ABSTRACT
The majority of existing digital preservation solutions are focusing on the long-term storage of digital content such as documents, images, video, audio files and other domain specific data. Preservation of an Information Technology infrastructure for supporting business processes is a much more challenging task. It requires the preservation of software and hardware stacks as well as relevant contexts, which together, provide an execution layer for running business processes. The proposed TIMBUS architecture addresses limitations of existing digital preservation solutions and provides a complete framework for preserving business processes implemented upon a service oriented architecture.

Keywords
digital preservation, business process

1. INTRODUCTION
Providing business continuity is an important task facing many multi-national companies. Failure to provide business continuity often leads to substantial financial losses and may cause total or partial loss of business. The most common approach to address potential adverse circumstances or events is to provide effective Business Continuity Management (BCM). The main objective of BCM is to access different risk factors and establish contingency plans for minimising impact of potential hazardous events on existing business processes (BPs).

Many BPs are heavily dependent on sophisticated information technology (IT) infrastructure, which is supporting different business transactions and providing critical information for making important business decisions. Constant evolution of the technology landscape brings new challenges for any business organisation to support their IT infrastructure, where new hardware and software solutions are developed and adopted on a regular basis. These new versions of hardware and software components often have backward compatibility limitations. In some contexts digital preservation (DP) is one of the most effective solution for dealing with evolving digital infrastructures.

The majority of existing DP solutions focus on the long-term storage of digital content such as documents, images, video and audio files. Preservation of an IT infrastructure for supporting BPs is a much more challenging task. It requires the preservation of software and hardware stacks as well as relevant contexts, which together, provide an execution layer for running BPs.

DP architecture developed within the TIMBUS[12] project provides a unique set of solutions going beyond the scope of existing DP approaches. It covers all aspects of traditional DP system such as preserving a digital content but also addresses enterprise risk analysis and business continuity planning. It covers a wider scope of DP processes, which includes Intelligent Enterprise Risk Management (IERM) for automatic identification and prioritisation of risks within an enterprise and ability to minimize those risks by taking a specific set of actions including DP.

The TIMBUS system identifies a set of interdependent BPs from the enterprise logs, automatically detects and captures relevant context meta data, packages the collected information and provides facilities for long term preservation, monitoring and maintenance. The TIMBUS system enables the redeployment and re-execution of the partial or complete BP at a future time.

A high level overview of relevant research projects covering various aspects of DP, commercial and open source solutions for performing DP is presented in the next section.

1.1 Related Work

The EC has long history of supporting DP research SCAPE [20], WF4EVER [2], PROTAG [19], APARSEN [3] and LIWA [16]. Many of the completed and currently running projects have made important contributions and are relevant to TIMBUS. SCAPE is developing a services based framework for preservation of large-scale, heterogeneous collections of complex digital objects by using semi-automated work-flows based on open source platforms. WF4EVER is developing a software architecture for the preservation of scientific work-flows for conducting complex research experiments in combination with relevant contexts. A smart multi-agent architecture for performing the long-term preservation of digital objects is developed in PROTAG project. It can be integrated with existing and new preservation systems to support various aspects of a DP work-flow. A sustainable digital information infrastructure for supporting permanent access to digitally encoded information is developing based on the APARSEN framework. LIWA has developed an architecture for Web content preservation, which supports capturing content from a wide variety of sources and performs the long term interpretation of constantly evolving data archive by filtering out irrelevant information.

The following projects have some degree of overlap with DP, where the main focus lies in providing framework for the long term access to particular information resources. In the scientific domain, projects like GENESI-DR[15] and PREPARINGDARIAH[18] provide infrastructure for establishing an open digital repository for world-wide researchers to seamlessly access and share data, information and knowledge originating within different areas of science. Long term preservation in libraries and museums is investigated by AR-COMEM[4], PATHS[17], AXES[1], PAPYRUS[8] and DECI-PHER[11] projects. AR-COMEM is focusing on transforming digital archives into memories structures, that can be utilised by specific community of experts, where PATHS is implementing an approach for interpreting heritage material and providing clear navigation tools for wide range of users. AXES is developing a set of tools for providing intelligent interactions with various types of digital content. An innovative ideas of understanding user queries in the context of different specific disciplines for improving underling search techniques are developed in PAPYRUS project. Using of semantic web technologies for analysing digital heritage are investigating in DECI-PHER project. ENSURE[13] provides the long-term usability of data produced or controlled by commercial organisations.

Processing of digitally preserved data are explored in the following projects SOAP[21], CULTURA[7], 5-COPFIM[14], ETHIO-SPARE[10], ARTSENSE[5], CHESS[9] and BLOG-FOR-EVER[6]. Innovative approaches to filtering, restructuring and facilitating experience of interaction with scientific publication are developed within the scope of SOAP and CULTURA projects. Information discovery aspects in digital archives relevant to the cultural heritage domain are investigated in 5-COPFIM, ETHIO-SPARE and ARTSENSE projects. User engaging techniques for providing better and more efficient access to historical and cultural information as well as modern blogs are developed in CHESS and BLOG-FOR-EVER projects.

There are a number of commercial and open source products available, which address different aspects of DP. SDB2 developed by world leading company in DP technologies provides services for storing and preserving critical digital information in reliable manner. DIAS3, developed by IBM, addresses various aspects of long-term usability of digital information over the past decade. Rosetta developed by ExLibris4 provides a highly scalable, secure, and easily managed DP system for preserving knowledge, libraries and other memory institution data around the world.

Alongside the commercial applications open source projects are available; Fedora-Commons, Greenstone, LOCKSS, Archimatica, DPSP, IRODS, DAITSS. CDS Invenio & CERN5 Document Server supports preservation of articles, books, journals, photos, videos etc. and used by large number of scientific institutions worldwide. DSpace6 developed by the Massachusetts Institute of Technology Libraries and Hewlett-Packard supports building of open digital repositories for publishing content. Eprints7 is a set of open-source software applications for building open access services to publishing and multimedia content, which support a number of features such as meta-data extraction, access control, flexible work-flows etc.

The large verity of research, commercial and open source, in area of DP shows that the problem of DP is well-understood for data-centric information scenarios. On the other hand, scenarios where important digital information has to be preserved together with the execution contexts have been less explored. Preservation is often considered as a set of activities carried out in isolation within a single domain, without taking into account the dependencies on third-party services, information and capabilities that will be necessary to validate digital information in the future. Many existing DP solutions focus on more simple data objects which are static in nature. The unique aspect of TIMBUS is that it attempts to advance state of the art by exploring how more complex digital objects can be preserved, such as BP's with the entire execution environment. TIMBUS provides the infrastructure, which supports the user in identifying what BP's to keep, why and for how long they need to be kept.

Many modern BP's are exposed to the outside world via service oriented architectures (SOA). SOA is one of the most popular approaches, used by modern companies, for facilitating their business activities over the Internet. It provides a fast, reliable and convenient way to reach a large volume of customers world-wide. The long-term preservation of SOA based solutions is a critical necessity faced by many companies to ensure some level of business continuity. The focus on DP of BP's, where SOA is used as a framework for deliv-

ering services, is the main aim the TIMBUS project. Since understanding of SOA is critical for the successful design of the TIMBUS DP architecture, a high level overview is presented below.

1.2 Service Oriented Architecture
The term “service” defines a system of organised resources used for supplying specific needs to particular individuals or organisations. Services address relevant concepts from different domains such as economy, business, science, etc. A typical service-based model in business combines the following three service layers: Business Service, E-Service and Web-Service.

- **Business Service** represents the non-material equivalent of goods. They are defined as a set of activities supplied by service providers to service customers in order to deliver a specific set of values. Traditionally the majority of these services are discovered and invoked manually, while their realisation may performed by manual, semi-automated or automated fashion.

- **E-Service** is provided and executed by electronic systems in an automated fashion. IT provides an infrastructure for developing concepts such as e-service or e-commerce (electronic-commerce). Such services are executed via transactions conducted over the Internet or an internal computer network. These on-line transactions include buying and selling goods, where business is done via Electronic Data Interchange (EDI). EDI is performed by a collection of software components communicated via standardised network protocols.

- **Web Service** is the e-service consumed via Web-based protocols or Web-based programs. Separation of logical and technical layers gives a possibility of using alternative technologies for the e-service implementation. The following three types of Web-service architectures can be identified: RPC Web Service, SOA Web Service and RESTful Web Service.

These services can be combined into two main business models used by service providers: **Software as a Service** (SaaS) and **Internet of Services** (IoS).

The SaaS Model is characterised by the following factors: provides a quicker-to-deploy strategy, quicker return of investment, frequent and automatic updates, independence from other IT components and improved usability; provides a low-risk alternative to traditionally licensed software; makes business units more focused on business transactions by eliminating dependence on supporting an IT infrastructure; facilitates a collaborative development of complex business models.

The initial focus of SaaS on the middle size companies has been expanded to the enterprise level, which changed the overall software applications market. It requires software vendors to carefully adjust their offers for meeting the constantly rising customer demand on SaaS solutions.

The IoS Model extends the concept of SaaS by providing mechanisms for discovering and invoking new services. It includes a variety of components such as standards, tools and applications for supporting business transactions. These components bring together service providers and consumers in the service-market place, where they can be more efficiently engaged in the verity of business activities.

IoS is also focusing on the creation of business networks, where elements of these networks could support SaaS models. IoS therefore provides infrastructures such as marketplace, brokerage, integration, interoperability, aggregation etc. for multiple services based on the SaaS model.

Rapid adoption of SaaS and IoS models indicates that many BPs are built on service-oriented architectures. Numerous services can be provided by different providers and operated from different geographical locations. A composition of outputs provided by each individual service is combined into particular business value, which can be utilised further by service consumers. Despite the clear advantages of SaaS and IoS, there is a danger of disappearing services and service providers (due to various reasons) by leaving some BPs partially incomplete. Considering that business continuity is not only a company desirable requirement, but also frequently a legal obligation, DP of BPs becomes as important factor of the modern business strategy. Service providers will ultimately be responsible for incorporating TIMBUS-like preservation solutions into future offerings, to support the long-term sustainability of their business models. The TIMBUS architecture presented in the next section provides the complete solution for preservation of complex BPs.

2. ARCHITECTURE
A high-level view of the TIMBUS DP architecture is shown in Figure 1. It consists of five modules: **DP Agent**, **DP Acquisition**, **Intelligent Enterprise Risk Management (IERM)**, **Legality Life-cycle Management (LLM)** and **DP Engine**.

![Figure 1: The high-level view of the TIMBUS DP architecture.](image)

The **DP Agent Module** is running within the **Source environment**, and capturing resources required for performing DP. The collected resources are utilised by the **DP Acquisition Module**, which extracts relevant contexts and combines them into a **Context Model Instance** (CMI). This model is
annotated in IERM and LLM Modules with different risk factors and assessed according to the specified annotations. A generated risk assessment report is used by the DP Engine Module for selecting the most suitable preservation strategy. The selected strategy is translated into a preservation plan, which includes the complete set of instruction for execution process. During a redeployment phase the DP Engine Module identifies a difference between preserved and currently available environments. The identified difference is used for planning and execution by a redeployment process. All steps of preservation and redeployment processes can also be verified by a specific subset of components integrated into the DP Engine Module.

The DP system is integrated with Source and Redeployment environments. Source environment is a combination of all IT and non-IT related resources, which support the execution of BPs and need to be fully or partially preserved according to identified risk factors. The source environment consists of all infrastructure and software components required at run-time. Context information is also required for future usability, including but not limited to dependencies between business process components and the business process itself. Redeployment environment is a combination of IT and non-IT related resources forming an infrastructure which supports the execution of archived BPs, which can be fully or partially redeployed based on information stored within the DP System Archive.

Preservation and redeployment processes are controlled via four graphical user interfaces (GUI): Contexts Acquisition, Risk Assessment, Legality Assessment and Preservation & Redeployment. The Contexts Acquisition GUI controls processes of contexts mining and creation of CMI. The Risk Assessment and Legality Assessment GUIs control the annotation of CMI and risk impact assessment processes. Preservation & Redeployment defines the core set of tools for controlling planning, execution and validation processes.

2.1 DP Agent Module
The DP Agent Module (see Figure 2) is a combination of software components, which are running within the Source environment and capturing resources required for performing DP.

![Figure 2: The architecture of the DP Agent Module.](Image)

The agent’s key component Resource Capturer has a transparent, plug-in type architecture, which allows connecting to different resource capturing components for various IT systems. There are four main plug-in components included into the initial design: Static Dependency Capturer, Dynamic Dependencies Capturer, Contexts Capturer and Event-logs Capturer.

These plug-in components collect the key set of data required for carrying out further steps of DP. Obtained data are packaged before transferring to the DP Acquisition Module. They can be archived and/or encrypted to provide the required level of transferring efficiency and security. The created data package is transferred to the DP Acquisition Module via the secure peer-to-peer connection.

Control of DP Agents is performed via the secure communication channel, which is used for exchanging control messages. It allows control of the resource capturing process on multiple instances of the DP Agents from the single instance of the DP Acquisition Module. Such approach significantly simplifies a deployment process and minimises a cost of managing the large scale IT systems.

2.2 DP Data Acquisition
The DP Acquisition Module (see Figure 3) is a combination of software components, which are used for collecting and combining dependencies, contexts and event-logs from different DP Agents into the CMI. It consists of three software components: Contexts Miner, Contexts Monitor and Model Weaver.

![Figure 3: The architecture of the DP Acquisition Module.](Image)

The Contexts Miner collects data from different DP Agents and performs extraction of different types of information defined by the Context Model (CM). At the high-level of abstraction the mining process can be split into three parts: dependencies extraction, contexts extraction and BPs extraction. The dependency extractor identifies a set of software and hardware components operating within an IT landscape and establishes relations between them. The contexts extractor discovers relevant context information relevant to the BPs, which need to be taken into consideration during the DP process. The BPs extractor analyses enterprise event-logs and extracts distinct BPs and their interrelations.

The Contexts Monitor receives data discovered during the mining step and performs their evaluation. The main purpose of this evaluation is to establish whether or not discovered resources contain a critical amount of data required to initiate regeneration of CMI. For example, lets assume a monitoring database hosting customer data. If a sales team member introduces a new customer record, it is not going
to be considered as the critical event requires regeneration of CMI. However, if a member of the IT supporting team modifies the database design, then it may cause a significant impact on business logic regeneration of CMI for capturing introduced changes.

The Model Weaver combines discovered dependencies, relevant contexts and BPs into a single CMI. A few representational schemes for the CM were analysed within the TIMBUS Project. Web Ontology Language\(^8\) (OWL) was selected as the most suitable model for representing the unified view on collected resources and BPs. The OWL standard combines different consecutive approaches from the Semantic Web community. OWL provides a more expressive way to define relation mappings between resources and BPs discovered within the TIMBUS project than any other relevant model. Resources identified during the mining process are represented in OWL by entities. Entities can be further sub-divided into classes and instances. Class represents an abstraction, which combines instances with the common type. Each class aggregate is a common subset of properties shared between encapsulated instances. Decisions of subdividing instances are carried out during a model designing phase. Relations between entities are labelled by descriptive terms, which allow to form meaningful connections between two or more element and perform reasoning queries.

As a result of the data acquisition operations generated, CMI contains all necessary components for performing risk assessment carried out by the IERM Module, which is described in the next section.

### 2.3 Intelligent Enterprise Risk Management Module

The IERM Module (see Figure 4) is a combination of software components, which are used for assessing risks associated with BPs and dependent resources. This module generates a report describing risk levels and cost values associated with failure of particular subset of BPs. It consists of four software components: Risk Model Builder, Risk Annotator, Risk Impact Assessment and Risk Monitor.

The Risk Model Builder allows an expert to populate Risk Model with relevant risk factors to a specific subset of BPs. For instance, if a particular business is heavily dependent on consumption of natural gas, the relevant risk factors will include financial losses due to supply shortages, fluctuation of market prices due to political and economical situation, natural disaster etc. When relevant risk factors are defined, the Risk Annotator allows the user to assign them to BP instances defined CMI. This process is performed in a semi-automatic fashion, where IERM prompts the most suitable risk factors for particular BP instance and then an expert accepts or modifies the proposed suggestion. Annotated CMI components are formed into the Unified Risk Model (URM). URM is a sub-model of CMI, which is only focused on supporting simulation operations. The Risk Impact Assessment tool uses URM to assess the impact of different risk factors on BPs, business objectives and Key Performance Indicators (KPIs). The risk impact assessment is performed by constructing a Petri Net Model\(^{[27]}\) and running simulation processes. Result of these simulations are analysed to find weak points in examined BP models and compiled into the Risk Assessment Report (RAR).

The Risk Monitor constantly monitors the DP System Archive and CMI. It tries to detect any changes within the monitoring environment, which may lead to appearance of risk events. If the risk event is detected the monitor triggers the simulation process carried out by the Risk Impact Assessment and Legality Impact Assessment tools. The legality impact assessment is performed by the LLM, which is presented in the next section.

### 2.4 Legality Life-cycle Management Module

The LLM Module (see Figure 5) is a combination of software components, which are used for assessing impacts of legal issues on BPs. This module consists of two software components: Legalities Annotator and Legality Impact Assessment.

The Legalities Annotator allows an expert to define legal and contractual issues relevant to a particular organisation or...
project and check whether or not relevant resources and BPs from the URM are compliant with these issues. Considering the high complexity of this task the majority of annotation operations are supervised by an expert. Annotated URM elements are placed into the Legalities Store, which is created to support the legality impact modelling process.

When the Legalities Store is populated the Legalities Impact Assessment tool checks whether or not stored legality rules are enforced for the discovered set of BPs defined in URM. Results of this assessment are sent back to the Risk Impact Assessment tool in the IERM module, which takes the calculated legal risk into consideration and uses it in conjunction with other risk factors.

The RAR created by IERM and LLM contains important information about BPs and various level of risks and cost associated with their failure. This information is utilised by DP Engine described in the next section, which identifies the most suitable preservation and redeployment strategy and performs its execution.

2.5 DP Engine
The DP Engine Module is a combination of software components, which are used for generating preservation and redeployment plans by utilising the RAR and CMI. This module also provides mechanisms for verification and testing different stages of preservation and redeployment processes. The DP Engine consists of three distinct cycles: Preservation, Redeployment and Verification & Feedback.

2.5.1 Preservation Cycle
The preservation cycle (see Figure 6) includes elements for preparing the preservation plan and performing its execution. It consists of the following elements: Preservation Alternatives Assessment, Preservation Execution Planner, Process Preservation Executor, Preservation Monitor and DP System Archive.

![Figure 6: The architecture of the DP Engine Module for Preservation Cycle.](image)

The Preservation Alternatives Assessment component analyses the generated RAR and CMI to identify the most suitable preservation strategy for most critical BPs. The assessment process takes into consideration risks associated with each BP and identifies the most effective preservation strategy. The strategy selection is performed in collaboration with an expert in an interactive mode, where the system provides different preservation alternatives and gives the expert priority to make the final decision. The selected strategy is analysed and converted into a list of instructions by the Preservation Execution Planner. These instructions can be executed in manual, semi-automatic or automatic fashion depending on complexity of the underlying processes. Execution of prepared instructions is carried out in the Process Preservation Executor. If an interaction is related to preservation of a specific IT entity, then the executor performs the automatic extraction of the requested components from the underlying IT landscape. It is followed by a set of transformation and packaging operations, required for long-term storing of selected IT entities in the DP System Archive. All processes are closely monitored by Preservation Monitor. It detects any deviations from the original script and notifies the Preservation Execution Planner, which initiates a re-scheduling phase. All decisions made during the preservation cycle are logged together with preservation steps in the specific log-containers within the DP System Archive.

2.5.2 Redeployment Cycle
The redeployment cycle (see Figure 7) includes elements for preparing the redeployment plan and performing its execution. It consists of the following elements: Redeployment Alternative Assessment, Redeployment Execution Planner, Process Redeployment Executor, Redeployment Monitor and DP System Archive.

![Figure 7: The architecture of the DP Engine Module for Redeployment Cycle.](image)

The redeployment cycle performs the opposite operations to preservation. The Redeployment Alternative Assessment collects the information about IT landscapes, one which is
initially preserved and another which is currently running within the Redeployment environment. Base on the collected information it identifies missing components in the currently running environment and performs assessment and selection of the best redeployment strategy. The selected strategy is utilised by the Redeployment Execution Planner. It generates a list of actions which exhume the selected IT components to the redeployment environment. It is important to mention that not all steps in the redeployment plan are IT related. Some of them may required verification of particular legal issues, installing the specific hardware equipment etc. The prepared redeployment plan is passed to Process Redeployment Executor which works in a semi-automatic fashion. It automatically executes steps for redeploying IT entities from the DP System Archive to the redeployment environment. For all other steps, which cannot be completed without an external input, it provides an assisting interface, which guides execution of these steps. All redeployment processes are closely monitored by Redeployment Monitor. It detects any deviations from the original script and notifies the Redeployment Execution Planner, which initiates a re-planning phase. All decisions are made during the redeployment cycle are logged together with redeployment steps in the specific log-containers within the DP System Archive.

2.5.3 Validation and Feedback Cycle
The Validation and Feedback cycle (see Figure 8) includes elements for verification and testing the preservation redeployment processes. It consists of the following elements: Preservation Log Gap Detector and Verification & Feedback.

![Figure 8: The architecture of the DP Engine Module for Validation & Feedback Cycle.](Image)

The Preservation Log Gap Detector compares the preservation and redeployment logs on potential inconsistencies. These inconsistencies may occur due to a variety of different reasons such as failures with hardware or software components during preservation or redeployment phases, unresolved legal issues, execution failures of manual steps etc. The collected information about potential issues is supplied to the Verification & Feedback component, which generates a set of instructions for resolving occurred issues. Considering the high complexity of this system, all operations in this phase are supervised by an expert. Another important function supported by this cycle is testing and rerunning of preserved BPs and detects potential problems with the redeployment process in advanced.

3. CONCLUSIONS
The proposed TIMBUS DP Architecture provides a complete framework for preserving BPs with all relevant dependencies and contexts. It has a generic, transparent and extendable design, which overcomes limitations in existing DP solutions. It is fully compliant with all requirements and use-case scenarios developing within the TIMBUS project. These use-case scenarios cover preservation of complex BPs in commercial and scientific domains, where such aspects as initial data acquisition and processing, discovery of BPs with all relevant dependencies, enterprise and life-cycle risk management, selection and execution of the best preservation and redeployment strategies play an important part in providing long-term sustainability of business solutions.

The proposed architecture represents the complete solution for performing preservation of modern BPs and utilises the latest innovations in the area of digital preservation and combines the unique set of knowledge and expertise of all TIMBUS partners.

4. ACKNOWLEDGEMENTS
This publication would not have been possible without the support of TIMBUS project members. The authors wishes to express their gratitude to all TIMBUS members who were abundantly helpful and offered invaluable assistance, support and guidance.
