The rest of the telescope had to be shielded against the solar radiation as, due to its size, cooling of the entire satellite was not an option.

Some of Herschel's main objectives were galactic evolution in the early universe, star formation and correlation to the ISM, and atmospheric composition of comets and other objects close to earth.

2.1 Instrumentation

Herschel, formerly known as FIRST (Far Infrared and Sub-millimeter Telescope), carried three instruments in its science payload. PACS and SPIRE being photometric cameras as well as spectrometers, and a high resolution spectrometer named HIFI. In case of further interest, the reader can refer to Swinyard et al. (2010) and Ivison et al. (2010) for detailed insight on SPIRE and HIFI.

Figure 1: A computer generated view of the Herschel Space Observatory at L2, with adjusted position of shield to block off solar radiation. Picture by ESA¹

Figure 2: *Filter response curves for PACS taken from Poglitsch et al. (2010).*

2.1.1 PACS

The instrument PACS (Photoconductor Array Camera and Spectrometer) (Poglitsch et al., 2010) was built to be a general purpose instrument for wavelengths between 60 μm to 210 μm , consisting of a multi-color photometer, and an imaging spectrometer.

When used in photometry mode, PACS used its two 16 x 25 pixel Ge:Ga photoconductor arrays at the same time, enabling it to take images in two of its three color bands simultaneously. In a field of view of $\sim 1.75' \times 3.5'$ imaging was possible in the bands 60 - 85 μm , 85 - 125 μm , and 125 - 210 μm (see Figure 2).

In spectroscopy mode, a field of view over $47'' \times 47''$ in 5 x 5 pixels and a spectral resolution of $\sim 175 \text{ km s}^{-1}$ was achieved, via its two silicon bolometer arrays with 16 x 32 and 32 x 64 pixels.

The most common observation technique for this instrument was called scan map, standard for larger areas in the sky. A scan map consisted of a series of images, taken as the telescope slowly moved its field of view along parallel lines over the area of the target. Three speeds were available for this technique in photometric mode ($10'' \text{ s}^{-1}$, $20'' \text{ s}^{-1}$, and $60'' \text{ s}^{-1}$), and two in parallel PACS/SPIRE mode ($20'' \text{ s}^{-1}$, $60'' \text{ s}^{-1}$) (see Figure 4).

Figure 3: *The PACS instrument. Image taken from Poglitsch et al. (2010).*

Figure 4: *Top: Schematic path of the telescope field of view over a large area to be observed. Bottom: Image of the scanned area of HD 159330 at 100 μ m. Image taken from Poglitsch et al. (2010).*

2.1.2 SPIRE and HIFI

The existence of these two instruments will be mentioned briefly here, as only SPIRE was involved in the collection of data for the MESS sample. The objects of interest to this thesis, however, were too faint for reasonable science with this additional spectroscopic data. In case of further interest, the reader can refer to SPIRE (Swinyard et al., 2010) and HIFI (Ivison et al., 2010) for detailed insight.

Figure 5: A typical MESS image. Herschel PACS B-band image of CAS A at $70\mu\text{m}$, with a nicely visible central object and several near point-like sources surrounding it. The edges of the frame are irregular due to the imaging mode "scan map", and very noisy due to that technique, as described above and in section 3. Image dimensions of 2030×2116 pixels, corresponding to $33.83' \times 35.27'$.

3 Data - The MESS Sample

The data used for this thesis has been part of a Herschel key program with guaranteed observing time called MESS (Mass-loss of Evolved StarS) (Groenewegen et al., 2011). The aim of this program was research in the field of AGB (Asymptotic Giant Branch) stars, post-AGB stars, planetary nebulae (PNe), luminous blue variables, red supergiants, SNRs and Wolf-Rayet-Stars. For this undertaking, a sample of ~ 140 objects has been observed, with additional spectral data for 50 of those objects.

All images for photometry were taken in scan map mode, with the a scan speed of $20''\text{s}^{-1}$, and afterwards imaging of the same object orthogonal to the original scan direction was done. The theoretical aim was to produce images of homogeneous exposure time at the center of the target of about 31 seconds.

The flux calibration at $70\mu\text{m}$ amounted to $\sim 10\%$ and at $160\mu\text{m}$ to $\sim 15\%$ (see Poglitsch et al., 2010).

The raw image data has been processed by a pipeline based on scanamorphos (Poglitsch et al., 2010; Roussel, 2013). The scanamorphos pipeline is a fully automated algorithm to post-process scan observations from Herschel. Its main features are subtraction of thermal and non-thermal low frequency noise, masking cosmic rays, and projection of the data onto a map. The resulting data consists of a multi-layer FITS (Flexible Image Transport System) (Wells et al., 1981) file with the respective layers for a scan map, error map, total drifts and a weight map. Additionally, the J2000 world coordinate system (WCS) is applied to each frame. The scan map is the science ready map, where all corrections and calibrations are applied. The pipeline processes most of these operations without the need for a noise model or Fourier-space filtering, but solely with the redundant data resulting from observations with multiple instruments at the same time.

The data of the MESS team makes use of a modified version of scanamorphos at different levels adapted to the needs of the MESS dataset (see Groenewegen et al., 2011, Appendix B), due to the fact that Herschel performed observations in a different scan mode than described in section 2.1.1. The objects of interest to the MESS team needed the longest exposure time at the center of the image. Therefore a scan mode named cross-scan was chosen, which combines scan maps of the object taken in the usual scan mode, and then a run across the target area orthogonal to the original scan direction. The described operation continued for several times, on average 3-4 times for each filter. This method requires special care, as the high pass filter is likely to detect bright central sources that are not artifacts. They appear as such due to the comparatively long exposure time relative to the rest of the image. The data itself is not of uniform dimension. The pixel area of the final image varies slightly among the same object in the B, G, R filters, as well as (sometimes greatly) among all the objects observed.

Spectroscopy was also done to a certain extend for a subsample, however, as all objects of interest in this thesis were much too faint for spectroscopically conclusive analysis, further description of data quality in this regard is obsolete.

About ~ 100 objects had noticeably significant features of mainly point source like sources in the background of various frames of B, G and/or R filters. Further research for this sample has been carried out and is described in the following sections 5 & 6.

4 Tools

4.1 SExtractor

The program SExtractor (Source Extractor) is a widely used and accepted tool in the astronomical society around the world, written by Bertin & Arnouts (1996) that automatically detects sources in astronomical data, preferably in the form of FITS (Flexible Image Transport System) (Wells et al., 1981) files, and performs aperture photometry and various calculations on them. Some of these include aperture photometry, de-blending, background subtraction, star - galaxy classification, and association between objects in separate filters. The photometry SExtractor performs is sufficiently good for a quick first look at the data. However, if one wants to exercise more qualitative research on a few selected objects with known positions, a more accurate way (e.g. HIPE, IRAF etc.) would be advisable.

SExtractor is operated via command-line syntax, and has several modes of output to the screen. The mode used in the code is set to default, displaying a set of information for each individual frame, including the number of objects found in the respective image. If one does not want or need the display output, it can also be set to silent mode, which is more suitable for fully automated pipeline modes.

Over the past few years there were some major and minor updates to SExtractor made public. The version used in this thesis is SExtractor v2.19.5., however portions of the code will also be usable when run with the last stable release SExtractor 2.8.6, that is also implemented in the latest SCISOFT 7.7 package ²

4.2 Python

Python is a high level scripting language, used throughout various fields of operation. The syntax of the code is characterized by indentation, providing readability on one hand, and eliminating the necessity for semicolons and other line terminators as in other programming languages, on the other hand.

Popular for its versatility, Python provides object oriented programming, as well as procedural and functional programming.

This and the shallow learning curve makes Python a very intuitive, usable and common tool in natural sciences, even though there are languages, that have much better performance regarding speed, like C or Fortran or any other low level programming language

²SCISOFT package at ESO: <http://www.eso.org/sci/software/scisoft/> visited on 28.9.2014. Picture provided and copyright by ESO.

available.

If one wants to go through large FITS files, or large amounts of data in general, performing heavy calculations like fourier transformations, numerical calculations and so on, Python might not be the best fit for this job. If performance is not that much of an issue, or a quick look at a smaller subsample is sufficient, then Python is a nice and handy tool for science.

There are many libraries and plugins available for specific needs in astronomy for Python. A handful of these packages were used in the code, for example pyfits, a plugin for handling FITS files, along with others. The version of Python used in this thesis is 2.7.6. It is imperative not to use newer versions of Python, as some commands have changed with newer releases, and the code will not be executable for this matter.

Python 2.7.2 is also featured in the SCISOFT 7.7 package, which should suffice to run the code as well.

5 Data Analysis

5.1 Goals

In order to extract the information needed to do science from the given frames (see Figure 5), we first need to establish what it is we need to extract.

The goals of this research consist of detection of the positions of all tentatively confirmed real objects, perform photometry on them, if possible calculate color values for our new measurements, and acquire estimates for star formation rates and L_{TIR} where applicable. As all detected objects show significant brightness in the IR wavelength regime between $70\mu\text{m}$ - $160\mu\text{m}$ and appear as near point like source with average diameters of $20''$ to $60''$, the probability of the majority of these sources being IR galaxies, LIRGS and ULIRGS is a reasonable assumption.

5.2 Automated Steps

A starting point would be taking a look at the raw data, and determining what kind of workload is ahead of us. There are about ~ 320 frames for ~ 140 objects that were observed for the MESS sample, and in each frame there are roughly 2-5 interesting sources on average at the first glance. If done manually, this would mean that somewhere between 600 - 1500 positions need to be measured individually. This seems like a tedious task that is meant for automation. So we decide to let SExtractor do the work, and prepare all frames for automation.

In the second step, aperture photometry has to be done for each object, and we need to verify the nature of these sources, thus, we need to set boundaries for a correct detection. Thirdly, a crosscorrelation between the objects detected in their respective frames needs to take place, so we can measure the same object in more than one filter. This is crucial in two ways. For one, this also proves that the detected source is a real object and not some kind of artifact, and for the other and equally important, we obtain the ability to get colors for our sample. In the next step, we put our list of coordinates for these sources into various databases from surveys that are available on the internet (NED), and see if some of the detected objects have already been measured at other wavelengths.

On a side note, it is necessary to mention the still experimental, non functional piece of automated code documented in section 6.1.5, that is part of the program. Consisting of an approach to determine the surface brightness of each object, and calculating the surface luminosity from that, providing the invaluable convenience of being independent of

distance. This part is still actively calculated and printed in the output, although the data does not refer to any real result as of yet. However, this approach is worth pursuing, as it has major advantages, and will be finished after the completion of this thesis.

5.3 Non-Automated Steps

The manual part of analysis commences, as we continue from this point on, by examining only objects found in more than one filter from our sample.

This cuts down the work load dramatically, but needs a more detailed and diverse approach to collecting additional data.

We start by looking up all of the crosscorrelated sources that were found in NED (NASA/IPAC Extragalactic Database) (Mazzarella & NED Team, 2007) and gather as much complementary measurements across the whole energy spectrum as possible. This task uses various databases and catalogs (Sloan Digital Sky Survey (Ahn et al., 2012), WISE (Cutri & et al., 2014; Wright et al., 2010), and 2MASS (Skrutskie et al., 2006)), and is therefore rather complex to code, especially when we look at a sample of about ~20 - 30 objects. The benefit of coding it despite of that, would be the scalability of the sample put into this algorithm, yet the workload however, would exceed the time frame for completion of this thesis.

With the collected measurements, one is able to plot spectral energy distributions (SED) for each object in the sample.

Fortunately, some of the objects have already been measured in SDSS DR9 (Ahn et al., 2012) with information about the spectroscopic redshift available. We therefore can at least correct our measurements for distance, as these catalog redshifts are rather reliable, being extracted from spectroscopic data.

Now we can fit and normalize calculated models for this wavelength regime (Chary & Elbaz, 2001) to our plots, and discern between object types.

With that knowledge, we can correct the rest of our sample that fits the models for distance, as we know the values for fluxes that are corrected for distance and the values for the ones that are not.

At last, we can determine star formation rates from our distance corrected measurements according to Calzetti et al. (2010) at $70\mu\text{m}$ as well as $160\mu\text{m}$ and compare the quality of our results, and calculate estimates for L_{TIR} according to Galametz et al. (2013).

6 Data Analysis - In Depth

6.1 Automated Analysis in Detail

6.1.1 First Step - File Preparation

Looking at the files from the MESS sample, we find the following file structure:

```
./mess-scanam-21/  
├── 3C 58 SN 1181-B-CLEAN/  
├── 3C 58 SN 1181-G-CLEAN/  
├── 3C 58 SN 1181-R-CLEAN/  
├── AFGL 190-B-CLEAN/  
├── AFGL 190-R-CLEAN/  
├── AFGL 278-B-CLEAN/  
└── AFGL 278-R-CLEAN/
```

We need to copy our Python script and the configuration files for SExtractor into the root directory. In this case the root directory is **/mess-scanam-21/**.

The filestructure is inconvenient, as we would like the filter frames for the corresponding central objects to be in the same directory. Thus a piece of code is written to do just that, and as a result we get a new directory with paired files in their respective folders:

```
./mess-scanam-21-paired/  
├── 3C 58 SN 1181  
├── AFGL 190  
└── AFGL 278
```

Now we need to take a look at the FITS files inside these directories and find that SExtractor 2.19.5, as well as previous versions, have difficulties with the filenames with special characters in the following form:

3C 58 SN 1181-B-CLEAN_astro_1.0_pacs 70_0.fits

3C 58 SN 1181-G-CLEAN_astro_1.0_pacs100_0.fits

3C 58 SN 1181-R-CLEAN_astro_2.0_pacs160_0.fits

Therefore, we can rename those files as a quick fix like this:

```
./mess-scanam-21-paired/
├── 3C 58 SN 1181
│   ├── B.fits
│   ├── G.fits
│   └── R.fits
├── AFGL 190
│   ├── B.fits
│   └── R.fits
└── AFGL 278
    ├── B.fits
    └── R.fits
```

Since these are already located inside their correspondingly named folders, the ambiguity among the filenames does not pose a problem. The original files & file structure is left intact in order to provide a full set of untouched, original data. As backing up is always necessary, all files have to be copied. We are therefore in need of at least twice the discsize needed for the raw data.

Lastly, all SExtractor configuration files are copied to the new destination. SExtractor needs these files to be in each working directory it operates on.

Hereby the files have been prepared for further analysis with SExtractor, ending one of the two most time consuming parts of the code.

6.1.2 Second Step - Source Detection and Photometry

We can now start running SExtractor with some command line options to provide check-images for detection and apertures in each frame for each object. A convolution mask called MEXHAT (Cayón et al., 2001) has been chosen for detection of faint and extended sources, as this kind of mask seems to provide the best results.

Aperture photometry for galaxies is not as easy as for stars, because galaxies do not have uniform light profiles. This happens due to a distribution effect of stars in a given galaxy. Furthermore, galaxies do not have sharp edges. We therefore make use of apertures that adopt various approaches to provide some kind of uniformity in our measurements.

We chose two kinds of apertures. One being a Kron aperture (Kron, 1980), based on a luminosity weighted radius of the object.

The other one is a Petrosian aperture (Petrosian, 1976). This aperture is defined by the shape of the averaged light profile of an object, and determines its radius with a certain value as a threshold.

The reason for this dual system emerges from the idea to provide a comparison between aperture types when using the still experimental and not yet functional part of the code to perform surface photometry, with benefits listed in section 5.2. In the following analysis we chose to use the petrosian aperture type, for the obvious reason that it encloses 90% of the light of an object (see Petrosian, 1976). We can take a look at one of the check images, in order to confirm that these settings are valid.

Figure 6: A typical check image of CAS A from the MESS sample, with Kron (inner ring) and Petrosian (outer ring) apertures drawn for each detected object. Notice the amount of objects found at the edges and in the place of the central, resolved and extended source. Image dimensions of 2030 x 2116 pixels, corresponding to 33.83' x 35.27'.

We can confirm that SExtractor has detected almost all objects of interest, yet there are a lot of artifacts and wrong detections as well. It is a difficult task to provide an algorithm to get rid of objects at the center because the central source does not cover the same pixel area in each filter. Even worse, the different objects do not cover the same area among each other.

Figure 7: *Masked check image of CAS A, with original apertures drawn, and red rectangles as objects that were not excluded by the masking algorithm. Image dimensions of 2030 x 2116 pixels, corresponding to 33.83' x 35.27'.*

The idea is to relate the extension of the central object to the total dimension of the frame. We find that the central source roughly covers $f = \sim 10\%$ of the total image size. A simple relation that we can code and put into the script looks like this:

$$r_{mask} = \frac{(x_{dim} + y_{dim})}{2} \cdot f \quad (16)$$

We can call this the radius of the central mask for the sake of simplicity, and define the radius of an object as:

$$r_{object} = \sqrt{(x_{object} - x_{center})^2 + (y_{object} - y_{center})^2} \quad (17)$$

For every object the relation $r_{object} > r_{mask}$ needs to be fulfilled.

We can now turn our focus onto to the edges of the frame, which are very noisy as implicitly discussed in section 3.

This task seems to be a bit more challenging. The irregular shape of the edge makes it difficult to determine which source to keep, and which one to cut. We do not want to cut down the frame until we have a rectangular piece of the original image that is smooth, as this will exclude too much valuable information. A lightly advanced idea is to define a radius around each source, and throw out detections where the radius vector passes areas outside of the image. For performance reasons, we do not ask for the whole circle in the area, but only use directions orthogonal and in the direction of the position vector of the object itself.

We look at the position vector of the object relative to the center and calculate each component with a set factor (here the factor is set to $g = 90$) as an extension in order to test for adjacency to the border.

$$\begin{aligned} x_{outer-thresh} &= x_{object} + \frac{(x_{object} - x_{center})}{r_{object}} \cdot g \\ y_{outer-thresh} &= y_{object} + \frac{(y_{object} - y_{center})}{r_{object}} \cdot g \end{aligned} \quad (18)$$

We can also define the orthogonal direction of that position by

$$\begin{aligned} x_{outer-perpen} &= x_{object} + \frac{(-y_{object} + y_{center})}{r_{object}} \cdot g \\ y_{outer-perpen} &= y_{object} + \frac{(x_{object} - x_{center})}{r_{object}} \cdot g \end{aligned} \quad (19)$$

And complementary the other orthogonal direction

$$\begin{aligned} x_{outer-perpen-other} &= x_{object} + \frac{(y_{object} - y_{center})}{r_{object}} \cdot g \\ y_{outer-perpen-other} &= y_{object} + \frac{(-x_{object} + x_{center})}{r_{object}} \cdot g \end{aligned} \quad (20)$$

If any of these positions deliver values of -1.0×10^{30} , which is the value that SExtractor sets in its check images for regions outside of the frame, the object is excluded from the sample.

The screen output of this part of code also features the number of objects found with masking in relation to total object number found for each frame by SExtractor. This offers a quick first look at the stability of detection. We expect 0 to ~5 objects of interest in each frame from a quick first visual inspection of the data. If we are confronted with values outside of that range, the code offers an easy way of making our inner masking radius larger or smaller by altering the last value (f) in equation 16. Likewise we can configure the radius for detection of objects at the edge by modifying the last value (g) in equations (18), (19) & (20).

We end up with a robust routine to automatically mask unwanted regions of a frame in the MESS sample (see Figure 7), and collect only interesting detections, that are now ready for further analysis.

6.1.3 Third Step - Matching Detected Sources

This optional part of the code uses the ASSOC mode of SExtractor. It is designed to measure sources in one filter frame, and then use those positions in other filter frames. Obviously this is of great use whenever information about the color of an object is required. As none of the resulting output is used in this code, this feature is strictly of informal nature to the user. It has been included as a tool for testing the manually established results of analysis, but is not included in these methods. It is deliberately put out of common operation in the code.

If the need for it ever arises, it is still available to the user.

6.1.4 Fourth Step - Crosscorrelation with NED

Our list of mask-filtered objects has now to be run through an online database for further information. Several astronomical databases feature automated queries via codes.

According to our assumption about the nature of the detected objects, we can safely say that the online database NED (NASA/IPAC Extragalactic Database) (Mazzarella & NED Team, 2007) is a reasonable starting point.

This portal offers some plugins as well as url based queries for automation. The later has been chosen for this code, and is used as follows with the only restriction that crosscorrelation will take place within a radius of 9" at most. This is chosen due to the fact, that the pointing of Herschel was not better than 4".

The output from the last step of the code consists of separate files with measurements for each detected object in each line. The code provides a list of all objects featured in all frames at 70 μ m , 100 μ m and 160 μ m individually.

As we encounter some limitations of the portal and the Python plugin named *urllib2*, we are obliged to work around that.

The first problem arises from the portal interface of NED itself, by limiting the query for correlating object positions for 500 objects at most in one run. This, however, is cut in half by said plugin. Our Python routine can handle 250 sources at most at a time. So we start off by splitting our big files for each filter into smaller ones, with the corresponding number of entries each.

Now we can feed those lists into NED and get the whole HTML source code as output. With basic knowledge of the structure of HTML we can quickly eliminate all unwanted information and leave only an ascii list of bar separated values for further inspection. We then format these results in the way we need it, and save them in a file.

By having collected the results, we are ready to put the split files from our own detections

back together into one big one for each frame, and start correlating the results from NED to our detections of object positions.

The correlation between original positions and NED detected ones is done by comparing each set of coordinates with the other. The NED output is formatted in a way that prints the input set of coordinates in the line with the closest separation in arcseconds (") into its output, and the rest of matches that have larger separations without the original coordinates beneath them. This enables us, to always get the closest match quite easily, by looking for the input coordinates in the respective output column of NED. After formatting our new correlated output file nicely into one big file for each frame we can now merge these files and collect each filter measurement for each position into one big master file in our root directory called *master_table_SFR_complete.cat*.

Finally we have everything we need for manual analysis.

It has to be mentioned that there is also a part of commented code by default, that enables the user to decide to delete temporary files, that are not necessary anymore. It is wise however, to keep those files, in order to check if all steps of detection and analysis are done correctly, and therefore to find out what went wrong at which step if problems arise.

6.1.5 (Fifth Step) - Experimental Surface Photometry

As an elegant approach to this topic, we initially chose to adopt surface photometry for our research. The advantage of this features the ability to not have to care about distance effects in the data. With the majority of the objects at an angular size of ~20" - 60" we are scratching the limit of reliability of this technique.

Unfortunately, there seems to be some fundamental problem in the formulation of the reduction method and therefore this part of the code has been tagged with comments and warns the user that the output of this routine is not finished yet.

The steps we take in the code are calculation of surface brightness of the detected objects for measurements in Kron and Petrosian (Kron, 1980; Petrosian, 1976) apertures, which seems to work nicely. We acquire a surface brightness by applying the following equation

$$\mu_{SB} = m_{obj} + 2.5 \cdot (Area) \quad (21)$$

The next step is the conversion of surface brightness to physical units

$L_{surface}(\lambda) [L_{\odot} kpc^{-2}]$ as follows

$$L_{surface} = 10^{-0.4(\mu_{SB} - M_{\odot} - 21.572)} \cdot 1000^2 \quad (22)$$

The last term converts the units of the result from $[L_{\odot} pc^{-2}]$ to $[L_{\odot} kpc^{-2}]$. We also need to apply a value to M_{\odot} which should be the bolometric absolute brightness of the Sun at $M_{\odot, Bol} = 4.74 [mag]$, yet by doing so, we generate values of $\sim 10^{20-30} [erg s^{-1} kpc^{-2}]$ difference to the expected range of results of $\sim 10^{38-44} [erg s^{-1} kpc^{-2}]$. There must clearly be a mistake either in the conversion of units or in the formulation itself.

Thus the values calculated do not represent real results.

This additional part of the code runs in the background and parts of its calculations are also printed in the final output file mentioned above.

6.2 Non-Automated Analysis in Detail

6.2.1 First Step - Object Confirmation

In the first step of non-automated analysis, we take a look at our automatically generated master table and filter for entries with more than one measurement in the various filters. As a reference we use the B filter detections at $70\mu\text{m}$, because this has been found to be the most reliable wavelength for detection of IR objects, as influencing radiation of other processes has the least effect at this wavelength. However, we only take into account object detections in at least two filters, as there can still be a lot of spurious artifacts of dust and molecular clouds that lead to wrong detections, especially at larger wavelengths i.e. the R filter at $160\mu\text{m}$. We find 52 B-G-R-correlations, 151 B-G-correlations and 173 B-R-correlations (see Table 5, 6 & 7).

6.2.2 Second Step - Collecting Additional Data

As a starting point, we will now inspect the objects that are most likely to refer to real objects. In order to do that, we tighten the conditions to detection in all three filters. Out of the rather small sample of 52 objects we find that 7 positions were crosscorrelated to entries in NED. It is obvious now that this truncated list of objects really is possible to be handled manually.

By querying these objects via Vizier³ a lot of existing data is presented, and homogeneous surveys for all objects have to be chosen. We take into account the SDSS survey (Ahn et al., 2012), for the availability of information in SDSS filters (ugriz) covering visual wavelengths between 374 nm and 890 nm, and, if fortunate, even reliable spectroscopic redshifts. The 2MASS catalog (Skrutskie et al., 2006) is used for wavelengths between $1.25\mu\text{m}$ and $2.15\mu\text{m}$. Another survey suitable was WISE (Cutri & et al., 2014; Wright et al., 2010), delivering measurements in the near infrared wavelength regime between $3.4\mu\text{m}$ and $22\mu\text{m}$. From there on, our own measurements continue the data into the far infrared between $70\mu\text{m}$ and $160\mu\text{m}$.

After a first look at the SED of these objects, we can assume our approach delivers correct results and continue by querying the rest of our data that has been identified by NED via Vizier. In total we find data for 22 objects, and extend the number of objects with redshift information to 7 hits.

³Vizier online: <http://vizier.u-strasbg.fr/viz-bin/VizieR> visited on 28.9.2014

6.2.3 Third Step - Correcting for Distance

Now that we have a small sample of redshifts, that seem to belong to the same class of object, we can start correcting the rest of the sample for distance that fits the same pattern. By taking the relation for cosmological redshift

$$z = \frac{v}{c} \quad (23)$$

and using the equation

$$v = d \cdot H_0 \quad (24)$$

where d is the distance of the object in Mpc.

We adopt the hubble constant to be $H_0 = 100 [km s^{-1} Mpc^{-1}]$ for the sake of simplicity. After some simple operations we find that the distance can be formulated like this

$$d = \frac{c \cdot z}{H_0} \quad (25)$$

For each redshift the distance is calculated, and the associated data is corrected for cosmological extinction. We also put this method to a test by calculating distances for the already known sample with SDSS redshifts, and derive correct distances up until the 2nd decimal point. That value confirms quite obviously that the method is adapted correctly. This leaves us with the opportunity to calculate distances from the distance module for the rest of the sample, as we now know the absolute and apparent magnitude for the same type of object. The basic distance module without extinction is defined as follows

$$m - M = 5 \log(d) - 5 \quad (26)$$

Having calculated the distances for the rest of the sample, and applied distance corrections to them as well, we can continue to the next step.

6.2.4 Fourth Step - SED and Modeling

This makes plotting a distance corrected SED for each of these objects possible. We find a significant shape among the individual objects. Apart from the visual part of the spectrum, we can neglect effects of extinction by dust for our intentions. This is not the most reliable approach if one wants to obtain precisely measured, qualitative results, but is sufficient for a quick classification and overview, which is our goal for the moment. By following our initial notion about the nature of these objects, we try adopting calculated models for IR galaxies for this range of wavelengths between 374nm and 160 μ m according to Chary & Elbaz (2001).

Figure 8: (a) showing model data by Chary & Elbaz (2001). The models are normalized to a flux of IC 1296 at 3.35 μ m. Additionally we plot the model SED of an elliptical galaxy (red, short curve) by Coleman et al. (1980); Benítez et al. (2004). (b) showing a SED plot for the 6 identified objects that have spectroscopic redshifts from SDSS.

The SED models (Chary & Elbaz, 2001) used in Figure 8a include a standard example of an ULIRG, a model of a merging galaxy indicated as merger in the plot, a Seyfert 1 galaxy, an ULIRG with a QSO and a peculiar IR galaxy.

All these models show a significant resemblance to the data we provide, although none of these models fit the measurements exactly. This can be due to the lack of the possibility to correct for extinction in the SDSS filters in the visible regime. However, as IR data is largely independent of extinction, the longer part of wavelengths should show a tighter fit to the model. A k-correction was applied to the data. It turned out however, that this correction accounts for 0.01 mag, which is well within the error of our measurements, and thus, neglected in further analysis.

Additionally the model of an elliptical galaxy (Coleman et al., 1980; Benítez et al., 2004) for a partial area of the IR wavelength range has been plotted to show that all our measured galaxies exhibit features of an elliptic galaxy as well, if no information about the longer wavelengths is present.

We normalize the model data to a suitable flux at a chosen wavelength of an object of our sample, in order to directly compare our results with the theoretical curves. This particular wavelength has been chosen for three reasons. One being the fact that it lies at the median of the number of measurement points, the second one derives from the little influence of extinction to IR data. We also find that this wavelength has the smallest spread between interpolation points of the model data, resulting in maximal reliability. We do so by following the established steps for calculating magnitudes from fluxes and vice versa. We take a look at the definition of the magnitude system

$$m_{obj} = -2.5 \cdot \log\left(\frac{f_{\lambda,obj}}{f_{\lambda,Vega}}\right) \quad (27)$$

Where $f_{\lambda,obj}$ is the flux of an object at the wavelength λ , and $f_{\lambda,Vega}$ is the flux of a photometric reference point, in this case Vega, at the same wavelength.

We can see that a magnitude is defined by the ratio of two fluxes, and therefor independent of the system of units used, however we will adopt Jansky [Jy] as the standard unit system for our fluxes in our calculations.

There are more systems than just Vega for reference fluxes, but we will confine to this one, as this was also used for data reduction by the MESS team. A listing of values used is provided in Table 1.

By reorganizing equation (27) we get

$$f_{\lambda,obj} = f_{\lambda,Vega} \cdot 10^{-\frac{m_{obj}}{2.5}} \quad (28)$$

With this set of equations we can now convert all magnitudes calculated by SExtractor to fluxes and homogenize the rest of our additional measurements collected from online databases.

In order to use the values calculated from models, which are given in units of F_{λ} , we have to convert those with the following relation:

$$f_{Jy} = 3.33564095 \times 10^4 \cdot F_{\lambda}[\text{erg/cm}^2/\text{s}/\text{A}] \cdot \lambda^2[\text{A}^2] \quad (29)$$

We can see the results of the application of these few easy steps in Figure 8a.

It is obvious that our suspicion has been confirmed. The rough shape of the model SED's follows the same pattern as our measurements. There is a clearly visible deviation from the model for most of the data, suggesting further research on that matter. In this thesis however, we will acknowledge this circumstance and move on with our last step of data analysis.

Table 1: The Vega-System reference points for flux calibration

Filter	$\lambda[\mu\text{m}]$	$f_{\lambda, \text{Vega}} [\text{Jy}]$
u	0.354	3676
g	0.475	3640
r	0.622	3645
i	0.763	3641
z	0.905	3631
j	1.25	1577
h	1.65	1050
k	2.17	674.90
w1	3.35	309.54
w2	4.6	171.78
w3	11.6	31.67
w4	22.1	8.36
Herschel B	70	0.78
Herschel G	100	0.38
Herschel R	160	0.14

6.2.5 Fifth Step - SFR Estimation

We finally arrive at our last step of manual analysis with enough knowledge about the objects we have found to make profound predictions based on proven assumptions. The main goal of this thesis was to calculate star formation rates from IR data of photometric Herschel measurements, if the objects we detect actually turn out to be IR and ULIRG galaxies. Therefore we follow Calzetti et al. (2010), who showed that there is a relation between IR measurements of galaxies that show significant luminosity elevations, and their star formation rates. By collecting data across the whole energy spectrum Calzetti et al. was able to determine the SFR for a large sample of well known objects in differ-

ent ways and therefore provide very accurate estimates of said value for this class of objects. She then correlated these estimates to luminosities and surface brightnesses of these objects measured in filter bands ranging from 24 μm (Spitzer, (Mainzer et al., 2003)) to 160 μm (Herschel, (Pilbratt et al., 2010)) and showed that a relation between these two quantities exist within a set of given boundary values.

The luminosity at a given frequency is defined by

$$L_\nu = 4\pi R^2 f_\nu \quad (30)$$

From (Calzetti et al., 2010) we adopt two equations:

$$SFR(70\mu m) [M_\odot yr^{-1}] = \frac{L(70\mu m) [erg s^{-1}]}{1.43 \times 10^{43}} \quad (31)$$

for $L(70\mu m) \geq 1.4 \times 10^{42} [erg s^{-1}]$. This estimate does inherent a dispersion of at least ~ 1 order of magnitude.

A second relation for measurements at 160 μm is provided:

$$SFR(160\mu m) [M_\odot yr^{-1}] = \frac{L(160\mu m) [erg s^{-1}]}{7.0 \times 10^{42}} \quad (32)$$

for $L(160\mu m) > 1.0 \times 10^{42} [erg s^{-1}]$. The derivation of SFR from L(160 μm) has almost twice the dispersion of that from L(70 μm), and therefore is not as a good estimator for this value as L(70 μm). This arises from the influence of heating of dust and by non-star-forming populations when using radiation at 160 μm exclusively.

In the end, we provide calculated data for 22 identified objects in both wavelengths with estimates of their respective error.

6.2.6 Sixth Step - Total Infrared Luminosity Estimation

The total infrared luminosity (L_{TIR}) is an estimate of how much radiation a galaxy emits throughout the whole infrared spectrum of light. According to Galametz et al. (2013) we define it by

$$L_{TIR} = \int_{3\mu m}^{1100\mu m} L_{\nu} d\nu \quad (33)$$

We can derive L_{TIR} [$ergs^{-1}$] from our own measurements at $70\mu m$ (B) and $160\mu m$ (R), by using the following relations found by Galametz et al. (2013).

$$\log L_{TIR} = a_i \log(\nu L_{\nu}(i)) + b_i \quad (34)$$

and the following table of coefficients

Table 2: Shortened table of coefficients for calculation of L_{TIR} . Taken from Galametz et al. (2013).

Wavelength	a_i	b_i
$70 \mu m$	$0.973 \pm(0.002)$	$0.567 \pm(0.013)$
$160 \mu m$	$1.024 \pm(0.003)$	$0.176 \pm(0.018)$

This approach is consistent up to $z \sim 2$ according to Galametz et al. (2013), who derived this relation from near by resolved and known galaxies. We would have been able to provide further analysis if our sample had contained G filter measurements for all objects. With the current set we only would have been able to show that all detected objects in this thesis are indeed submillimeter galaxies (SMG).

The results are presented in table 4 in section 7.

7 Results

At first we will have a look at a set of color magnitude diagrams created from the complete sample of detected objects with respective Herschel B($70\mu m$), G($100\mu m$), and/or R($160\mu m$) measurements.

While the CMD (Color Magnitude Diagram) for B-R colors against B magnitude (see Figure 9a) does not deliver decisive information for sample selection, the next CMD for B-G colors against B (see Figure 9b) at least tells us that we are most likely dealing with the same class of object at different distances.

If we make our sample smaller and only take objects with all three filter bands into account, we can plot color-color diagrams for further inspection (see Figure 10a & 10b).

Figure 9:

(a) showing a CMD diagram for all 173 objects with B and R measurements against apparent B magnitude. Unfortunately inconclusive for sample selection. (b) showing a CMD diagram for all 151 objects with B and G measurements against apparent B magnitude. Clearly visible correlation between $B-G$ color and apparent B magnitude.

Figure 10:

(a) showing a color color diagram for $B-G$ and $G-R$, no correlation visible. (b) showing a color color diagram for $B-G$ - $B-R$, a clear relation between these two colors is visible.

We can also plot all data for our sample of 6 identified objects with known distances. By trying to keep the following Figure 11 as simple and clear as possible, we have to make a compromise by not plotting the distance corrected data for all 26 objects. Instead, we will put the data for the 6 objects that had SDSS redshift information with the distance corrected fluxes into the plot, and leave the rest of the data un-plotted. The shape of the SED of the averaged objects clearly fits the model data at a first approximation, so there is no point in overloading the figure even more.

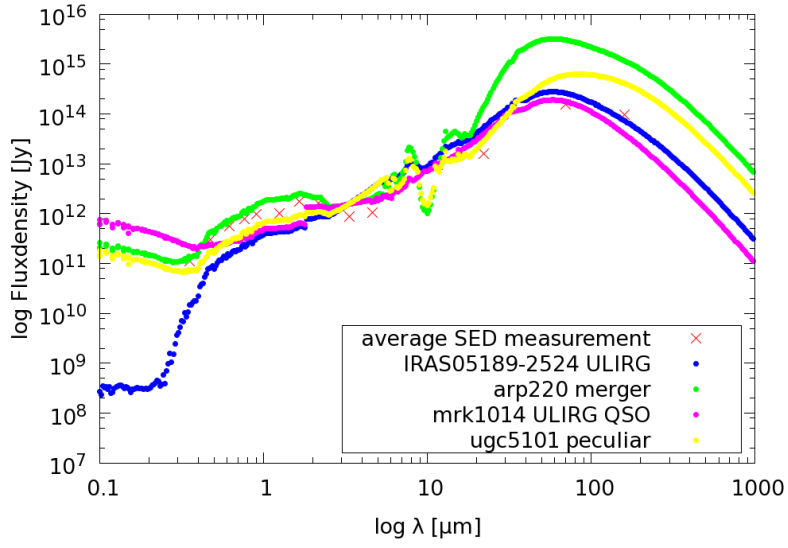

Figure 11: *Plots for 6 objects with distance correction and normalized model data to $3.35\mu\text{m}$ averaged to a single measurement for each filter.*

With our calculation for the derivation of SFRs for the selected sample we can plot the following Figure 12.

Figure 12: *SFR against redshift for the 26 identified objects in our sample with derived distances. Errorbars for z for all but the ones with SDSS redshifts.*

In Figure 12 we find a strong correlation between SFR and z . We expect galaxies at greater distances to start interacting with each other, causing phases of starbursts. This effect does get larger as we look farther away and, fortunately, this is also what we observe in this thesis.

We can now plot another CMD diagram for our sample with known & calculated distances and find a tighter correlation between these two measurements in Figure 13.

Figure 13: *CMD for color B-R against absolute B magnitude.*

A nice correlation is clearly visible in Figure 13 for all objects with distances $d \lesssim 700Mpc$ corresponding to $z \lesssim 0.13$.

Finally, we present the results (see table 3) with estimates for distance, redshift, L_ν and SFR. Additionally we provide estimates for TIR (Total Infrared Luminosity) for the same set of well known objects with the respective errors (see table 4). The overall object type has $L_{TIR} \simeq 10^{11} L_\odot$ allowing of classification of the objects to the class of LIRGs (Luminous Infrared Galaxy) with ULIRGs starting at $L_{TIR} \simeq 10^{12} L_\odot$. We find three objects to be in the range of ULIRGs with $L_{TIR} \geq 10^{12} L_\odot$, however we must keep in mind that these objects also are the ones with the greatest distances in the sample, and thus these results may not be as reliable as the rest of the of the sample.

This concludes this section, and leaves us with a lot of untouched topics. We remind the reader that this thesis is mainly meant to be about the methodology to accomplish analysis of large amounts of data, and simply shows the possibility of practical adaption to this kind of task.

Table 3: Results Table: Distance (d), Redshift (z), Luminosity in $[erg s^{-1}]$ at $70\mu m (L_{\nu}(70))$, Luminosity in $[erg s^{-1}]$ at $160\mu m (L_{\nu}(160))$, SFR in $[M_{\odot} yr^{-1}]$ derived at $70\mu m (SFR(70))$, and SFR in $[M_{\odot} yr^{-1}]$ derived at $160\mu m (SFR(160))$. Individual errors are indicated next to each column of measurement to right. The first 6 objects have redshift estimates from SDSS and therefore, no error estimate is available.

8 Conclusions

In this thesis, we discussed some basic concepts of infrared radiation and its applications. A quick, abridged, yet comprehensive overview of the physics of star formation and dynamical behavior within a galaxy has been presented. We took a brief look into the Herschel Space Observatory and its main instrument that has been used for our research. The origin of the data provided by the MESS group has been outlined. We then give insight into our approach of analyzing this data with an epitomized look at the tools used. In the main part, we constituted a semi-automatic pipeline written in Python for handling medium sized amounts of photometric Herschel data. The basic steps were depicted and then formulated in detail. Finally, the manual part of analysis has been demonstrated and results were presented. We show that we observed properties of sources that confirmed our assumption about the class of object we presumed to be dealing with. An estimate for SFRs (Table 3) and TIR (Table 4) for these LIRGS has been established and we present calculated distances and redshifts for this sample of objects. Additionally, tables with B, G and R measurements and calculated colors for the whole sample (where possible) are included in the Appendix (see Table 5, 6 & 7)

This thesis has been based on the notion that there is a lot more science to do with data, apart from the initial purpose that it has been recorded for. We therefore emphasize the need creativity and creation of automated routines that can handle large amounts of data and extract new information, adding to new results for the astronomical community and a sophisticated scientific insight into the processes within our universe.

9 Outlook

In the future, we would like to extend the results for SFR estimates to the part of our sample, that has no yet been identified in other catalogs. In order to accomplish that, we can take another look at the color color plots from section 7. With these plots, we are theoretically able to distinguish between object classes. All we need is to determine where our desired objects are supposed to show up in the color-color plots. This has not been done for this thesis, as time was a factor. The basic approach, however, would be to look up already calculated model data for colors of this object type in the literature and correlate those results to ours. Another, more consistent approach, would be to show a dependency for the desired colors of LIRGs & ULIRGs within our Herschel filter data, by fitting a curve to a B-G against B-R plot for objects that qualify for these constrains, and then applying that result to the rest of our sample, where no further analysis has been carried out yet.

This will contribute additional data and insight into future research on star formation in IR galaxies, LIRGs and ULIRGS.

Acknowledgements

I would like to convey sincere gratitude to Prof. W. W. Zeilinger for constant support, constructive feedback and careful reading of this thesis, my dear colleagues at the Institute for Astrophysics at the University of Vienna, my family and friends, and all people who supported me on my journey to becoming a scientist.

This research has made use of the NASA/IPAC Extragalactic Database (NED), which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.

This publication makes use of data products from the Wide-field Infrared Survey Explorer, which is a joint project of the University of California, Los Angeles, and the Jet Propulsion Laboratory/California Institute of Technology, funded by the National Aeronautics and Space Administration.

CURRICULUM VITAE

Personal Data

Name: Michael
Last Name: Mach
Date of Birth: 01.01.1983
Place of Birth: Vienna
Citizenship : AT

Education

1989 – 1993 Elementary School Alterlaa, 1230 Vienna
1993 – 2002 Secondary School Bundesgymnasium und Bundesrealgymnasium 23, 1230 Vienna Anton Baumgartnerstr. 123 (Matura)
2013 Bakk.rer.nat. of Astronomy at University of Vienna
Thesis Title: Observation of the Local Bubble
Supervisor: Prof. Breitschwerdt / Prof. Zeilinger
11/2014 projected acquisition of MSc. Of Astronomy at University of Vienna
Thesis Title: Properties of Extragalactic Objects with Herschel Data
Supervisor: Prof. Zeilinger / Prof. Kerschbaum

Languages

German (mothertongue)
English (fluent)
Spanish (working knowledge)
Italian (working knowledge)

Soft Skills

Advanced Knowledge of:

Python, Fortran, SExtractor, Aladin, Skycat, ds9,
Unix, Linux, IRAF, R, gnuplot, Scisoft-Package, Html,
Javascript, Office/OpenOffice , LaTeX

Working Knowledge in:

C, C++, HIPE, Topcat, Css

Other Education

B- Drivers License

Scientific Employment

- WS 2013 Tutor for Mathematics 1A at the Department for Earth Sciences at the University of Vienna (Dorfi / Reimers)
- SS 2014 Tutor for Mathematics 1B + own Tutorium at the Department for Earth Sciences at the University of Vienna (Dorfi / Reimers)
- Tutor for Mathematics II at the Department for Earth Sciences at the University of Vienna (Dorfi / Reimers)
- Tutor for "beobachtungsorientiertes Praktikum" at the department for Astrophysics at the University of Vienna (Zeilinger/Alves/Forbich/Hacar Gonzales)
